Intrathecal methotrexate causes an aseptic meningitis in 10 to 50 percent of patients, primarily after administration by lumbar puncture rather than via ventricular cannula.[10] Patients complain of headache, nausea, vomiting, and neck stiffness, and can become febrile and lethargic. Symptoms usually begin 2 to 4 hours after drug administration and can last up to a few days (Table 28-5). A CSF pleocytosis is often present and can mimic acute bacterial meningitis, except that it occurs too soon after injection to be caused by bacterial growth. The symptoms are self-limited, and there is no specific treatment, though corticosteroids can reduce the inflammation and have been used as therapy. The drug may be readministered without recurrent aseptic meningitis, and prophylactic oral corticosteroids may help. Transverse myelopathy is a less common complication of intrathecal methotrexate. The symptoms include back pain followed by weakness, sensory changes, and sphincter dysfunction; they usually start between 30 minutes and 2 days after drug administration, but can be delayed by up to 2 weeks.[1] Concurrent radiotherapy may be a risk factor. Recovery may be incomplete and further intrathecal chemotherapy is contraindicated.[10] Acute encephalopathy is rare, but can occur if the intraventricular catheter is misplaced into the brain parenchyma rather than in the ventricle. Other complications include seizures, cranial neuropathies, PRES, lumbosacral polyradiculopathy, and sudden death.

TABLE 28-5 ■ Methotrexate Toxicity*

Route of Administration	Dose	Toxic Effect
Oral or intravenous	Standard	Leukoencephalopathy
Intravenous	High	Acute transient encephalopathy Chronic leukoencephalopathy
Intra-arterial	Standard	Hemorrhagic cerebral infarction
Intrathecal	Standard	Acute aseptic meningitis, paraplegia, seizures Chronic leukoencephalopathy, cerebral atrophy, and calcification

*Toxicity may be enhanced by cranial irradiation and/or other systemic chemotherapeutic agents.

Cytarabine intrathecally can also cause aseptic meningitis in approximately 10 percent of patients. Aseptic meningitis occurred in more patients (40%) when the cytarabine was given as the liposomal preparation, DepoCyt, but this is no longer available. Dexamethasone should be taken prophylactically at a dose of 4 mg twice daily for 5 days, starting the day prior to administration, to decrease the risk of aseptic meningitis and arachnoiditis. Transverse myelopathy can develop a few days to months following treatment. Other complications include seizures, headaches, and encephalopathy.

Intrathecal thiotepa can cause aseptic meningitis and rarely a myelopathy. Topotecan intrathecally can cause aseptic meningitis and, less commonly, seizures as well as leukoencephalopathy.

Rituximab is given intrathecally to treat leptomeningeal lymphoma. Headache, cramps, and reversible back pain associated with paraparesis can occur, as well as neuropathic pain, leukoencephalopathy, transient diplopia, nausea and vomiting, and paresthesias. Intrathecal traztuzumab has been used for leptomeningeal metastases from HER2-positive breast cancer. Aseptic meningitis has not been reported with intrathecal rituximab or traztuzumab, but use of those drugs via the intrathecal route is relatively recent.

RADIATION THERAPY

Therapeutic ionizing irradiation may damage neural structures when they are included in the radiation portal, whether the cancer undergoing RT is within or outside the nervous system. Nervous

TABLE 28-6 ■ Radiation-Induced Injury: Direct Damage to the Central Nervous System

Time After Radiation	Clinical Findings	Possible Mechanisms
Brain		
Acute (minutes to days)	Increased intracranial pressure	Acute vasogenic edema
Early delayed (weeks)	Pseudoprogression Brainstem encephalopathy Somnolence syndrome	Demyelination
Delayed (months to years)		
Necrosis	Diffuse: dementia (rare) Focal: simulates recurrent tumor	Glial and vascular destruction
Leukoencephalopathy	Asymptomatic or dementia	Unknown Atrophy Spongiosis of white matter Normal-pressure hydrocephalus
Spinal Cord		
Early delayed (weeks)	Lhermitte sign	Demyelination
Delayed (months to years)		
Spinal cord necrosis	Transverse myelopathy	Glial and vascular destruction
Motor neuron disease	Flaccid paraparesis, amyotrophy	Unknown
Arachnoiditis	Often asymptomatic	Radiation-induced damage to the leptomeninges
Hemorrhage	Acute myelopathy	Vascular lesions

system injury can also occur secondarily when irradiation damages blood vessels supplying the brain or the endocrine organs necessary for normal nervous system function, or when the irradiation causes tumors that compress or destroy nervous system structures. Nervous system dysfunction caused by RT can occur acutely or may be delayed by weeks, months, or even years following the successful completion of treatment. The likelihood that RT will damage the nervous system depends on the total dose delivered to the nervous system, the dose per fraction, the total volume of nervous system irradiated, the time after completion of RT, the presence of other systemic diseases that enhance the side effects of irradiation (e.g., diabetes, hypertension), and other unidentifiable host factors. Detailed reviews of RT-induced neurotoxicity can be found elsewhere.[1,11]

Primary Neurologic Damage

BRAIN

Encephalopathy caused by RT occurs in three forms: acute, early delayed (weeks to months), and late delayed (months to years), as summarized in Table 28-6.

Acute Encephalopathy

Acute encephalopathy usually follows large RT fractions given to patients with increased ICP from primary or metastatic brain tumor, particularly in the absence of corticosteroid coverage.[1] Immediately following treatment, susceptible patients develop headache, nausea, vomiting, somnolence, fever, and worsening of neurologic symptoms, rarely severe enough to culminate in cerebral herniation and death. Acute encephalopathy usually follows the first radiation fraction and becomes progressively less severe with each ensuing fraction. Usually, the disorder is mild, with the patient developing headache and nausea in the evening following irradiation.

The pathogenesis of the disorder is uncertain. There are variable data to suggest it is secondary to a rise in ICP, with cerebral edema following breakdown of the blood–brain barrier by ionizing irradiation, particularly with fractions of 300 cGy or more. Therefore, patients harboring large brain tumors, particularly with signs of increased ICP, should be treated with doses of 200 cGy or less per fraction. All patients undergoing brain irradiation should be protected with corticosteroids (8 to 16 mg of dexamethasone daily) preferably for at least 24 hours before the start of RT. Both clinical and experimental evidence indicate that corticosteroids ameliorate the acute complications of irradiation.

Early Delayed Encephalopathy

Early delayed encephalopathy, which is thought to be due to demyelination, usually begins in the second or third month after irradiation but can begin anywhere from 2 weeks to 4 months after treatment. If the patient has a glioblastoma, the symptoms of early delayed encephalopathy often simulate tumor progression ("pseudoprogression"). The risk of pseudoprogression is increased in those patients whose tumor contains a methylated promoter of the O^6-methylguanine-DNA methyltransferase (*MGMT*) gene, a DNA repair enzyme. For example, the patient may develop recurrence of headache, lethargy, and worsening of lateralizing signs. Changes on neuroimaging may include an increase in size of the lesion and sometimes the new appearance of contrast enhancement. These changes resolve spontaneously if the disorder is due to radiation encephalopathy rather than tumor recurrence, and the resolution can be hastened by corticosteroids. The patient and the scan remain improved after corticosteroids are discontinued, indicating that the disorder was not tumor recurrence.

A rare and serious early delayed neurologic syndrome is brainstem encephalopathy following irradiation of posterior fossa tumors or when the brainstem has been included in the irradiated field for head and neck cancer. The most frequent symptoms are ataxia, diplopia, dysarthria, and nystagmus. Most patients recover spontaneously within 6 to 8 weeks. Rarely, the symptoms progress to stupor, coma, and death.

Late Delayed Radiation Injury

Radiation Necrosis

Late delayed radiation necrosis usually begins 1 to 2 years after the completion of RT. In patients who are treated for primary or metastatic brain tumors, symptoms generally recapitulate those of the brain tumor, leading the physician to suspect tumor recurrence. A second clinical picture occurs when the patient's brain was included in the radiation portal, but there was no underlying brain tumor. Examples include irradiation of head and neck tumors, including pituitary tumors, and prophylactic cranial irradiation.[1] Because only a portion of the brain has usually been irradiated and there was no previous brain damage, new focal neurologic signs are the rule. For example, bilateral medial temporal destruction sometimes follows irradiation for nasopharyngeal or pituitary tumors, and frontal or temporal lobe destruction follows treatment for ocular or maxillary sinus tumors. The clinical features are similar to those of a brain tumor, with focal signs, depending on the site of brain damage, and increased ICP if the lesion is sufficiently large. The MRI usually reveals a mass, often with contrast enhancement (Fig. 28-2). FDG-PET, MR spectroscopy, and advanced MRI sequences may help differentiate between necrosis and tumor. Elevated cerebral blood volume on MR perfusion sequences, restricted diffusion with hypointensity on ADC images of MRI, and hypermetabolism on FDG-PET all favor recurrent tumor rather than radiation necrosis, but a definitive diagnosis can be made only pathologically.

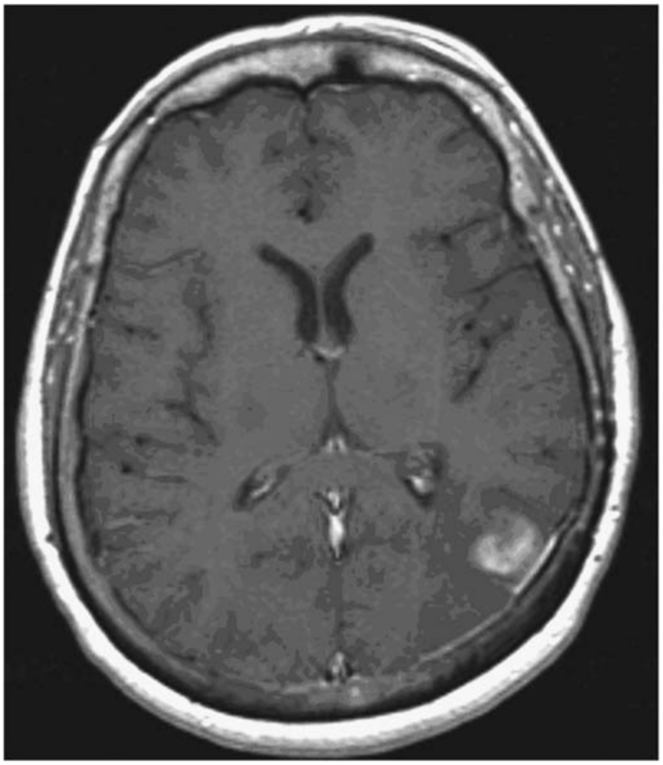

FIGURE 28-2 ■ Radiation necrosis. T1-weighted, postcontrast MRI 9 months after stereotactic radiosurgery for a left parietal, dural-based metastasis. The lesion was hypointense on precontrast T1-weighted sequences.

Radiation necrosis is often treated initially with corticosteroids; however, patients may respond only transiently. Bevacizumab has also shown clinical and radiographic benefit in the treatment of radiation necrosis and can allow steroid dosage to be decreased. When patients are symptomatic despite medical therapy or they develop morbidity from treatment, radiation necrosis may be treated by surgical resection. Other suggested treatments, such as vitamin E, pentoxifylline, hyperbaric oxygen, antiplatelet agents, and anticoagulation, are based on the rationale that the disorder is characterized by fibrinoid necrosis of vessels, but they have not proved useful in most patients.

SMART Syndrome

Stroke-like migraine attacks after RT, or SMART syndrome, are a rare complication of cranial irradiation that may occur 1 to 10 years after treatment. The syndrome is characterized by migraine-like headaches associated with transient neurologic signs, which may be accompanied by seizures. MRI may show focal contrast enhancement that resolves over time without intervention.[12] The mechanism is thought to be due to neuronal dysfunction, and not cerebral vascular activity.

Cerebral Atrophy

Cerebral atrophy often follows whole-brain irradiation, and it may be accompanied by periventricular leukoencephalopathy. The atrophy may occur in patients irradiated prophylactically or in those with a brain tumor that was eradicated by radiotherapy. It usually begins 6 to 12 months after RT. The patient may be asymptomatic or suffer memory loss, which may be severe. Some patients have gait abnormalities and urgency incontinence, suggesting normal-pressure hydrocephalus, and they may respond to ventriculoperitoneal shunt. Symptomatic patients generally have greater degrees of atrophy and ventricular dilatation than asymptomatic patients. Cerebral atrophy occurs in children receiving prophylactic brain irradiation for acute leukemia, and it is associated with learning disabilities.

SPINAL CORD

There are no acute effects of radiation on the spinal cord.

Early Delayed Radiation Myelopathy

Early delayed radiation myelopathy is common after irradiation of the neck (Table 28-6). Several weeks after irradiation, the patient develops Lhermitte sign that persists for weeks or months and then disappears spontaneously. This may be associated with delayed somatosensory evoked potentials. Symptoms are thought due to demyelination of the posterior columns of the spinal cord, but they do not predict the development of late delayed radiation spinal cord injury.

Late Delayed Radiation Myelopathy

Late delayed radiation myelopathy appears in two forms. The first and most common is characterized by progressive myelopathy, often beginning as a Brown-Séquard syndrome and progressing over weeks or months to cause paraparesis or quadriparesis. Usually the symptoms progress subacutely, but in some instances they progress over several years and, at times, may stabilize, leaving the patient with only mild or moderate paraparesis. MRI is usually nonspecific but helps to exclude metastatic spinal cord compression or intramedullary metastasis. Hyperintense changes of the irradiated vertebral bodies due to fat replacement of bone marrow may outline the radiation field even if the details of the RT port are unknown. In the acute stages the spinal cord is swollen and the damaged area may enhance with contrast material; spinal cord atrophy develops later. There is no good treatment, although corticosteroids sometimes delay progression of the lesion. Other potential therapies include hyperbaric oxygen and anticoagulation but they do not give benefit reliably.

A second form of late delayed radiation myelopathy is a rare motor neuron syndrome that characteristically follows pelvic irradiation or after craniospinal irradiation for medulloblastoma.[13] This disorder occurs 3 months to 23 years following irradiation and is characterized by the subacute onset of flaccid leg weakness affecting both distal and proximal muscles accompanied by atrophy, fasciculations, and areflexia. It is usually bilateral and symmetric but may be asymmetric or restricted to one leg. Sensory, sphincter, and sexual functions are normal. The CSF may contain an increased protein concentration. Imaging is typically normal. Although electromyography reveals varying degrees of denervation, sensory and motor nerve conduction velocities are normal. It is difficult to differentiate the disorder from a pure motor polyneuropathy, isolated motor neuron loss, or the paraneoplastic syndrome of subacute motor neuronopathy. The deficit usually stabilizes after several months to a few years; often patients are still able to walk, but some may become paraplegic.

Another lower motor neuron syndrome caused by irradiation is dropped head syndrome, which can occur after mantle radiation in the treatment of Hodgkin lymphoma. Amyotrophy of the neck and shoulder muscles is associated with reduced cervical range of motion, weakness in the neck flexors and extensors, neck pain, and a posture in which the head is dropped forward and resting on the chest.

CRANIAL NERVES

The clinical features of radiation injury to the cranial and peripheral nerves and the special senses are shown in Table 28-7. Anosmia may follow irradiation. Taste is affected in almost every patient who undergoes cranial radiotherapy. Visual loss may follow irradiation of the eye or brain. It may be caused by radiation-induced "dry eye syndrome," glaucoma, or cataract; more commonly, it result from retinopathy or optic neuropathy. The optic neuropathy following irradiation begins 7 to 26 months after RT and is characterized by painless monocular or bilateral blindness. Papilledema and retinal hemorrhages may be present. Hearing loss may also follow RT to the brain or ear. Radiation-induced otitis media appears during or shortly following cranial RT and causes a conductive hearing loss that may require myringotomy for relief. It is different from the sensorineural hearing loss that is a late delayed RT effect and that has been attributed to an endarteritis producing vascular damage of the cochlear or acoustic nerve.[1] The lower cranial nerves, particularly the hypoglossal nerves, are often involved as a late delayed effect of RT delivered to the neck. Lower cranial neuropathy can be delayed for over 10 years. Electrophysiologic studies commonly show myokymia and myokymic discharges. Recurrent laryngeal, vagal, and sympathetic fibers (Horner syndrome) may be involved as well.

TABLE 28-7 ■ Radiation-Induced Injury: Damage to the Cranial and Peripheral Nerves and Organs of Special Sense

Cranial Nerves

  - Retinopathy
  - Optic neuropathy
  - Central retinal artery occlusion
- Taste and smell
  - Acute, transient loss of taste and smell during radiation therapy
  - Chronic loss of smell (rare)
- Involvement of the lower cranial nerves
  - Twelfth nerve most frequently affected

Brachial Plexus Neuropathies

- Acute?
- Early delayed (rare)
- Delayed brachial plexopathy

Delayed Lumbosacral Plexopathy

PERIPHERAL NERVES

There are no acute changes in peripheral nerve function following RT. Early delayed brachial plexus dysfunction is characterized by paresthesias in the hand and forearm, sometimes associated with pain and accompanied by weakness and atrophy in a C6 to T1 distribution.[1] Nerve conduction studies reveal segmental slowing, and the course is characterized by recovery over a few weeks or months. This disorder is particularly common in patients with breast cancer because the brachial plexus is frequently included in the radiotherapy port of the primary cancer.

Late delayed radiation plexopathy has been reported after irradiation of either the brachial[1] or lumbosacral plexus, although the former is more common. The disorder usually occurs a year or more after RT doses of or exceeding 5,000 cGy. Brachial plexopathy is characterized by paresthesias and weakness of the hand or arm. Sensory loss, particularly in the fingers and hand, is seen early but the numbness and weakness often progress to a complete plexopathy, rendering the entire arm useless. This disorder is frequently accompanied by lymphedema and palpable induration in the supraclavicular fossa. Radiation-induced plexopathy is usually painless, which distinguishes it from tumor plexopathy, which is typically painful. Myokymia on electrodiagnostic testing in the territory of affected nerves is characteristic of radiation damage as opposed to tumor infiltration of the plexus. CT scan or MRI usually reveals a diffuse loss of tissue planes without a mass. Occasionally, radiation damage can produce a marked fibrotic reaction causing a mass of fibrosis that cannot be distinguished from tumor, but FDG-PET discriminates tumor from fibrosis. There is no treatment for radiation plexopathy, although painful paresthesias may be relieved by amitriptyline or gabapentin (or other treatments for neuropathic pain).

Lumbosacral plexopathy causes painless weakness of one or both legs. The disorder often affects the foot, and sensory impairment as well as weakness is present in most cases. Electromyography frequently reveals myokymic discharges, which differentiate the process from tumor recurrence. Radiation-induced lumbosacral plexopathy is often slowly progressive over many years. The pathogenesis of RT plexopathy is thought to be related to fibrosis causing damage to Schwann cells, rather than stemming from direct damage to the nerves themselves.

Secondary Neurologic Involvement

Radiogenic Tumors

The manner in which the nervous system may be affected secondarily after RT is summarized in Table 28-8.

TABLE 28-8 ■ Secondary Involvement of the Nervous System Following Radiation Therapy

Radiation-Induced Tumors
Meningiomas–atypical, malignant
Sarcomas–malignant
Gliomas–malignant
Schwannomas–malignant
Vascular Lesions
Stenosis/occlusion of the supraclinoid internal carotid
Moyamoya syndrome
Extracranial stenosis/occlusion
Carotid rupture (rare)
Endocrinopathy
Primary hypothyroidism
Hyperparathyroidism
Hypothalamic pituitary dysfunction
Growth hormone deficiency (most frequent)
Hyperprolactinemia
Cortisol deficiency (rare)
Gonadotropin deficiency (rare)

Radiation-induced tumors, including meningiomas, sarcomas, and, less frequently, gliomas and malignant schwannomas, may appear years to decades after irradiation of nervous system tissue; secondary tumors may develop even after low doses of RT. Children who received low-dose scalp RT for tinea capitis had an increase in the incidence of meningiomas and higher rates of multiple meningiomas and recurrence compared to nonirradiated control patients. Malignant or atypical nerve sheath tumors may follow irradiation of the brachial, cervical, or lumbar plexuses. Signs and symptoms of radiogenic tumors are no different from tumors that arise without prior RT, and their surgical treatment is similar. Some patients may be able to tolerate additional RT or chemotherapy if the tumor is malignant and cannot be excised totally.

Vascular Abnormalities

Atherosclerosis of large intracranial or extracranial blood vessels may follow RT by months to years. Patients may develop TIA or cerebral infarcts. Arteriography reveals stenosis or occlusion of the artery within the radiation portal. A particularly vulnerable area is the supraclinoid portion of the internal carotid artery in children who received brain irradiation; this occlusion is sometimes associated with moyamoya syndrome. The pathology of radiation-induced vascular occlusion is similar to severe atherosclerosis, although there may be marked periarterial fibrosis as well. This condition is characterized by atherosclerosis restricted to the vessel segment within the RT field without evidence of widespread involvement elsewhere, by the younger age of the affected patients, and by the atypical location of the stenotic carotid segments. If appropriate, endarterectomy or carotid stenting can be performed successfully on patients with extracranial vascular disease.

Cavernomas may also develop as a complication of cranial or spinal RT, occurring as early as 1 year after treatment but typically many years later. They may be at higher risk of bleeding compared to cavernomas unassociated with prior RT (Fig. 28-3).

A few patients have been described with hemorrhage in the spinal cord developing many years after

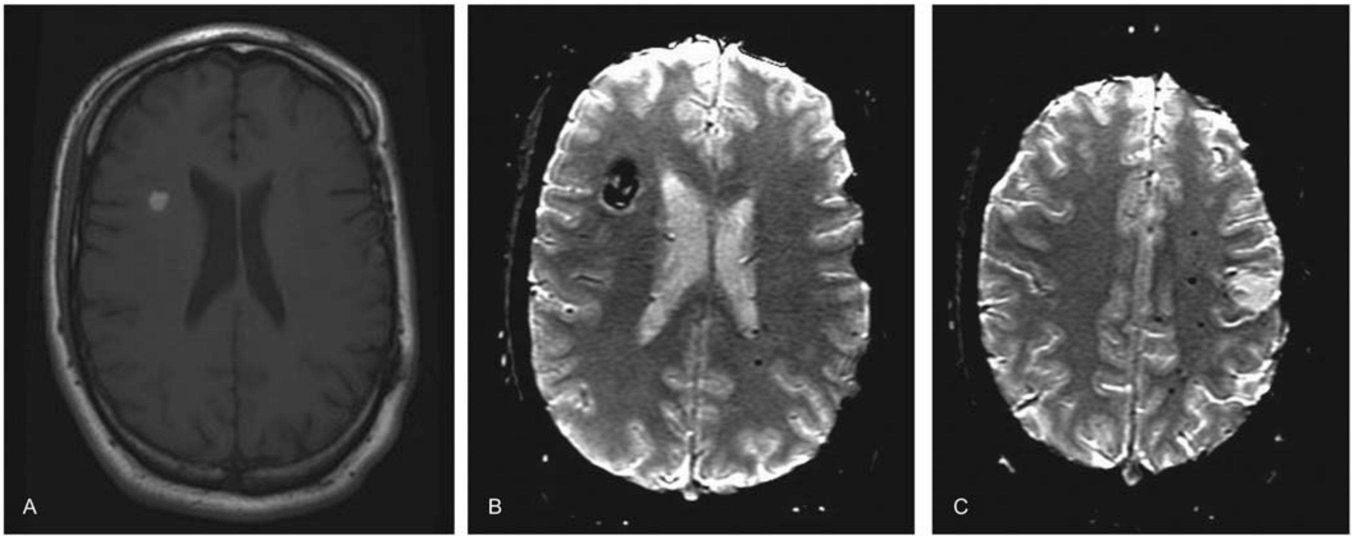

FIGURE 28-3 ■ Radiation-induced cavernomas (images *A*–*C* are different sequences from the same MRI). *A*, T1-weighted, precontrast MRI 6 years after focal radiation for a left frontal grade 2 astrocytoma, showing hemorrhage. *B*, Susceptibility-weighted imaging (SWI) demonstrating a hemorrhagic cavernoma in the right frontal lobe. *C*, SWI demonstrating multiple microbleeds in the left hemisphere.

irradiation. Characteristically, 8 to 30 years after RT to the spine, a patient without prior neurologic symptoms suddenly develops back pain and leg weakness. MRI suggests acute or subacute hemorrhage, but no other lesions are found. The patient typically improves, and the symptoms may resolve entirely. A few patients have had recurrent episodes of spinal cord hemorrhage. The pathogenesis is probably related to telangiectatic vascular changes caused by the RT, but anecdotally we have noticed that hemorrhage is often preceded by heavy use of nonsteroidal anti-inflammatory drugs.

- Stepwise Approach to Neurogenic Bladder Dysfunction

Lower urinary tract dysfunction is common in patients with neurologic disease. The neurogenic bladder can result from lesions affecting any part of the nervous system. Symptoms are often bothersome and may have a significant impact on quality of life. Some patients may also be at risk of developing changes in the upper urinary tract and even renal impairment.

NEUROLOGIC CONTROL OF THE BLADDER

The essential function of the lower urinary tract (bladder and urethra) is storage of urine and its elimination at appropriate times. This function ultimately depends on a local spinal reflex arc which is regulated by supraspinal input to preserve continence until appropriate.

Neurologic control of the key bladder functions of storage and voiding is accomplished by a neural network involving regions of the cortex, brainstem, and spinal cord. The peripheral innervation of the detrusor and sphincter is vital in the execution of this central control. Understanding of the neurologic control of the bladder was derived initially from animal studies, and then refined using functional imaging studies.[1] Experiments on decerebrate cats in the

Aminoff's Neurology and General Medicine, Sixth Edition.

1920s led to the understanding that the mid-pons played an integral role in micturition. This same region was later stimulated electrically in cats to produce detrusor contractions. Subsequent work demonstrated that stimulation of the medial region of the dorsomedial pontine tegmentum led to relaxation of urethral pressure, silence of the pelvic floor electromyogram, and an increase of detrusor pressures; as a result, this area became known as the pontine micturition center. Later studies established functional continuity of the intermediolateral cell column in the sacral spinal cord to this region.

Brain Centers

The development of functional imaging modalities such as positron emission tomography (PET) and functional magnetic resonance imaging (MRI) has allowed further understanding of the central control of micturition.[1,2] Activation occurs in the region of the medioposterior pons during voiding and in the region of the ventrolateral pontine tegmentum in subjects unable to void in the scanner. In the cortex, PET studies have suggested that the right inferior frontal gyrus and the right anterior cingulate gyrus are activated during voiding along with several other regions including the cerebellum, hypothalamus, thalamus, subthalamic nucleus, and the periaqueductal gray.

Innervation of the Lower Urinary Tract

The bladder is one of the few visceral organs with voluntary control; it receives innervation from both the autonomic and somatic systems (Fig. 29-1). Parasympathetic fibers arise from neurons in the S2 to S4 segments, activating muscarinic receptors of the detrusor muscle. Sympathetic fibers from the thoracolumbar segments (T11 to L1) pass through the hypogastric nerve and pelvic plexus and activate the β3 receptors of the detrusor muscle and α-adrenergic receptors of the internal urethral sphincter and bladder neck. Somatic fibers pass through the pudendal nerve and activate nicotinic receptors of the external urethral (and anal) sphincter. Sensations of bladder fullness are conveyed to the spinal cord through all these sets of nerves.

Storage Phase

The bladder is in the storage phase 98 percent of the time. During this phase, passive distension of the bladder results in low-level afferent firing. This firing leads to reflex inhibition of parasympathetic efferents and activation of both the sympathetic outflow innervating the internal urethral sphincter and pudendal outflow innervating the external urethral sphincter; these responses promote continence. Ascending afferent signals relay at the periaqueductal gray before reaching cortical centers. Signals from the pontine micturition center are essentially inhibitory and promote storage.

Voiding Phase

When the bladder is perceived to be full and it is a socially appropriate time and place to void, facilitatory signals from the pontine micturition center result in parasympathetically mediated contractions of the detrusor muscle and inhibition of the sympathetic and pudendal outflow (leading to sphincter relaxation).

Central Mediation of Voiding

The decision to void is based on a combination of factors, including emotional state, an appreciation of the social environment, and sensory signals arising from the bladder. Knowledge of the extent to which one's bladder content is comfortable and "safe" is central in this process. Thus, voluntary control of the bladder and the urethra has two important aspects: registration of bladder filling sensations and manipulation of the firing of the voiding reflex, both of which are dependent on the periaqueductal gray.

Neurochemistry of the Urothelium and Bladder Pharmacology

The urothelium (the bladder epithelium) has specialized sensory and signaling properties that allow the bladder to respond to chemical and mechanical stimuli and to engage in reciprocal chemical communication with nerves in the bladder wall. The urothelium expresses nicotinic, muscarinic, tachykinin, adrenergic, bradykinin, and transient-receptor-potential vanilloid receptors. It has the ability to release chemical mediators such as adenosine triphosphate (ATP), acetylcholine (ACh), and nitric oxide,

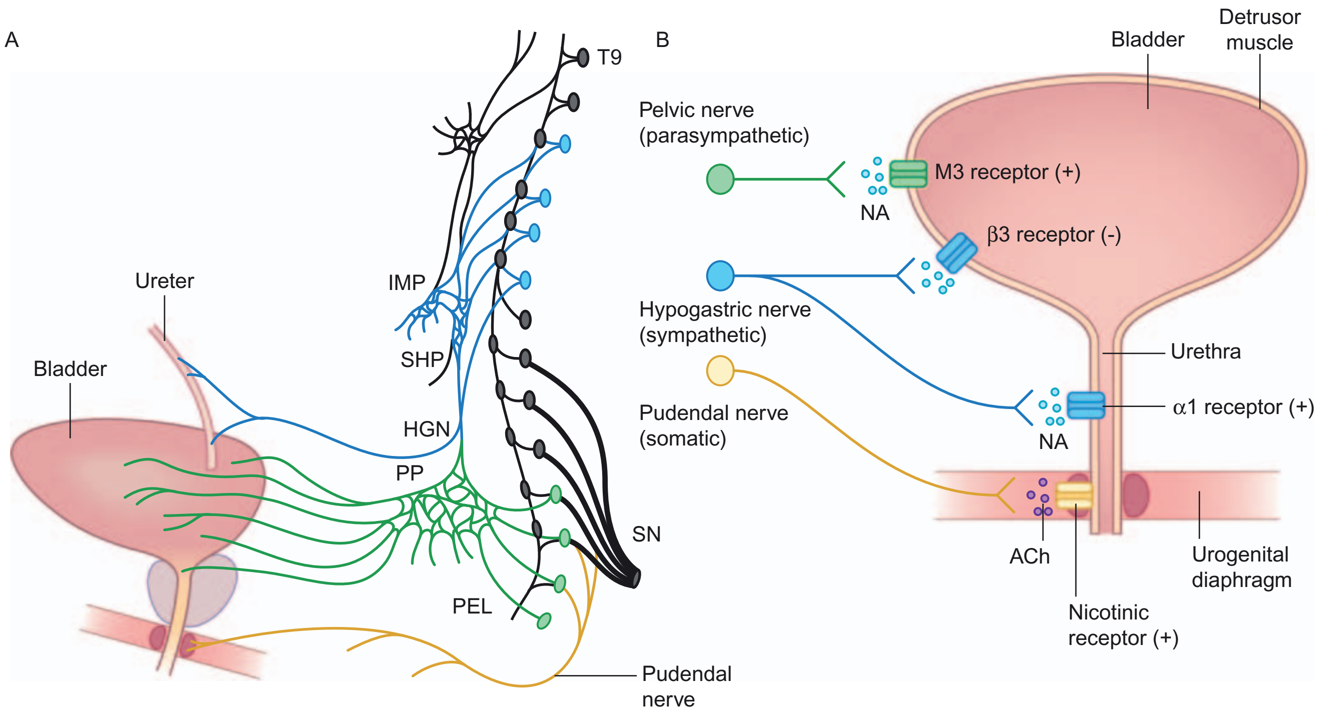

FIGURE 29-1 ■ Innervation of the lower urinary tract. *A*, Sympathetic fibers (shown in blue) originate in the T11–L2 segments in the spinal cord and run through the inferior mesenteric ganglia (inferior mesenteric plexus, IMP) and the hypogastric nerve (HGN) or through the paravertebral chain to enter the pelvic nerves at the base of the bladder and the urethra. Parasympathetic preganglionic fibers (shown in green) arise from the S2 to S4 spinal segments and travel in sacral roots and pelvic nerves (PEL) to ganglia in the pelvic plexus (PP) and in the bladder wall, which then supply parasympathetic innervation to the bladder. Somatic motor nerves (shown in yellow) that supply the striated muscles of the external urethral sphincter arise from S2 to S4 motor neurons and pass through the pudendal nerves. SHP, Superior hypogastric plexus; SN, sciatic nerve; T9, ninth thoracic root. *B*, Efferent pathways and neurotransmitter mechanisms that regulate the lower urinary tract. Parasympathetic postganglionic axons in the pelvic nerve release acetylcholine (ACh), which produces a bladder contraction by stimulating M3 muscarinic receptors in the bladder smooth muscle. Sympathetic postganglionic neurons release norepinephrine (NA), which activates β3 adrenergic receptors to relax bladder smooth muscle and activates β1 adrenergic receptors to contract urethral smooth muscle. Somatic axons in the pudendal nerve also release ACh, which produces a contraction of the external sphincter striated muscle by activating nicotinic cholinergic receptors. (From Fowler CJ, Griffiths D, de Groat WC: The neural control of micturition. Nat Rev Neurosci 9:453, 2008, Part (A) modified from de Groat WC. pp. 28–42. In Raz S (ed): Female Urology. 2nd Ed, Saunders, Philadelphia, 1996.)

which can regulate the activity of adjacent nerves and trigger local vascular changes or reflex bladder contractions.

The presence of muscarinic and nicotinic receptors in the urothelium has focused attention on the role of ACh as a chemical mediator of neural–urothelial interactions. ACh is released from the urothelium in response to chemical or mechanical stimuli. Thus, the clinical effect of antimuscarinic agents in overactive bladder conditions might not only lead to a motor response, but also influence the afferent pathway.[3]

Various neurotransmitters have been implicated in the central control of the lower urinary tract. Putative excitatory transmitters include glutamate, tachykinins, pituitary-adenylate-cyclase-activating polypeptide, nitric oxide, and ATP. Glutamate seems to be the essential transmitter in spinal and supraspinal reflex pathways that control the bladder and the external urethral sphincter. Inhibitory amino acids (γ-aminobutyric acid and glycine) and opioid peptides (enkephalins) exert a tonic inhibitory control in the pontine micturition center and regulate bladder capacity. These substances also have inhibitory actions in the spinal cord. Drugs used in management of the bladder symptoms have mainly developed in accordance with this neurochemistry.[3,4] Although antimuscarinics are the mainstay of

therapy, other agents have been developed that influence the vanilloid, cannabinoid, and β3 receptors, which are discussed below in the section on treatment.

NEUROGENIC BLADDER DYSFUNCTION

Lower urinary tract symptoms usually consist of problems with storage or problems with voiding (Table 29-1). The pattern of bladder dysfunction following neurologic disease depends to a large extent upon the level of the lesion.[2] The storage function of the bladder is affected following suprapontine or lesions below the pons but above the sacral spinal cord (Table 29-2) resulting in involuntary, spontaneous, or induced contractions of the detrusor muscle (detrusor overactivity), which can be identified during the filling phase of urodynamic testing. This voiding function can be affected by infrapontine lesions. Following spinal cord damage interrupting the connections between sacral and pontine centers, detrusor–sphincter dyssynergia may also occur, resulting in incomplete bladder emptying and abnormally high bladder pressures. With lesions of the conus medullaris, cauda equina, or peripheral nerves, voiding dysfunction predominates and results in poor-detrusor contraction and nonrelaxing urethral sphincters.

Cerebral Lesions

Disorders affecting the cortex or subcortical white matter often result in lower urinary tract symptoms. This occurs most commonly with lesions of the anteromedial frontal lobe, including the anterior part of the cingulate gyrus. The clinical picture is one of severe urgency and frequency of micturition with urge incontinence; the patient is usually socially aware and embarrassed by the incontinence. Urinary retention also has been described but is less common; a small number of patients have been described with urinary retention that resolved with treatment of the frontal lobe disorder.

Urinary incontinence may follow stroke, often with more anteriorly placed infarcts. It has not been possible to demonstrate a correlation between any specific lesion site and the urodynamic findings. The most common cystometric finding is that of detrusor overactivity, and voiding is usually well-coordinated. Patients with hemorrhagic stroke are more likely to have detrusor underactivity. Urinary incontinence at 7 days after stroke is predictive of poor survival, disability, and institutionalization independent of the patient's level of consciousness.

Small-vessel disease of the white matter (leukoaraiosis) has been associated with urgency incontinence as well as falls and cognitive disturbance, especially when it involves the frontal lobes. This may be an important cause of incontinence in functionally independent elderly.

A much less common cause of frontal involvement with urinary incontinence is normal-pressure

TABLE 29-2 ■ Results of the Diagnostic Evaluation for Patients with Suspected Neurogenic Bladder Dysfunction

	Suprapontine lesion, e.g., stroke, Parkinson disease	Infrapontine-suprasacral lesion, e.g., spinal cord injury, multiple sclerosis	Infrasacral lesion, e.g., conus medullaris tumor, cauda equina syndrome, peripheral neuropathy
History/bladder diary	Urgency, frequency, urgency incontinence	Urgency, frequency, urgency incontinence, hesitancy, interrupted stream	Hesitancy, interrupted stream
Postvoid residual (PVR) urine	PVR < 100 ml	±Elevated PVR	PVR > 100 ml
Uroflowmetry	Normal flow	Interrupted flow	Poor/absent flow
Urodynamics	Detrusor overactivity	Detrusor overactivity, detrusor–sphincter dyssynergia	Detrusor underactivity, sphincter insufficiency

hydrocephalus, where incontinence is a cardinal feature. Improvement in urodynamic function has been demonstrated in some patients within hours of lumbar puncture or shunting procedures.

The cause of urinary incontinence in patients with dementia is probably multifactorial, but frontal lobe degeneration probably plays a role. In a study of patients with progressive cognitive decline, incontinence was observed to not occur until more advanced stages of Alzheimer disease but occurred earlier in the course of dementia with Lewy bodies.

Basal Ganglia Lesions

PARKINSON DISEASE

Lower urinary tract symptoms are reported in 38 to 71 percent of patients with Parkinson disease (PD). Storage symptoms are the most common problem, seen in more than 60 percent of these patients, with considerable impact on quality of life. Nocturia is the most common symptom followed by urinary urgency; these are among the most common nonmotor symptoms of PD. Urodynamic studies typically show detrusor overactivity, probably due to neuronal loss in the substantia nigra disinhibiting the normal effect of the basal ganglia on the micturition reflex. Dopamine receptor stimulation through D1 receptors provides the main inhibitory influence on the micturition reflex normally, although dopaminergic stimulation in PD has little apparent impact.

Overactive bladder is common in patients with PD, and many patients have nocturnal polyuria. Patients may also report voiding difficulties and bradykinesia of the pelvic floor muscles resulting in pseudo-dyssynergia. Lower urinary tract symptoms may be multifactorial and other non-neurogenic factors such as prostatic enlargement may contribute. Other medical comorbidities such as diabetes mellitus, congestive cardiac failure, medications (such as diuretics), cerebrovascular disease, and cervical spondylosis may also play a role. Sleep disturbances and disturbed circadian rhythm, which are common in PD, may be closely associated with nocturia.[5]

MULTIPLE SYSTEM ATROPHY

Patients with parkinsonism and early and prominent urogenital complaints may have multiple system atrophy (MSA). Around 40 percent of these patients first present with lower urinary tract symptoms and 97 percent will experience these symptoms during the disease course. Urologic presentations include daytime frequency (about 45%), nocturnal frequency (nearly 70%), urinary urgency (60%), and urge incontinence (66 to 75%).

Bladder symptoms occur much earlier and are more disabling in MSA than PD. Although urgency and frequency occur in both conditions, patients with MSA are more likely than those with PD to have a high (>100 ml) postvoid residual volume, detrusor–sphincter dyssynergia, an open bladder neck at the start of bladder filling on videocystometrogram, and evidence of neurogenic changes on electromyography of the anal sphincter.

Brainstem Lesions

Although the pontine micturition center is essential for micturition, the rarity of brainstem lesions in clinical practice makes it less common to encounter bladder dysfunction secondary to brainstem lesions. In cases with brainstem tumors or other mass lesions, the clinical picture is usually dominated by other long tract and ocular features. Due to the proximity of the pontine micturition center to the medial longitudinal fasciculus, internuclear ophthalmoplegia is a common accompanying finding. Voiding difficulty is a rare but well-recognized symptom of a posterior fossa tumor. When urinary symptoms occur with brainstem stroke, lesions are usually situated dorsally. Brainstem involvement in multiple sclerosis is discussed separately.

Spinal Cord Lesions

The spinobulbar reflex arc is crucial in the control of bladder function in health. Following spinal cord lesions, interruption of this reflex, along with loss of supraspinal control, results in a local spinal reflex that drives bladder contractions. The localization of lesions can be guided by the type of bladder dysfunction observed.

The overactive neurogenic (spastic) bladder occurs following lesions that interrupt the connections between the pontine micturition center and sacral cord micturition centers. Commonly these myelopathic conditions cause quadriplegia or paraplegia. Clinically, patients present with detrusor contraction during bladder filling leading to detrusor overactivity, characterized by urinary frequency, urgency, urge incontinence, and inability to initiate micturition voluntarily. Bladder capacity is reduced, although residual urine may be increased. On examination, the bulbocavernosus and anal reflexes are preserved.

Autonomous neurogenic bladder (detrusor areflexia) may occur with complete lesions below the T12 segment that involve the conus medullaris and cauda equina. Common pathologies include sacral myelomeningocele and tumors of the conus medullaris and cauda equina. This type of neurogenic bladder also occurs during the initial shock phase following spinal cord injury; gradually over the course of weeks new reflexes emerge to drive bladder emptying and cause detrusor contractions in response to low filling volumes. The tone of the detrusor muscle is abolished, there is no awareness of fullness, and the clinical presentation is urinary retention. Overflow incontinence and increased residual urine develop later. On examination, associated saddle anesthesia with absence of the bulbocavernosus and superficial anal reflexes are common. Anal sphincter control is often affected similarly.

Motor paralytic bladder results from lesions involving the efferent motor fibers to the detrusor or the detrusor motor neurons in the sacral spinal cord. Common pathologies include lumbar spinal stenosis, lumbosacral meningomyelocele, or following abdominoperineal resection or radical hysterectomy. Clinically painful urinary retention or impaired bladder emptying is the presenting feature, and residual urine is markedly increased. The bulbocavernosus and superficial anal reflexes are usually absent, but sacral and bladder sensation are preserved.

Sensory paralytic bladder is caused by impairment of the afferent pathways innervating the bladder or by dysfunction of the posterior columns or lateral spinothalamic tract in the spinal cord. Classically, this condition has been described in tabes dorsalis, syringomyelia, and diabetes mellitus. Voluntary initiation of micturition may be retained. On examination, the bulbocavernosus and superficial anal reflexes are variably absent, decreased, or present.

This classification system does not often reflect clinical practice and deviations from these descriptions commonly occur. Following spinal cord injury, the stage of spinal shock is quite variable in presentation. The neurophysiology of recovery from spinal shock has been characterized mainly in cats where, following injury, dormant C fibers emerge as the major afferents, and a spinal segmental reflex is established that results in automatic voiding. The abnormally overactive, small-capacity bladder that characterizes spinal cord disease results in a clinical phenotype characterized by urinary urgency, frequency, and incontinence; however, patients with complete transection of the cord may not complain of urgency.

Bladder Dysfunction in Multiple Sclerosis

Lower urinary tract dysfunction can be one of the main features of multiple sclerosis. Urinary incontinence impacts quality of life for patients and is associated with considerable costs. Up to 75 percent of patients with multiple sclerosis have lower urinary tract symptoms, and overactive bladder and dyssynergia are the most common presentations. Urinary tract infections are common; infection is found in 30 percent of those reporting urinary symptoms. The incidence of lower urinary tract symptoms increases with lower extremity weakness from corticospinal tract dysfunction (usually from spinal cord involvement) and longer disease duration. As the neurologic condition progresses, lower urinary tract dysfunction may become more difficult to treat.

The most common urinary symptom in these patients is urgency, and detrusor overactivity is often seen on urodynamic testing. Patients sometimes initially report hesitancy, but those with more severe symptoms may be unable to initiate micturition voluntarily, emptying their bladders only through involuntary overactive contractions followed by interrupted urinary flow. Evidence of incomplete emptying may come from the need to pass urine again within 5 to 10 minutes (double voiding).

Multiple sclerosis is a dynamic disease, and symptoms may appear or worsen during a relapse and then remit or improve with neurologic remissions. Neurologic symptoms may deteriorate acutely when the patient has an infection, including that of the urinary tract. As the disease progresses, recurrent infections may result in the accumulation of deficits.[6]

Disturbances of Peripheral Innervation

Peripheral neuropathies may result in autonomic symptoms including bladder dysfunction.

DIABETIC NEUROPATHY

Lower urinary tract symptoms are common, although often asymptomatic, in patients with diabetes. Bladder dysfunction is generally accompanied by other symptoms and signs of a generalized neuropathy. The onset of the bladder dysfunction is insidious, with progressive loss of bladder sensation and impairment of bladder emptying over years, finally leading to chronic low-pressure urinary retention. Urodynamic studies demonstrate impaired detrusor contractility, reduced urine flow, increased postmicturition residual volume, and reduced bladder sensation. It seems likely that both afferent and efferent fibers of the local spinal reflex arc are involved, causing reduced awareness of bladder filling and decreased contractility.

Amyloid Neuropathy

Lower urinary tract symptoms generally appear early in the course of amyloid neuropathy and are present in 50 percent of patients within the first 3 years of the disease. Patients most often complain of difficulty in bladder emptying and incontinence, although bladder dysfunction may be asymptomatic. Urodynamic studies have demonstrated reduced bladder sensations, underactive detrusor, poor-urinary flow, and inappropriate opening of the bladder neck. Bladder wall thickening may be seen on ultrasound. Up to 10 percent of patients with familial amyloid neuropathy type I may proceed to end-stage renal disease, often reporting polyuria as an early symptom. Patients with specific mutations may be treated with liver transplantation, and the presence of postoperative urinary incontinence is associated with a higher post-transplant mortality.

Immune-Mediated Neuropathies

Traditionally immune-mediated neuropathies have not been associated with bladder dysfunction. However, many patients with Guillain–Barré syndrome (as high as 25%) report bladder symptoms; these symptoms are more common with more severe neuropathies, appearing after limb weakness is established. Both detrusor areflexia and bladder overactivity have been described. Long-term complications are unusual, and recovery of lower urinary tract symptoms follows the course of the neuropathy.

Autoimmune Autonomic Ganglionopathy

Bladder dysfunction is well-recognized in patients with autoimmune autonomic ganglionopathy. The usual presentation is that of the rapid onset of severe autonomic failure, with orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, erectile dysfunction, and sicca symptoms, often with ganglionic acetylcholine receptor (AChR) antibodies. Bladder dysfunction generally manifests as voiding difficulty and incomplete emptying. The severity and distribution of autonomic dysfunction appear to depend upon the level of antibody titers.

Pure Autonomic Failure

Pure autonomic failure is a synucleinopathy affecting the postganglionic fibers and may mimic MSA. Lewy body deposition is confined primarily to the autonomic ganglia. Nocturia and voiding dysfunction are common, and bladder emptying is often affected.

Myotonic Dystrophy

Although myotonic activity has not been found in either the sphincter or pelvic floor of patients with myotonic dystrophy, bladder symptoms may be prominent and difficult to treat, presumably because bladder smooth muscle is affected. With advancing disease, megacolon and fecal incontinence also may become intractable problems.

Urinary Retention

Urinary retention occurring in isolation is most often due to a urologic cause. However, in some cases a neurologic cause is responsible.[2,4] The differential diagnosis that should be considered once a structural urologic lesion is excluded is found in Table 29-3.

Fowler Syndrome

Urinary retention or symptoms of obstructed voiding in young women in the absence of overt neurologic disease have long puzzled urologists and neurologists alike; in the absence of any convincing organic cause, the condition was thought to be functional. A primary disorder of urethral sphincter relaxation (Fowler syndrome) is typically seen in young women postmenarche who present with retention and bladder capacities often exceeding a liter without experiencing expected urgency. Polycystic ovaries are often associated. Electromyography of striated muscle of the urethral sphincter reveals complex repetitive discharges and myotonia-like activity, called decelerating bursts. The urethral pressure profile and urethral sphincter

TABLE 29-3 ■ Differential Diagnosis in a Patient Presenting With Urinary Retention

Lesions of the conus medullaris or cauda equina
Compressive lesions
Trauma
Intervertebral disc prolapse
Tumor
Granuloma
Abscess
Noncompressive lesions
Vascular: infarction, ischemia (arteriovenous malformation)
Inflammation: myelitis, meningitis retention syndrome
Infection: herpes simplex, varicella zoster, cytomegalovirus
Other neurologic conditions
Spina bifida
Multiple system atrophy
Conditions associated with dysautonomia (e.g., pure autonomic failure, autonomic neuropathies)
Miscellaneous causes
Medications (e.g., opiates, anticholinergics, retigabine)
Fowler syndrome
Radical pelvic surgery
Chronic intestinal pseudo-obstruction
Primary detrusor muscle failure
Idiopathic

volume are elevated. Urinary retention is often successfully managed by sacral neuromodulation.

DIAGNOSTIC EVALUATION

History

The history of patients with suspected lower urinary tract dysfunction should address both storage and voiding. Patients with storage dysfunction complain of frequency of micturition, nocturia, urgency, and urge incontinence. Urgency, frequency, and nocturia, with or without incontinence, is called the "overactive bladder syndrome," "urge syndrome," or "urgency-frequency syndrome."[4] Patients experiencing voiding dysfunction report hesitancy for micturition, a slow and interrupted urinary stream, the need to strain to pass urine, and double voiding. The history of voiding dysfunction is often unreliable as patients may be unaware of incomplete bladder emptying; therefore, the history should be supplemented by a bladder scan, as discussed later. Occasionally, these patients with voiding dysfunction may experience complete urinary retention.

The pattern of lower urinary tract dysfunction is influenced by the site of the neurologic lesion (Table 29-2), and variation from this expected pattern warrants a search for additional problems such as urologic disease.

Bladder Diary

A bladder diary provides a real-time assessment of bladder symptoms and is considered an extension of the history. It provides an opportunity to record the frequency of micturition, volumes voided, episodes of incontinence, and fluid intake over the course of a few days and should be a part of any evaluation of suspected lower urinary tract dysfunction (Fig. 29-2).

Physical Examination

In patients without an established diagnosis, the neurologic examination helps guide whether urologic complaints are neurologic in origin. Bradykinesia or rigidity can point to basal ganglia disorders. Cerebellar ataxia, parkinsonism, and symptomatic postural hypotension should raise the suspicion of MSA. Other autonomic features such as erectile dysfunction, orthostatic hypotension, and constipation may suggest autonomic failure. The findings of saddle anesthesia and absent sacral reflexes (anal or bulbocavernous) point to a lesion of the conus medullaris or cauda equina. The lumbosacral spine should be examined for dimples, tufts of hair, nevi, or sinus, which can be signs of occult spina bifida.

If the neurologic examination is normal in a patient reporting only bladder dysfunction, more detailed investigations such as neuroimaging or physiologic testing are unlikely to reveal an underlying neurologic cause.

In the general physical examination, palpating the abdomen for an enlarged bladder may suggest upper urinary tract damage including stones; tenderness over the loins may occur as well. Digital rectal examination helps to evaluate for prostate enlargement.

	Time / Volume (ml)						Total Fluid Intake	Episodes of Leakage

FIGURE 29-2 ■ Bladder diary recorded over 24 h demonstrating increased daytime and nocturnal urinary frequency, low voided volumes, and incontinence. These findings are seen in patients with detrusor overactivity. (From Panicker JN, Kalsi V, de Seze M: Approach and evaluation of neurogenic bladder dysfunction. p. 61. In Fowler CJ, Panicker JN, Emmanuel A (eds): Pelvic Organ Dysfunction in Neurological Disease: Clinical Management and Rehabilitation. Cambridge University Press, Cambridge, 2010, with permission.)

INVESTIGATIONS

Bladder Scan

Estimating the postvoid residual of urine is an essential step in the investigation of a neurogenic bladder. This assessment is most commonly carried out with a portable bladder scanner or by "in—out" catheterization, especially in patients who perform intermittent self-catheterization. A single measurement of a postvoid residual may not be reliable, and therefore a series of measurements should be made over the course of 1 or 2 weeks.

Screening for Urinary Tract Infections

All patients with lower urinary tract symptoms should be screened for urinary tract infection. Combined rapid tests of urine using reagent strips ("dipstick" tests) have a negative predictive value of 98 percent. However, since the positive predictive value is only 50 percent, a positive test should be followed by a urine culture to confirm infection.

Ultrasound Scan

In patients known to be at risk of upper urinary tract disease, surveillance ultrasonography should be performed periodically to evaluate for upper urinary tract dilatation or renal scarring. Ultrasound may also detect complications of neurogenic bladder dysfunction such as bladder stones.

Urodynamic Studies

Urodynamic studies include measurements of urine flow rate and residual volume, cystometry during both filling and voiding, videocystometry, and urethral pressure profilometry.[7] The term "urodynamics" is often used incorrectly as a synonym for cystometry. From the patient's point of view, urodynamic studies can be divided into noninvasive tests and those tests requiring urethral catheterization.

NONINVASIVE BLADDER INVESTIGATIONS

Uroflowmetry is a valuable test that assesses voiding function. The urinary flow is calculated through a flow meter, usually fitted in a commode or urinal, based upon the power necessary to maintain a rotation speed. A graphic printout of the urinary flow is obtained and time taken to reach maximum flow, maximum and average flow rates, and the voided volume are analyzed (Fig. 29-3). It is important that the patient performs the test with a comfortably full bladder, preferably voiding volumes of at least 150 ml; privacy is essential and a spurious result may be obtained if the patient is not fully relaxed. The test usually complements a bladder scan, and significant outflow obstruction is unlikely if uroflowmetry demonstrates a normal urine flow rate with no significant postvoid residual in the bladder scan.

INVESTIGATIONS REQUIRING CATHETERIZATION

Cystometry assesses changes in the bladder during nonphysiologic filling and also the pressure—flow relationship during voiding. The detrusor pressure is derived by subtraction of the abdominal pressure (measured from a pressure transducer attached to a catheter inserted into the rectum) from the intravesical pressure (measured from a pressure transducer attached to a catheter inserted into the bladder). The rate of filling is recorded by a machine that pumps

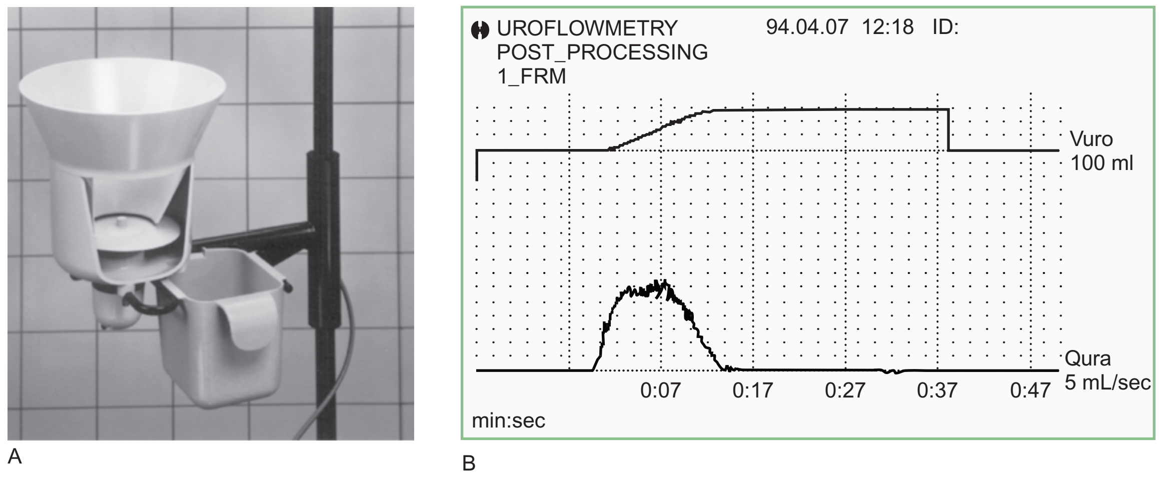

FIGURE 29-3 ■ *A*, Urinary flow meter. The side of the uroflow transducer has been cut away to show the disc at the base of the funnel, which rotates as urine passes into the collecting vessel. *B*, A normal printout from the uroflowmeter. A total of 290 ml was voided *(upper trace)*, with a maximum flow rate of 30 ml per sec *(lower trace)*. (From Dantec Medical A/S, Copenhagen, with permission.)

sterile water or saline through the catheter into the bladder. For speed and convenience, most laboratories use filling rates of between 50 and 100 ml per minute. This nonphysiologic rapid filling means that the full bladder capacity can be reached usually within 7 or 8 minutes. First sensation of bladder filling may be reported at around 100 ml, and full capacity is reached between 400 and 600 ml. In healthy subjects with a "stable" bladder, the bladder expands to contain this amount of fluid without an increase of pressure above 15 cmH_2O. The main abnormality sought during filling cystometry in patients with a neurologic disease is the presence of detrusor overactivity (Fig. 29-4) characterized by involuntary detrusor contractions which may be spontaneous or provoked. Detrusor overactivity of neurogenic origin is indistinguishable from other causes of detrusor overactivity on urodynamic testing. When bladder filling has been completed, the patient voids into the flow meter with the bladder and rectal lines still in place as valuable information can be obtained by measuring detrusor pressure and urine flow simultaneously.

Cystometry may be valuable in demonstrating the underlying pathophysiology of the lower urinary tract and may identify concomitant urologic conditions such as bladder outflow obstruction or stress incontinence. A general criticism is that findings on cystometry contribute little to elucidating the underlying disorder. In many patients with a neurogenic bladder, the "urodynamic diagnosis" does not influence management, and the need to perform a complete urodynamic study in all patients with a suspected neurogenic bladder is therefore unclear. The decision to carry out cystometry should include consideration of the underlying neurologic diagnosis, the perceived risk of upper tract damage, and sometimes, response to initial treatment. Patients with spinal cord injury, spina bifida, and possibly advanced multiple sclerosis should undergo urodynamic studies as part of the initial evaluation as they are at higher risk of upper tract involvement and renal impairment (although ultrasound is a less invasive method for monitoring the upper tract). In other conditions such as early multiple sclerosis, stroke, and PD, the risk for developing upper urinary tract damage is less, and the initial evaluation may be restricted to noninvasive tests; cystometry is indicated when bladder symptoms are unclear or in patients responding inadequately to first-line management.

Videocystometry

Videocystometry is cystometry carried out using a contrast-filling medium visualized radiographically. Urologists and urogynecologists have found videocystometry useful in detecting sphincter or bladder neck incompetence in patients with stress incontinence. The technique also gives additional information regarding morphologic changes that may occur as a consequence of neurogenic bladder dysfunction, including the presence of vesicoureteric reflux. The opportunity to inspect the outflow tract

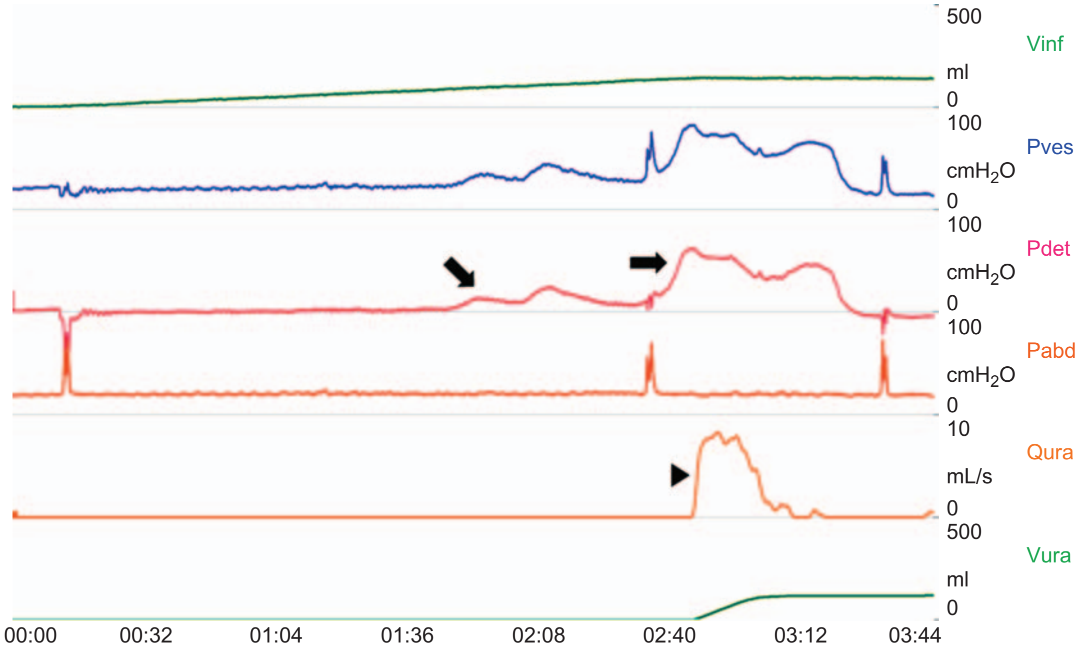

FIGURE 29-4 ■ Filling cystometry demonstrating detrusor overactivity. The dark orange line (Pabd) is the intra-abdominal pressure recorded by the rectal catheter, the dark blue line (Pves) is the intravesical pressure recorded by the bladder catheter. The pink line (Pdet) is the subtracted detrusor pressure (Pves − Pabd). Green lines represent volume infused during the test (Vinf) and volume voided (Vura), while the orange line represents urinary flow (Qura). The black arrows demonstrate detrusor overactivity and the black arrowhead indicates associated incontinence. (From Panicker JN, Fowler CJ: The bare essentials: uro-neurology. Pract Neurol 10:178, 2010, with permission.)

during voiding is of great value in patients with suspected obstruction.

Pelvic Neurophysiology

Various neurophysiologic investigations of the pelvic floor have been developed for assessing the innervation of muscles that are difficult to test clinically. Their clinical utility has been debated, and they currently play a role only in the assessment of patients presenting in specific clinical situations.

ELECTROMYOGRAPHY

Pelvic floor electromyography was first introduced with the aim of recognizing detrusor–sphincter dyssynergia, but it is currently performed only rarely. Technically the best signal is obtained using a needle electrode, but the discomfort from the needle itself can impair normal relaxation of the pelvic floor. Surface recording electrodes have been used, but they may record a considerable amount of noise artifact, which makes interpretation difficult. The value of the information provided is limited, and the demonstration of detrusor–sphincter dyssynergia is most often achieved by less invasive techniques such as videourodynamics.

Concentric needle electromyography of the pelvic floor is possible since motor units of the pelvic floor and sphincters fire tonically; they therefore may be captured conveniently using a trigger and delay line and subjected to individual motor unit analysis. Well-established normative values exist for the normal duration and amplitude of motor units recorded from these sphincter muscles.

Sphincter Electromyography for Suspected Cauda Equina Lesions

Lesions of the cauda equina are an important cause of pelvic floor dysfunction. Although electromyography may demonstrate pathologic spontaneous activity 3 weeks or more after injury, these changes of denervation often become lost in the tonically firing motor units of the sphincter. Most often with long-standing cauda equina syndrome, electromyography of the external anal sphincter demonstrates changes of chronic reinnervation, with a reduced interference pattern and enlarged motor units (>1 mV amplitude) along with polyphasic potentials.

Sphincter Electromyography in Multiple System Atrophy

Postmortem studies of MSA have demonstrated a selective loss of anterior horn cells in Onuf nuclei, which are spared in PD. This finding may explain the early urinary symptoms and sphincter involvement in MSA. Sacral cord involvement may precede central changes responsible for lower urinary tract symptoms in these patients. The central pathology of MSA may explain the symptoms of overactive bladder that may occur. The Onuf nucleus involvement may account for the abnormalities seen in the external urethral sphincter. These changes can be detected easily using electromyography (Fig. 29-5). There is debate on the role of anal sphincter electromyography in the diagnosis of MSA.

Sphincter Electromyography for Urinary Retention in Young Women

A characteristic abnormality in isolated urinary retention in young women can be found on urethral sphincter electromyography; complex repetitive discharges, akin to the sound of "helicopters" along with decelerating bursts, a signal somewhat like myotonia and akin to the sound of "underwater recording of whales," can be found. It has been proposed that this abnormal spontaneous activity results in an impairment of relaxation of the urethral sphincter, which may cause urinary retention in some women and obstructed voiding in others. This condition, known as Fowler syndrome (see above), is also characterized by elevated urethral pressures.

Penilo-Cavernosus (Bulbocavernosus) Reflex

The penilo-cavernosus reflex, formally known as the "bulbocavernosus" reflex, assesses the sacral root afferent and efferent pathways. The dorsal nerve of the penis (or clitoris) is electrically stimulated and recordings are made from the bulbocavernosus muscle, usually with a concentric needle. This test may be of value in patients with bladder dysfunction suspected to be secondary to cauda equina or lower motor neuron pathway damage. A normal response does not completely exclude the possibility of an axonal lesion.

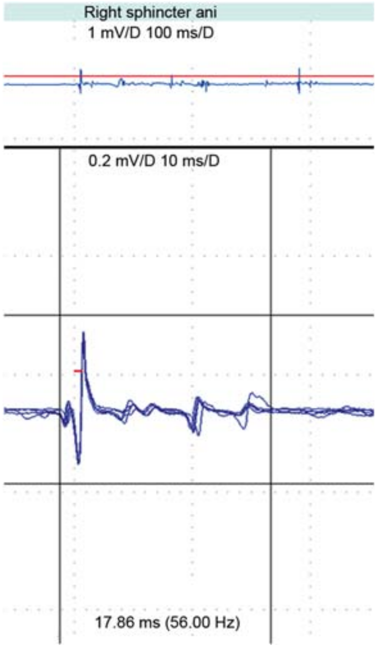

FIGURE 29-5 ■ Concentric needle electromyogram of the external anal sphincter from a 64-year-old man presenting with parkinsonism and urinary retention. Duration of the motor unit is 17.9 msec (normal <10 msec) with a mean duration of all the motor units recorded during the study of 22.9 msec; these prolonged motor units suggest chronic reinnervation and are compatible with a diagnosis of multiple system atrophy.

Pudendal Nerve Terminal Motor Latency

The only test of motor conduction for the pelvic floor is the pudendal nerve terminal motor latency. The response is obtained by stimulating the pudendal nerve either rectally or vaginally, adjacent to the ischial spine using a finger-mounted stimulating device with a recording electrode around the base of the finger that records from the external anal sphincter. Prolongation suggests pudendal nerve damage. However, as a prolonged latency is a relatively poor marker of denervation, the test has not proved contributory in the investigation of patients with suspected pudendal neuralgia.

PUDENDAL SOMATOSENSORY EVOKED POTENTIALS

Pudendal somatosensory evoked potentials can be recorded from the scalp following electrical stimulation of the dorsal nerve of the penis or clitoris. Although abnormal when a spinal cord lesion is the cause of sacral sensory loss or neurogenic detrusor overactivity, such pathology is usually apparent from the clinical examination. The latencies of the evoked potentials recorded are compared to those found with stimulation of the posterior tibial nerve.

COMPLICATIONS OF NEUROGENIC BLADDER DYSFUNCTION

Detrusor overactivity and reduced bladder wall compliance may lead to raised intravesical pressure, which can, in turn, lead to structural changes in the bladder wall such as trabeculations and diverticuli. The upper urinary tract (kidney and ureter) can also be affected through the vesicoureteric reflux, resulting in hydronephrosis along with renal impairment and possible failure. For reasons that are unclear, upper urinary tract damage and renal failure are less common in multiple sclerosis than in traumatic spinal cord injury or spina bifida. The risk of upper urinary tract damage is highest in patients who have raised intravesical pressure due to detrusor overactivity, low bladder compliance, and a competent bladder neck. Patients with a neurogenic bladder are prone to genitourinary tract infections such as cystitis, pyelonephritis, and epididymo-orchitis as well as bladder stones.

MANAGEMENT OF NEUROGENIC BLADDER DYSFUNCTION

The goals of managing neurogenic bladder dysfunction are to achieve urinary continence, prevent urinary tract infections, and preserve upper urinary tract function, all of which may improve the quality of life of patients with neurologic disease. The management of neurogenic bladder dysfunction must address both voiding and storage dysfunction (Fig. 29-6).

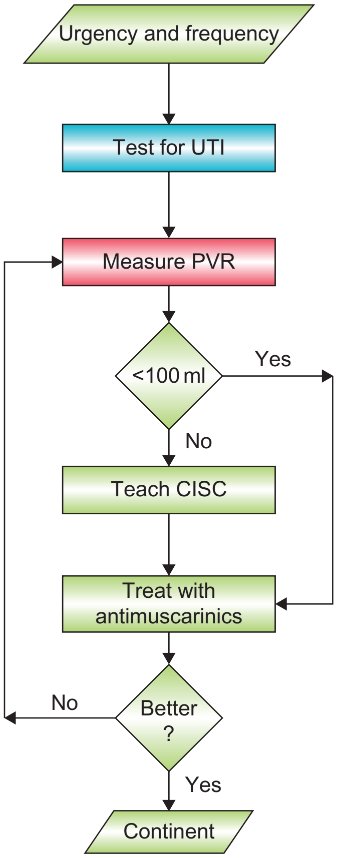

FIGURE 29-6 ■ Algorithm for the management of neurogenic lower urinary tract dysfunction. CISC, clean intermittent self-catheterization; PVR, postvoid residual urine; UTI, urinary tract infection. (From Fowler CJ, Panicker JN, Drake M, et al: A UK consensus on the management of the bladder in multiple sclerosis. J Neurol Neurosurg Psychiatry 80:470, 2009, with permission.)

Management of Voiding Dysfunction

A postvoid residual volume of more than 100 ml, or more than one-third of bladder capacity, is considered incomplete emptying. This voiding dysfunction can exacerbate detrusor overactivity, and an overactive bladder constantly stimulated by a residual volume responds with contraction, producing symptoms of urgency and frequency, making antimuscarinic medications less effective.

The widespread use of intermittent self-catheterization has greatly improved the management of neurogenic bladder dysfunction. There is no consensus regarding the amount of residual volume at which intermittent self-catheterization should be initiated. Sterile intermittent catheterization was previously the standard, but a clean, rather than sterile, technique has been found to be adequate. Intermittent catheterization is best performed by the patient, who should be taught by an experienced provider such as a nurse continence advisor. Neurologic lesions affecting manual dexterity, visual acuity, or cognitive function may require the patient to be assisted by a partner or other provider. The incidence of symptomatic urinary tract infections is low when catheterization is performed regularly.

α-Blockers can relax the internal urethral sphincter in men, and although they improve bladder emptying and reduce postvoid residual volumes, their use is usually not recommended unless concomitant prostatic enlargement is present. Botulinum toxin injections into the external urethral sphincter may improve bladder emptying in patients with spinal cord injury and significant voiding dysfunction. Suprapubic vibration using a mechanical "buzzer" is modestly effective in patients with multiple sclerosis who have incomplete bladder emptying and detrusor overactivity. The Credé maneuver (pressure applied from the umbilicus toward the pubis) and reflex voiding using nonforceful trigger techniques are usually not recommended as they may result in high detrusor pressure and incomplete bladder emptying during voiding.

Management of Storage Dysfunction

GENERAL MEASURES

Nonpharmacologic strategies are useful in the early stages of storage dysfunction when symptoms are mild. A restriction of fluid intake to around 1 to 2 liters daily is suggested, and it is often helpful to assess fluid balance by means of a bladder diary. Reduction of caffeine intake may reduce urgency and frequency, especially in patients who drink coffee or tea excessively. Bladder retraining, whereby patients void at regular timed intervals and then voluntarily "hold on" for increasingly longer periods of time, aims to restore the normal pattern of micturition. Pelvic floor exercises and neuromuscular stimulation may also be useful, once voiding dysfunction has been excluded, in the symptomatic treatment of an overactive bladder.[8]

ANTIMUSCARINIC MEDICATIONS

Detrusor overactivity is a major cause of incontinence in patients with neurogenic bladder disorders. The first-line treatment of detrusor overactivity is with antimuscarinic drugs, but the evidence for their efficacy is limited. A systematic review found no significant difference in efficacy between the various antimuscarinic drugs in patients with neurogenic bladder.[9] Oxybutinin was one of the earlier drugs introduced, but propiverine, trospium, propantheline, and tolterodine have all been shown to produce clinical and some urodynamic improvement in detrusor overactivity. Adverse events are due to nonspecific anticholinergic actions and include dry mouth, blurred vision for near objects, tachycardia, and constipation. These drugs can also block central muscarinic receptors and cause impairment of cognition and consciousness. Medications that have low selectivity for the M1 receptor, such as darifenacin, or restricted permeability across the blood–brain barrier, such as trospium, are probably less likely to cause cognitive disturbances which may be relevant in specific patient groups like PD.[10] The postvoid residual urine volume may increase following treatment and should be monitored by serial bladder scans. Many patients also have underlying voiding dysfunction, and it is often judicious to use antimuscarinic medications along with clean intermittent self-catheterization.

BETA-3 RECEPTOR AGONISTS

Mirabegron is a $\beta 3$ receptor agonist that has been approved for use in patients with neurogenic bladder symptoms. The advantage is that it does not have the antimuscarinic side effects. Common side effects include palpitations and increased blood pressure, so it is best to screen patients for cardiac risk factors before prescribing.[11]

DESMOPRESSIN

Desmopressin, a synthetic analogue of arginine vasopressin, reduces urine production and volume by promoting water reabsorption at the distal collecting tubules of the kidney. The evidence for its efficacy in the treatment of nocturia and daytime frequency in patients with multiple sclerosis suggests that it provides symptom relief for up to 6 hours. Desmopressin is useful also in managing patients with orthostatic hypotension. Side effects include the risk of hyponatremia, particularly in older patients, and it should be prescribed with caution in those with dependent leg edema or congestive heart failure. In patients over 65 years of age who are taking the drug, serum sodium levels should be measured at baseline and again at 3 and 7 days at the beginning of treatment or when the dose is changed.

CANNABINOIDS

Cannabinoids have limited efficacy on urinary disturbances in patients with multiple sclerosis. In one study of orally administered Δ^9-tetrahydrocannabinol extract, frequency, nocturia, and incontinence episodes were diminished. Oral nabiximols have demonstrated a significant reduction in the number of episodes of nocturia and of voids per day, as well as improvement in overall bladder control.

BOTULINUM TOXIN

Botulinum toxin was used initially on the basis that it blocks synaptic release of ACh from parasympathetic nerve endings and produces paralysis of the detrusor muscle along with a demonstrable increase in bladder capacity. Accumulating evidence indicates that the mechanism of action is more complex, however, and may involve afferent bladder innervation as well. Botulinum toxin type A injections of the detrusor muscle under cystoscopic guidance are now approved to manage refractory neurogenic detrusor overactivity in several countries, including the United States. The duration of effect is 9 to 13 months. Two pivotal phase III studies demonstrated that onabotulinumtoxinA significantly improves overactive bladder symptoms, urodynamic parameters, and quality of life, although patients often have to perform clean intermittent self-catheterization afterwards depending on the dose administered (30 to 42% in one study). Evidence also supports the efficacy of detrusor injections of botulinum toxin A in the treatment of neurogenic detrusor overactivity in adults with multiple sclerosis and spinal cord injury.[12] Studies also suggest that patients receiving botulinum toxin injections have fewer urinary tract infections and reduced catheter bypassing (urethral leakage while using an indwelling catheter).

VANILLOIDS

Despite the initial enthusiasm for its use, intravesical vanilloid therapy generally has been superseded by botulinum toxin treatments. Only a few centers worldwide offer resiniferatoxin treatment.

NERVE STIMULATION

Sacral Neuromodulation

An extradural sacral nerve stimulator can be useful in conditions resistant to antimuscarinic medications. The mechanism of action is likely stimulation of pelvic afferents, which are known to have an inhibitory effect on the detrusor. Implanting the stimulator requires evaluation during a test phase to determine whether the patient's symptoms are improved as judged by bladder diaries and measurement of residual volumes. If effective, the battery is implanted in a subcutaneous pocket and connected to the stimulating lead. The stimulator is continuously active, although it can be maintained at a subsensory level. There is only limited evidence supporting sacral neuromodulation in patients with progressive neurologic conditions.

Percutaneous Tibial Nerve Stimulation

Percutaneous tibial nerve stimulation (PTNS) has been found to be effective in neurologic patients reporting overactive bladder symptoms. It does not worsen voiding difficulties or increase the postvoid residual, unlike other treatments such as antimuscarinic agents or botulinum toxin. PTNS is an effective option for managing mild or moderate overactive bladder symptoms, and a typical treatment course consists of stimulating the nerve intermittently for 30 minutes over 12 sessions, typically weekly, through a fine-gauge stainless steel needle using a fixed-frequency, variable current strength electrical signal. Effects are relatively short lived and the need to return for maintenance top-up treatments is influenced by the degree of improvement of lower urinary tract symptoms.[13] Responders to treatment returning for maintenance PTNS more often report improvements in nocturia and perceived benefits over time, compared to those not returning for maintenance treatment.

Transcutaneous tibial nerve stimulation in volves stimulating the nerve using a cutaneous electrode which may be performed at home and has been shown to be safe and effective in patients with MS and stroke patients experiencing urgency incontinence. The advantages of tibial nerve stimulation include that it is noninvasive and has minimal adverse events.

Nerve Root Stimulators

In patients with complete spinal cord transection, but in whom the caudal section of the spinal cord and its roots are intact, implantation of a nerve root stimulator should be considered. Stimulating electrodes are placed around the lower sacral roots (S2 to S4) and activated by an external switching device. The stimulating electrodes are usually applied intrathecally to the anterior roots, and the posterior roots are severed at the same time. After the implant, adjustments are made to stimulation parameters so that the patient obtains maximum benefit in terms of making the bladder contract for voiding, assisting defecation, or producing penile erection. Although such devices are highly effective in selected cases, the additional neurologic deficit caused by the need for sectioning of the dorsal roots and resulting erectile dysfunction has reduced its acceptance. These stimulators are suitable only for patients with complete spinal cord lesions and are not effective in partial cord lesions or chronic neurologic disease.

SURGERY

Various surgical procedures to rectify a disorder causing incontinence in otherwise fit and healthy persons are often highly successful. Even after spinal cord injury, a surgical option might be the best solution for long-term bladder management. These

TABLE 29-4 ■ Situations Prompting Early Referral to a Urologist

- Hematuria
- Renal impairment
- Frequent urinary tract infections
- Suspicion of concomitant urologic pathologies such as bladder outlet obstruction due to prostate enlargement in men or stress incontinence in women
- Symptoms refractory to treatment
- Consideration of suprapubic catheterization
- Consideration of urologic procedures such as intradetrusor injections of botulinum toxin A or surgeries such as augmentation cystoplasty or urinary diversion

procedures are typically not effective in chronic and progressive neurologic conditions such as multiple sclerosis.

PERMANENT INDWELLING CATHETERS

When incontinence is refractory to management or the patient is no longer able to perform self-catheterization, an indwelling catheter may become necessary. The long-term complications of urethral catheters are well-known and include catheter bypassing, which occurs when strong detrusor contractions produce a rapid urine flow that cannot drain sufficiently quickly. A common response to bypassing is to use a wider-caliber catheter, and consequently the bladder closure mechanism becomes progressively stretched and destroyed. Bladder stones and recurrent infections are also more likely in patients with an indwelling catheter.

A preferred alternative to an indwelling urethral catheter is a suprapubic catheter, which can be inserted by a urologist. Extreme care is required since these patients often have small, contracted bladders, contributing to the risk of bowel perforation during placement. A suprapubic catheter is a better long-term alternative to urethral catheters since it preserves urethral integrity and sexual function, while leading to fewer problems with perineal hygiene.

Stepwise Approach to Neurogenic Bladder Dysfunction

The treatment options offered to a patient with lower urinary tract dysfunction should reflect the severity of bladder problems, which generally parallel the extent of neurologic disease. There are specific situations where patients should be seen early by a urology consultant (Table 29-4).

CONCLUDING COMMENTS

Sexual excitement and satisfaction from adequate stimuli are a normal component of a fulfilled life. The somatic and psychosocial factors involved may be compromised by neurologic disease. Sexual dysfunction may occur as the presenting symptom of a developing neurologic disease (e.g., erectile dysfunction in multiple system atrophy) or as an isolated phenomenon after local nerve injury (e.g., painful clitoral dysesthesia after pudendal nerve lesion), or it may be due to more general effects of a neurologic disorder.

Sexual disorders, such as loss of sexual desire, erectile dysfunction in men, decreased lubrication in women, and disturbances of ejaculation and orgasm, are common in patients with neurologic disorders but are usually not communicated by them to the neurologist. Sexual functioning needs to be addressed because it may be relevant for diagnosis, is a major determinant of quality of life, and may respond to treatment. The focus of this chapter is on the more classic neurologic dimension of sexuality as a physiologic function dependent on the integrity of neural control, on sexual

dysfunction as a consequence of neurologic disease, and on management of neurologic patients with sexual dysfunction.

SEXUAL FUNCTION AND THE NERVOUS SYSTEM

To the neurologist, sexual behavior involves a series of neurally controlled phenomena occurring in a hormonally defined milieu. Sexuality depends also on psychosocial factors, however, and the perspective of partnership and social issues should not be forgotten.

The sexual response is traditionally conceptualized as consisting of several phases, including desire, excitation, and orgasm. Although it has been criticized as male oriented, it still serves to structure the relevant observational, neuroanatomic, physiologic, and clinical issues for both genders. Differences in sexual behavior between men and women exist and are determined also by biologic factors.

Any lesion involving neural tissue relevant for sexual responses may cause dysfunction, as also may lesions of other neural structures more generally involved in control of sensation, motor function, cognition, and behavior (Fig. 30-1). Thus, all primary sensory areas plus the parietal and inferior temporal lobes process sexual stimuli, the forebrain regulates the initiation and the execution of sexual behavior, the medial preoptic area integrates sensory and hormonal signals, and the amygdala plays a role in the reward aspects of sexual function. Neurons from the paraventricular nucleus project to the thoracic and lumbosacral nuclei concerned with the sexual response, the hypothalamospinal projections being situated in the posterolateral funiculus of the spinal cord. Finally, the sympathetic, parasympathetic, and somatic efferents affect the sexual response, with genital afferents playing a part in the initiation of the cycle and in reinforcing the response. Furthermore, the hypothalamus controls the gonadotropic functions of the pituitary gland and thus prenatal development of genital organs, pubertal development, and the menstrual cycle; hormones finally influence the development of the nervous system.

Fertility and procreation are importantly linked to sexuality, but will not be discussed in depth here.

Desire

Desire or sexual interest (libido) refers to the extent that an individual responds to or seeks out erotic stimuli. This varies with time and circumstances, and its measurement depends on self-ratings of such items as the frequency of spontaneous sexual thoughts, the excitement provoked by them, and the resulting behavioral response. Desire is enhanced by sexual activity itself, exciting circumstances, new sexual partners, hypomania, and certain focal brain lesions (particularly of the frontal and temporal lobes). Depressed patients may develop more than their premorbid levels of sexual desire in response to antidepressant medication, as may patients with Parkinson disease in response to dopaminergic therapy. Sexual interest may be lowered by lack of opportunity, age, malnutrition, certain addictive or sedative drugs, debilitating illness, depression, epilepsy, and certain focal brain lesions.

Animal experiments have revealed dopaminergic-stimulating and serotonergic-inhibiting mechanisms controlling sexual interest. Androgens are necessary for normal libido, although there are some uncertainties related to this issue. In women, sexual desire is also associated with levels of free testosterone.

The rhinencephalon, including the limbic cortex, is important for sexual desire and behavior. The basal hypothalamus is particularly relevant; it is affected by tissue levels of the sex steroid hormones, and lesions involving it may lead to loss of desire. The medial preoptic area is involved in regulating sexual motivation and performance, and dopamine may regulate penile erection at this level. A functional magnetic resonance imaging (fMRI) study of sexual interest in men (by comparing erotic to sport clips) showed activation in the right parieto-occipital sulcus, the left superior occipital gyrus, and the precentral gyri. Functional imaging studies have demonstrated that the ovulatory cycle influences sexual interest and that activations in relevant brain areas are relatively greater in premenopausal than menopausal women.

Arousal

Sexual excitement results from genital stimulation, other sensory stimuli, or sexual ideation. The glans in both genders has a high receptor density: up to 80 to 90 percent of the nerve endings are free in the most superficial layer of mucosa. There are also corpuscular-type endings beneath the mucosal layer.

FIGURE 30-1 ■ Schematic representation of the autonomic and somatic innervation of the male *(left)* and female *(right)* sexual organs.

The receptors are of two types: slowly adapting distally and rapidly adapting proximally, with afferent C and A delta fibers. Surrounding the cavernous bodies are large nerve endings that resemble onions, with thick lamellae and a central nerve fiber connected to thick, myelinated nerve fibers. These nerve endings respond to deep pressure and vigorous movement. Receptors close to the cavernous bodies are influenced by the amount of engorgement of cavernous tissues so that touch may be experienced simply as touch or as a sexual stimulus depending on the degree of engorgement.

Sensory information from the glans and skin of the penis and clitoris is conveyed through bilateral branches of the pudendal nerve (the dorsal nerves of penis/clitoris), as shown schematically in Fig. 30-1. The afferents from the root of the penis (and from the anterior part of the scrotum) join the ilioinguinal nerve. Genital afferents synapse in the spinal cord via interneurons with both somatic and autonomic motor neurons; those afferents destined for supraspinal structures travel in the anterolateral funiculus. “Erotically colored” sensations from the genital region are conveyed by the spinothalamic pathways, and patients with selective damage to these tracts may complain of anorgasmia and ejaculatory failure. Orgasmic sensation is blocked by bilateral anterolateral section of the spinal cord (cordotomy).

Somatic sensory afferents deliver information on tactile sexual stimuli that, after synapsing in the sacral spinal cord, induce local sexual responses (i.e., erectile and glandular responses). Sensory information also passes to suprasacral regions and is operative in other reflex activity, leading to awareness of sexual excitation. Both thalamic and cortical areas receive sensory input from the genitals, and sexual feelings may be elicited when such areas are stimulated. In the primary sensory cortex the genitals are traditionally thought to be represented in the parasagittal area; functional imaging suggests localization on the medial edge of the hemispheric convexity.

Somatosensory input from other body parts (“erogenic zones”) may—subject to somatic and individual psychologic factors and dependent on context—also lead to sexual excitement. Adequate sexual excitation can be achieved by stimuli delivered through cranial nerves. Although such “extrinsic” excitation—similarly to that achieved by stimulation of sexual organs—should also be called reflex (because there may be little “intrinsic” contribution to the excitatory response), it has traditionally been called “psychogenic.” Cortical and subcortical structures related to the limbic system elicit erection when stimulated. (Mental imagery is the “real” psychogenic activator.)

In men during visually evoked sexual arousal, regional cerebral blood-flow measurements by positron emission tomography (PET) have demonstrated activation of the inferior temporal cortex (a visual association region) bilaterally, of the right insula and inferior frontal cortex (regions processing sensory information and motivational state), and the left anterior cingulate cortex (involved in neuroendocrine function).[1] Sexual arousal correlated with the magnitude of hypothalamic activation but was more pronounced in men than women. The occipitotemporal region was more activated in men, and the parietal lobe in women.[2]

Sexual excitement leads to a complex response of the autonomic nervous system, and also to typical posturing in different species; in humans this behavior has been studied little but is understood to be influenced by psychosocial and cultural factors.

Parasympathetic efferents from the S2 to S4 spinal segments, traveling through the sacral plexus and cavernosal nerves, initiate erection (Fig. 30-1). (The male erection has to be firm enough for vaginal penetration, and maintained throughout intercourse to bring about ejaculation, which in turn should deliver sperm to the uterine cervix.)

Blood flow in the penile artery, or the corresponding artery in the clitoris, increases. The smooth muscle of the cavernosal sinuses in the penile corpora relax, and the helicine arterioles branching from cavernosal arteries, selectively shunt blood flow to the lacunar spaces of the cavernosal bodies, filling them with blood. Subtunical venules are compressed so that corporeal venous return is restricted, resulting in increasing intracorporeal pressure. The pressure stabilizes at approximately systolic blood pressure, resulting in penile (and clitoral) tumescence and rigidity. Continued sacral parasympathetic activity maintains this erection.

The nerves of the corpora cavernosa have anatomic characteristics different from other nerves. The intracavernous nerves are located in fibrous tunnels, into which numerous fibrous bundles are attached. Contraction of striated pelvic floor muscles, the ischiocavernous muscles in particular, brought about through pudendal nerve activity, increases the rigidity of erection.

In women, parasympathetic activity causes clitoral erection, engorgement of the labia, and vaginal lubrication. The lubrication during sexual arousal is due to transudation through the vaginal wall. Another source is secretion from paraurethral glands (emptying into the urethra). Increased vaginal blood-flow, lubrication, and erection of cavernous tissue in the clitoris and around the outer part of the vagina are the female homologues of the male erectile response; indeed, lubrication occurs during rapid-eye-movement sleep in women. The response is dependent on innervation and a normal estrogen level.

In the periphery, the main proerectile transmitter is nitric oxide, which is colocalized with vasoactive intestinal peptide and acetylcholine; the main anti-erectile neurotransmitter is norepinephrine. The same mechanisms are responsible for clitoral erection.

Erections can still occur in men and animals after lesions of the sacral cord and pelvic nerves. This is due to the "alternative" proerectile pathway mediated through the hypogastric nerve. This explains the so-called psychogenic erections of paraplegics with conus or cauda equina lesions but preserved thoracolumbar segments. Similarly, women with injury to the sacral spinal cord and an ability to perceive pinprick in the T12 to L2 segments may retain the capacity for psychogenic genital vasocongestion. In women with complete spinal cord injuries and preserved sacral segments, such a response is as a rule obtained only by manual genital stimulation. Thus, the reflex–"psychogenic" dichotomy of the genital sexual response can be seen in both sexes.

Inhibitory influences on the sexual response also exist. In nucleus paragigantocellularis a majority of the serotonergic neurons project to the spinal cord (traveling in the lateral funiculus) and provide tonic inhibition of sexual reflexes in the rat.

Orgasm

Seminal emission begins during arousal and, with continued sensory stimulation, orgasm is triggered, with ejaculation of the urethral contents resulting from the rhythmic phasic contractions of perineal and pelvic floor muscles. Ejaculation is effected by integrated sympathetic outflow from T11 to L2 segments traveling through the sympathetic chain and hypogastric plexus and along the pelvic and pudendal nerves, and by somatic efferents traveling through the pudendal nerves. Although the predominant neural control of the male accessory sexual organs is sympathetic (adrenergic and purinergic), the secretion of seminal fluid is under parasympathetic control. Sympathetic activity causes smooth muscle contraction in the seminal vesicles, vas deferens, and prostate to deliver seminal fluid to the posterior urethra; in the bladder neck to prevent retrograde ejaculation; and in the corpora cavernosa to cause detumescence. The latter "antierectile" activity is inhibited during erection through spinal coordination of reflex action.

The female orgasmic response consists of rhythmic contractions of pelvic floor muscles, the uterus, fallopian tubes, and paraurethral glands; expulsions from the paraurethral (Skene) glands through the urethra may occur (so-called female ejaculation). Women may achieve orgasms by stimulation outside the genital region and probably do so more easily than men, but the most notable difference from men is that women may achieve multiple consecutive orgasms.

Motor innervation of the pelvic floor muscles as well as the ischiocavernosus and bulbocavernosus muscles is conveyed through pudendal nerve branches from below. However, the most relevant motor innervation of the levator ani ("pelvic floor") muscle is directly from the sacral plexus via the levator ani nerve. Electromyographic recording of the pelvic floor muscles in women during vibratory clitoral stimulation shows intermittent activity associated with contractions on a background of continuous activity. During ejaculation in males, repeated bursts of electromyographic activity precede and follow expulsion of semen. The sensation of orgasm, however, is not dependent on pelvic muscle contractions. Men report that orgasmic sensation begins before, and lasts longer than, bursts of electromyographic activity in the perineal muscles.

Orgasm can be separated conceptually (but not easily physiologically) from emission and ejaculation. PET imaging during orgasm has shown deactivation of frontal regions and the left temporal lobe; cerebellum and pons were activated (Fig. 30-2). There were only minor differences between the sexes.[2]

After orgasm (during the "resolution" or "refractory" phase), fMRI reveals activation of amygdala and the temporal lobes, and—for a short period—of the septal area.

Anorgasmia is very rare in neurologically normal men, but 13 percent of women between the ages of 18 and 26 years have never achieved orgasm, with the incidence declining to a minimum of 3 percent in women between the ages of 51 and 64 years.[3]

Ejaculation can be absent with an intact orgasm in lesions of the hypogastric plexus and under the influence of some drugs.

Topographic Anatomy of Nerves in the Pelvis

Hum Brain Mapp 30:3089, 2009, with permission.)

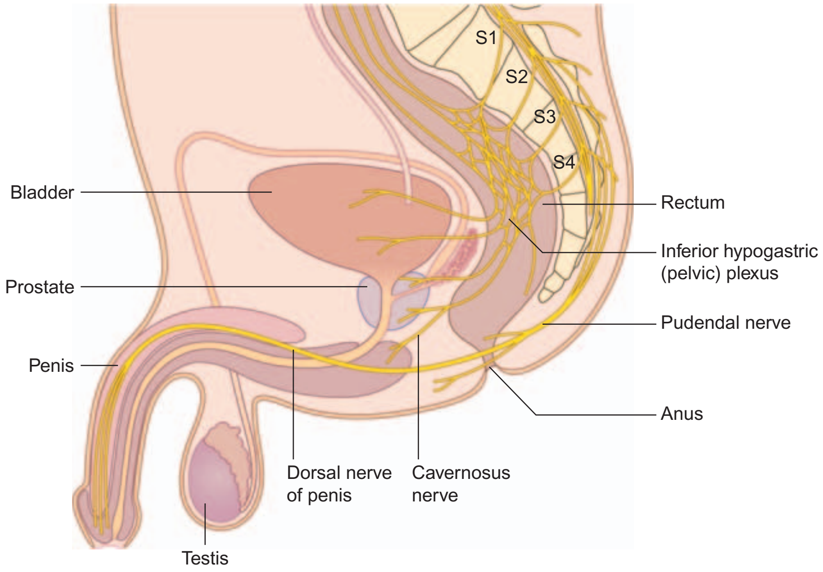

FIGURE 30-3 ■ Anatomy in males of the pudendal nerve (indicating its vulnerability to compression during cycling), and of the pelvic plexus and cavernous nerves (indicating their vulnerability during perineal or pelvic surgery).

abdominal and pelvic surgery is necessary for good postoperative results. In the pelvis and abdomen, autonomic structures related to genital innervation are situated in the retroperitoneal space. The superior hypogastric plexus is located anterior to the aortic bifurcation at the level of the fifth lumbar vertebral body and sacral promontory between the common iliac arteries. It divides caudally into the right and left hypogastric nerves. Within the pelvis, these nerves become the inferior hypogastric (pelvic) plexus, which is joined on each side by the pelvic nerves. In males, the inferior hypogastric plexus is lateral to the rectum, seminal vesicle, prostate, and the posterior part of the urinary bladder (Fig. 30-3). The lesser and greater cavernosal nerves originate from the anterior part, are joined by fibers from the pudendal nerves, and pass below the pubic arch. In females, the inferior hypogastric (pelvic) plexus gives off uterine nerves, branches for the vagina and cervix, and connections with the paracervical plexus.

In order to preserve neural structures relevant to sexual function during surgical procedures, the anatomy must be understood, surgical technique must be meticulous, and specific intraoperative "mapping" and "monitoring" procedures may be required.

Further details on the anatomy and physiology of the sexual response in men and women are provided elsewhere.[4,5]

Change in Sexual Function With Aging

There is little research on sexual functioning in the elderly. It is not easy to disentangle the changes due to aging and its related psychosocial problems from those due to any of the many different disorders that are common in the elderly (such as hypertension, cardiovascular disorders, lower urinary tract dysfunction, and depression) or to the effects of medication. Regardless, the sexual habits, desires, and preferences of the reasonably healthy elderly do not change, but the frequency of sexual activity generally decreases. Only 26 percent of those aged 75 to 85 years report sexual activity during the previous 12 months.[6] Men need more time and greater stimulation to achieve and maintain erections and to reach orgasm. They have a decreased sensation of impending ejaculation and decreased ejaculatory volume. Their refractory period after detumescence is prolonged. Their testosterone level decreases (but exogenous administration of androgens does not increase libido). Hormonal changes in menopausal women lead to loss of pubic hair and a change in the distribution of body fat tissue; libido diminishes and the vaginal wall thins, with decreased elasticity and lubrication. In some women, however, libido may actually increase after the menopause. In fact, 74% of women above 65 years of age continue to engage in sexual activity at least once a week.[6] Decreased sexual thoughts and frequency of intercourse after menopause are more closely correlated with testosterone than estrogen levels, but there is no clear relationship between low sexual desire and serum testosterone. In the very old (80 to 102 years old), touching and caressing is the most common form of sexual expression.

EVALUATION OF PATIENTS WITH SEXUAL DYSFUNCTION AND NEUROLOGIC DISORDERS

The breadth of the history and clinical examination will be tailored by the individual physician's interests and practice habits, but inquiry about sexual function should not be reserved for male patients. With the advent of effective treatment for erectile dysfunction, many physicians take a pragmatic approach to treatment and inquire about little more than whether erectile dysfunction is present. However, there is more to sexual dysfunction than erectile dysfunction, and more to treating any dysfunction than simply prescribing a pill. Dysfunction in an individual patient—even in the presence of neurologic disease—may be due entirely or in part to psychosocial, vascular, endocrine, or other causes.

History

The history should include details of neurologic disease as well as any past history of urologic/gynecologic, cardiovascular, endocrine, psychologic, and psychiatric disturbances. History of disorders of the sex organs, trauma and surgical procedures, the use of prescription drugs, smoking and alcohol habits, and possible drug abuse should also be elicited. The patient's sexual expectations, needs, and behavior should be defined as well as any misconceptions. Before diagnosing dysfunction of sexual organs, the level of actual desire should be established. The term *hypoactive sexual desire disorder* (HSDD) is used to define a persistent or recurrent reduction in desire for sexual activity, alone or with a partner, with inability to respond to sexual cues that would be expected to trigger a sexual response; these symptoms need to cause personal distress. If present in men, the disorder may be associated with impotence; in women it often occurs with the female sexual arousal disorder (FSAD), which is a persistent or recurrent inability to attain or maintain sufficient sexual excitement that causes personal distress.

Men should be asked about erectile function (the occurrence of nocturnal erections, morning erections, and erections evoked by genital, visual, auditory, or psychogenic stimuli) and women about vaginal lubrication. The nature of ejaculation should be determined, and in particular whether it is premature, retarded, absent, or dribbling (i.e., emissions occur through the urethra without the activity of pelvic floor muscles). Retrograde ejaculation, described as "dry ejaculation," means that ejaculum has entered the bladder. Finally it should be clarified whether the patient can achieve orgasm, and the quality of orgasmic sensations and experiences should be noted. In some circumstances it may be helpful to interview the patient's partner.

Formal questionnaires can be used to obtain standardized information on male and female sexual function. They are particularly relevant in research.

Clinical Examination

Sexual development, height and weight, changes in pigmentation and body hair, and the presence of galactorrhea should be noted. The external genitalia should be examined. Palpation of peripheral pulses (arms, legs, penis), auscultation of the heart, and blood pressure measurement are recommended.

A standard neurologic examination, with inspection of the lower back (for nevus, hypertrichosis, or sinus), the feet (for deformity or muscle atrophy), and the anogenital area may reveal signs of underlying neurologic disease. Examination of the anogenital region involves palpation of the bulbocavernosus muscles in the male, testing for voluntary contraction ("move the penis") and reflex contraction. The anal sphincter (also levator ani) is palpated for tone, voluntary contraction, and reflex contraction in both sexes by rectal examination. The cremasteric reflex (the L1 segment) and the bulbocavernosus and anal reflexes (S2 to S4/5 segments) should be tested.

Investigation of Genital Reaction and Arousal

In men, spontaneous and physiologically induced erection can be studied with a variety of techniques. Spontaneous nocturnal penile tumescence and rigidity can be measured in the sleep laboratory using mercury strain gauges (measuring penile expansion), visual inspection, measurement of buckling force (for assessment of rigidity), and polygraphic confirmation of sleep phases. Continuous monitoring of nocturnal penile tumescence and rigidity can be obtained by a rigidometer during normal sleeping conditions at home and also during daytime napping or in the awake, sexually stimulated state. Various low-cost screening tests for nocturnal penile expansion have been proposed, but their validity is questionable. Testing for nocturnal erections, however, does not reliably distinguish psychologic from central nervous system (CNS) causes of erectile dysfunction. The aforementioned testing remains mainly of research interest.

An intracorporeal penile injection of a vasoactive substance, such as prostaglandin E_1, will induce an erection (in the absence of major vascular pathology), thus strengthening the suspicion of a neurogenic or psychogenic cause of erectile dysfunction. Intracorporeal injection of vasoactive agents has been proposed as an established diagnostic tool in patients undergoing assessment for possible neurogenic erectile dysfunction and is safe when performed by experienced physicians, with an acceptable complication rate.

Suspected vasogenic erectile dysfunction may require the testing of penile vasculature (blood pressure and vascular competence) by a urologist. The purpose of testing should always be defined; pharmacologic testing may be sufficient for the majority of patients, and invasive tests reserved for those in whom surgery is contemplated.

In women, both direct and indirect methods are used to measure blood-flow changes in the labia and vagina. Noncontrast dynamic magnetic resonance imaging (MRI) can assess female sexual arousal quantitatively. All these tests are only of research interest; it has been stressed that vaginal vasocongestion to erotic stimuli may be unaccompanied by erotic feelings, and subjective indices should therefore be obtained when physiologic measurements are made.

Investigations of Neurologic Function

Functional tests are direct extensions of the clinical examination. Special devices and algorithms can be used for quantifying sensory perception on the genital organs and in the perineum. The measurement of vibratory perception (biothesiometry; measuring the vibration perception threshold) on the glans has been advocated for diagnosing sensory neuropathy in male and female patients. The vibration perception threshold on the penis (glans and shaft) in neurologically healthy men is similar to that of the feet, whereas in females this threshold (best measured on the clitoris, labia majora, and perineum) is the same as in the hands. Tests evaluating small-fiber function (e.g., testing for penile thermal sensation) may be more informative about the neural control of erection.

TABLE 30-1 ■ Tests for Assessing Sacral or Suprasegmental Neural Lesions

Somatic Sensory
Quantitative sensory testing
Dorsal penile nerve neurography
Pudendal somatosensory evoked potentials
Visceral Sensory
Somatosensory evoked potentials to proximal urethra/bladder neck stimulation
Bladder sensitivity testing
Somatic Motor
Electromyography
Motor evoked potentials
Sacral Reflex
Bulbocavernosus reflex
Anal reflex
Sacral reflex to proximal urethra/bladder neck stimulation
Autonomic
Sympathetic skin response
Neurocardiac testing
Cystometry

Several neurophysiologic tests have been suggested for assessing sacral or suprasegmental lesions (Table 30-1). Tests measuring conduction through somatic nervous pathways (motor, sensory, and reflex) might be expected to be useful because most lesions should involve both somatic and autonomic neural pathways, and abnormalities obtained on testing the former could be extrapolated to the latter. Even so, these tests are sensitive only to demyelination and not to axonal lesions, which predominate in clinical practice. Electromyography may demonstrate the activation patterns of striated muscles but is mainly used to differentiate normal from denervated (reinnervated) muscle. Controversy exists about the source and nature of the signals recorded in penile and clitoral electromyography, and the findings have no diagnostic relevance. The lumbosacral sympathetic system may be tested by the sympathetic skin response from the perineum (and penis).

The role in clinical practice of these and the other tests shown in Table 30-1 is limited. In terms of validity, experience, and available normative values, only electromyography (in muscles of the lower sacral myotomes) and the recording of sacral reflex responses and somatosensory evoked potentials (SEPs) to pudendal nerve stimulation are recommended. The patients with possible or probable neurogenic sexual dysfunction in whom such testing might yield a result relevant for diagnosis and prognosis (though rarely important for decisions on therapy) are those with suspected lesions in the peripheral sacral reflex arc. In these patients, support for the presence or absence of a neurologic lesion can be obtained; this may have medicolegal implications. The relationship between a neurologic lesion (or, for that matter, any neurophysiologic test abnormality) and sexual dysfunction is complex; in women with multiple sclerosis, for instance, latency of pudendal (and tibial) SEPs fails to predict the extent of sexual dysfunction.

Hormone Measurement

When patients with sexual dysfunction have symptoms or signs indicating endocrine dysfunction, hormone assays—or rather, endocrinologic consultation—may be necessary. The hormones to be studied depend on the circumstances (sex, age, and onset and nature of symptoms).

SEXUAL DYSFUNCTION IN PATIENTS WITH NEUROLOGIC DISEASE

Sexual dysfunction, such as lack of libido (in both sexes), erectile dysfunction and disturbances of ejaculation (in men), and deficient lubrication, dyspareunia, and problems with orgasm (in women), is not uncommon in the general population. In patient populations with disorders of the CNS, the prevalence of sexual dysfunction is reportedly higher, although few comparative studies have been done.

Insofar as many neurologic diseases affect primarily elderly patients and also carry the burdens of any chronic affection, the sexual dysfunction "specific" to the neurologic lesion(s) has to be ascertained against the background of valid control groups.

Head and Brain Injuries

Some cognitive impairment, personality change, and sensorimotor disability may remain after traumatic brain injury. Sexual dysfunction (either as a consequence of the cerebral lesion or psychosocial factors) occurs at a significantly greater frequency in these individuals.[7] Decreased or increased sexual desire, erectile failure, and retarded ejaculation may occur, at least in part as a consequence of post-traumatic pituitary dysfunction. Frontal and temporal lesions seem to result more often in sexual disturbances than parieto-occipital lesions. Hypersexuality, disinhibited and inappropriate sexual behavior, sexually aggressive behavior, and changes in sexual preference sometimes follow basal frontal and limbic brain injury and may lead to sex offences. Bilateral anterior temporal lesions may result in the Klüver–Bucy syndrome with hypersexuality and pansexuality (i.e., sexual drive that is directed not only toward humans but also toward animals and inanimate objects).

Cerebrovascular Disease

Decline in desire and the frequency of intercourse after stroke is not unexpected; the best predictor of decreased sexuality between partners is the degree of dependence in activities of daily living. From various studies, about 75 percent of patients who were sexually active before the stroke report a subsequent decrease in coital frequency. Poor-sexual functioning may persist even with otherwise good improvement.

Many men become impotent after a stroke; orgasmic and ejaculatory dysfunction is also common. Both erections and ejaculation may return within a year after stroke. Decreased vaginal lubrication and inability to achieve orgasm occur in women.

Sexual problems after a stroke may be complicated by other deficits, poor-personal image, lack of coping and, particularly, depression.

Patients and their partners may avoid sexual intercourse out of concern that another stroke may be precipitated. The heart rate during sexual activity may exceed 180 beats per minute in men and reach similar values in women; the workload during sexual activity is similar to that of climbing stairs or walking briskly. Although the exact risk of stroke during sexual activity is not known, it seems to be low. Patients and their partners may thus be reassured that, in resuming sexual activity, the gains in most instances outweigh any slight risks. These issues should be addressed in counseling.

Hypersexuality after stroke has been described, but seems to be rare.

Epilepsy

Epilepsy is associated with sexual problems, more often in men than women. Various types of abnormal behavior, hypersexuality, and, most commonly, hyposexuality have been reported, particularly in temporal lobe epilepsy. Satisfaction with life and sexuality is better in patients who are seizure free. The extent to which social and psychologic factors bear on sexual dysfunction is not clear. It is helpful to determine whether disturbances relate to seizures or occur during the interictal period.[8]

SEIZURES AND SEXUAL SYMPTOMS

Arousal and intercourse can provoke an epileptic attack through several pathophysiologic mechanisms; sexual phenomena may occur as part of an epileptic seizure; and sexual behavior may change in epileptic patients. Hyperventilation accompanying sexual activity can provoke generalized epileptic seizures. Sexual fantasies as well as genital stimuli (masturbation) or orgasm may trigger reflex epilepsy. Sensations in the genital organs may be manifestations of a partial epileptic seizure arising from a genital sensory cortical area. Motor symptoms such as erection and ejaculation or the sensory experience of an orgasm may also occur, the latter particularly from right mesiotemporal foci.

Such events may be experienced by patients as sexual or nonsexual. Pelvic sexual movements, as a part of epileptic automatisms, or compulsive masturbation in front of others may occur during or after a seizure. Complex sexual experiences may occur during an epileptic seizure in patients with complex partial epilepsy, most often in patients with temporal lobe lesions. Sexual automatisms may also occur with frontal lobe lesions.

Deviant sexual behaviors (e.g., exhibitionism, fetishism, or violent sexual behavior) have been related to epilepsy and interpreted as ictal phenomena. Only a few cases have been reported, but the episodic nature of the behavior and its occasional disappearance after treatment favor a causal connection between the behavior and the epilepsy. Complex partial seizures usually occurred, and lesions were present in one or both temporal lobes. Deviant behavior sometimes correlates with the presence of continuous seizure discharges in the electroencephalogram (psychomotor status).

INTERICTAL PHENOMENA

Patients with epilepsy, regardless of gender, often report a loss of sexual desire, reduced sexual activity, or inhibited sexual arousal; the prevalence of these complaints varies in different studies. Sexual interest is more reduced in patients with left temporal lobe lesions. Paranoid delusions of a sexual nature (such as of being violated) occur in some epileptic patients.

In men with temporal lobe damage and epilepsy, however, desire is sometimes preserved but erectile function is impaired and ejaculatory dysfunction may occur. Nocturnal tumescence may be lost.

Antiepileptic drugs, especially the older agents (phenytoin, phenobarbital, primidone, carbamazepine, and valproate), may lead to hormonal changes (particularly increased estradiol and decreased free testosterone levels in men), as well as decreased sexual desire and performance in both sexes. Menstrual irregularities are common among women with epilepsy. Antiepileptic drugs may influence morphology and motility of spermatozoa. The effect of the newer anticonvulsant drugs on sexual function is claimed to be less (for instance, for oxcarbazepine and lamotrigine). Sexual function is occasionally restored by surgery for epilepsy.

Parkinson Disease

Bladder and bowel dysfunction in Parkinson disease is related to specific autonomic nervous system involvement, and the same is probably true for some of the abnormalities in sexuality. The dopaminergic system is intimately involved in neural circuits controlling desire and arousal. Parkinsonian patients of both sexes show a decrease in libido, frequency of intercourse, and ability to reach orgasm. In men, erection and ejaculation are disproportionately affected. Women with parkinsonism report difficulties with arousal, vaginal tightness, involuntary urination, and sexual dissatisfaction. Depression is common in parkinsonian patients and may affect sexual activity; its treatment may further compromise sexual function.

Tremor may be enhanced during sexual arousal, thereby limiting the patient. Muscle rigidity and bradykinesia may also make sexual activities more difficult and may be worse in the late evenings if dose scheduling is aimed at favoring daytime activities.

Dopaminergic treatment may result in an apparent increase, or normalization, of libido without a corresponding improvement in parkinsonism. A true increase in desire and hypersexuality may occur as an adverse reaction to treatment with levodopa and, particularly, with dopamine agonists. On the order of 3 percent of treated patients demonstrate hypersexuality and probably even more do so among those treated with dopamine agonists; this has been attributed to D3 receptor hyperactivation. Spontaneous erections have been reported in patients receiving levodopa. Apomorphine treatment may result in erections and benefits sexual function, as does cabergoline.

Deep-brain stimulation of the subthalamic nucleus may have a positive influence on sexual well-being in Parkinson disease, in that male (but not female) patients are reportedly more satisfied with their sexual life. Hypersexuality has been reported as a side effect.

Multiple System Atrophy

Erectile dysfunction is an early sign of multiple system atrophy and indeed is the most frequent first symptom, beginning several years before the diagnosis is made (meaning that it often develops in men in their early 50s or late 40s). By the time of diagnosis, a large proportion of male patients were also unable to ejaculate. In women, reduced genital sensitivity (as compared to parkinsonian patients and controls) has been reported.

Patients have a decrease in desire, the ability to reach orgasm, and the frequency of intercourse. They may, however, develop hypersexuality with dopaminergic treatment.

Other Extrapyramidal Disorders

In families with Huntington disease, members who ultimately develop the disease tend to have more children than those who are spared. Approximately 10 percent of patients with Huntington disease have increased sexual activity, sometimes associated with mania or hypomania. Habitual promiscuity and marital infidelity may be early or initial symptoms of the disease. However, patients may have difficulty in becoming sexually aroused. Paraphilias such as sexual aggression, exhibitionism, and pedophilia may occur.

Disinhibited sexual behavior is common in patients with Gilles de la Tourette syndrome, and increased sexual activity has been reported in patients with Wilson disease.

Hypothalamic and Pituitary Disorders

Hypothalamic or pituitary dysfunction is usually caused by a pituitary adenoma; less common types of tumors in this region include craniopharyngiomas, meningiomas, optic gliomas, hypothalamic hamartomas, and metastases. Three-fourths of patients with hypothalamic or pituitary tumors have decreased or absent libido at the time of diagnosis. The figures are higher for large tumors that extend into the suprasellar region than for intrasellar tumors. Decreased libido (related to low serum testosterone levels) is also the first symptom in most men with small pituitary tumors and hyperprolactinemia, but is not a symptom for which patients commonly seek medical advice. Hence, the diagnosis is usually postponed until other symptoms appear, and it may be as long as a decade after the onset of changes in sexual behavior before the pituitary tumor becomes apparent. Erectile dysfunction is also common but, because of reduced sexual interest, is less distressing.

Most women with hypothalamic or pituitary disorders have amenorrhea. Women with hypoprolactinemia reportedly complain more commonly of loss of sexual desire than those with normal serum prolactin levels.

A low serum testosterone level in patients with erectile dysfunction does not necessarily signify a space-occupying lesion in the hypothalamic or pituitary region: a neuroimaging study of 164 impotent men with repeatedly low serum testosterone levels detected potentially serious lesions (pituitary lesions greater than 5 mm or any hypothalamic lesion) in 11, including 5 pituitary microadenomas (5 mm or more), 4 pituitary macroadenomas, and 2 hypothalamic lesions.[9]

Multiple Sclerosis

Disturbances of sexual function are common in patients with multiple sclerosis, regardless of gender, and affect eventually the majority of patients.[10] Sexual dysfunction decreases the patients' quality of life. Most such disturbances are thought to relate to spinal cord involvement and are generally, but not always, associated with urinary symptoms and lower limb involvement. Sexual dysfunction has also been correlated with destructive lesions in the pons, as detected by MRI, in patients with relapsing-remitting multiple sclerosis.

Erectile dysfunction is rare initially, but becomes more common with evolution of multiple sclerosis. Interest in resuming sexual activity persists in most patients. Spontaneous improvement in erectile function sometimes occurs. Problems with ejaculation are frequent and are often coupled to the erectile dysfunction. Anorgasmia has been correlated with evidence on MRI of brainstem and corticospinal abnormalities as well as with total area of lesions.

Decreased vaginal lubrication and sensory disturbances involving the genital region (hypoesthesia, hyperesthesia, and different types of pain) are common and may be apparent already in the early stages of multiple sclerosis. Sacral-segment dysesthesias may be so severe that patients are unable to bear direct genital or nongenital contact. Electrodiagnostic data—cortical evoked potentials of the dorsal nerve of the clitoris—suggest that pudendal somatosensory input is necessary for female orgasmic function, and that this may be disturbed even in early MS.

Some patients experience decreased libido; emotional and cognitive disturbances may be contributory. Increased sexual desire occasionally constitutes a problem. Other symptoms related to multiple sclerosis, such as fatigue, depression, cognitive dysfunction, spasticity in the lower limbs, urinary and bowel disturbances, and the use of aids to manage incontinence, can inhibit sexuality, as can paroxysmal motor and sensory disturbances triggered by sexual intercourse.

Lesions of the Spinal Cord

A spinal cord injury or lesion may lead to major neurologic deficits that in men initially often overshadow sexual disturbances such as a loss of normal erectile and ejaculatory function and of the ability to procreate naturally. For women, the resulting sexual dysfunction is often regarded as less limiting but is definitely important. The effects on erection, ejaculation, vaginal lubrication, and orgasm relate to the level and completeness of the lesion.

After complete cord transection, reflex function in all segments of the isolated spinal cord is completely lost (spinal shock) for a variable period lasting from a few hours to several weeks. Incomplete or slowly developing lesions may be associated with little or no spinal shock. The male genital reflexes (reflex penile erection and the bulbocavernosus and cremaster reflexes) are abolished or profoundly depressed during the period of spinal shock, and erectile and ejaculatory functions are abolished. Because of the occurrence of spinal shock, it is usually impossible to predict the extent or severity of sexual dysfunction, including whether erectile and ejaculatory functions will recover, in men within the first weeks after injury. With complete lesions of the spinal cord, the penis may become enlarged and semierect from passive engorgement of the corpora cavernosa due to paralytic vasodilation after the interruption of vasoconstrictor fibers in the anterolateral tracts of the spinal cord. As spinal shock subsides, reflex activity and spasticity may develop in the lower extremities and reflex functioning is regained of the bladder and bowels. In patients with upper motor neuron lesions, the erection reflex becomes part of the autonomic function of the isolated cord and may appear with tactile stimuli of various types and intensity, including stimuli to the penis, independent of cerebral participation and before the reflex responses of skeletal muscles are fully developed.

With complete destruction of the lower sacral spinal cord segments (the conus medullaris), reflex erection and lubrication are usually lost and the striated ejaculatory muscles are paralyzed. With spinal cord lesion between the level of the lower thoracic segments and the conus, both cerebral and reflex erection and lubrication may be possible, even though the patient cannot feel the sexual organs. Loss of sacral sensation does not necessarily imply anorgasmia. Although ejaculatory contractions cannot be felt when a complete lesion of the spinal cord exists above the conus, autonomic components of the orgasm can be experienced. Hyperesthesia often occurs just above or at the level of the spinal cord lesion, and may be useful as an erogenous zone. Although bladder, bowel, and sexual dysfunction often co-exist, this is not necessarily the case; sexual function may be preserved in spite of severe neurogenic bladder dysfunction, presumably owing to preservation of the thoracic sympathetic outflow.

A meta-analysis of 24 studies of more than 2,500 men with spinal cord injuries showed that a median of 80 percent (range, 54 to 95%) reported spontaneous erections.[10] The percentage of men reporting ejaculation without therapeutic assistance was much lower (median, 15%; range, 0 to 52%). Fewer (26%) of the patients with complete lower sacral lesions had erectile capacity than those with complete upper cord lesions or incomplete lesions at any level (90 to 99%). However, there is much individual variation, and an accurate prognosis for future sexual function may not be possible in individual cases.

Patients with incomplete spinal cord injury retain the ability for psychogenic genital vasocongestion if pinprick sensation is preserved in the T11 to T12 segments; only reflexogenic responses are obtained in those with complete spinal cord injury. After spinal cord injury, women menstruate and are able to conceive and give birth, although those with a paralyzed pelvic floor are at risk of overstretching and perineal tears. Autonomic hyperreflexia (Chapter 8) may occur in those with a lesion above T6 or T7.

Preoccupation with future sexual performance occurs early after injury, and it may be easier for men to accept motor deficits than sexual problems. Sexual readjustment depends on the individual, on previous sexual habits, and on the cooperation of partners. In one study, sexual readjustment was closely and positively correlated with a young age at injury, frequency of sexual intercourse, and willingness to experiment with alternative sexual expressions. Physical and social independence and a high mood level were further positive determinants of sexual adaptation after injury.[11]

The semen of men with spinal cord injury is characterized by small volume, low sperm count, and low sperm mobility. Reduced fertility cannot therefore be attributed completely to ejaculatory dysfunction. Collection of semen very early after the injury makes it possible to store semen of good quality for future insemination.

The ability to ejaculate by masturbation or sexual intercourse is impaired in most men with severe injury of the spinal cord; consequently, pregnancies caused by such men are rare without medical intervention. Ejaculation can be provoked in many paraplegic men through vibratory stimulation or electrostimulation (with careful blood pressure monitoring because of the risk of autonomic dysreflexia). Repeated vibration-induced ejaculations result in increased volume of semen, a larger number of motile sperms, and improved sperm penetration capacity. Insemination with autologous semen obtained in such a way has resulted in pregnancies.

Orgasms may occur in men with spinal cord injury but may differ from those that occurred before the injury. Women with such injuries may also achieve orgasm; indeed, some women with apparently complete lesions can do so, perhaps because of afferents from the cervix traveling with the vagus nerve. Latency to orgasm is greater in women with spinal cord injury than in normal subjects, but the descriptions of orgasm are indistinguishable.

Cauda Equina Lesions and Lumbar Stenosis

Although complete lesions of the cauda equina damage the parasympathetic erectile pathways to the penis, a number of men (approximately one-fourth) are still able to achieve an erection psychogenically, mediated probably by the sympathetic erectile pathway involving the hypogastric plexus. There are also ejaculatory disturbances (delayed or absent, but occasionally premature ejaculation), penile sensory loss, paresthesias, dysesthesias, and even pain syndromes. In a group of men with cauda equina lesions of differing causes and variable severity, only 15 percent reported normal sexual function.[12] Women report loss of erotic sensation, dyspareunia, loss of lubrication, loss of feeling during vaginal intercourse, difficulties in achieving orgasm, and changes in the feeling of orgasm.

Involvement of lower sacral nerve roots by any process can lead to “positive” as well as “negative” functional symptoms. Sensory symptoms and deficits involving the genitals are not necessarily accompanied by impotence. Spontaneous erections on walking are occasionally reported in patients with symptomatic lumbar stenosis.

Spinal Malformations

Any type of dysraphism may be associated with neurologic symptoms that may include sexual disturbances, but data from large patient populations are lacking. Meningomyelocele as a rule gives rise, among other disturbances, to sexual dysfunction, depending on the severity of the malformation. Some boys have no genital sensations at all, with loss of erection and orgasm; some have isolated erections without emission. Loss of genital sensations is the major complaint in girls.

Erectile dysfunction may occur in patients with Arnold–Chiari malformations; the onset of sexual symptoms is generally after the development of other neurologic disturbances.

Localized Nerve Lesions

Trauma may cause pudendal nerve injury, leading to loss of penile sensation, dysesthesias, pain syndromes, and dribbling ejaculation because of perineal muscle denervation. Among long-distance cyclists, it was found in one study that 22 percent had penile sensory symptoms and 13 percent had erectile dysfunction; symptoms were transient but persisted for up to 8 months.[13]

Erectile dysfunction may follow pelvic fracture, especially when urethral injury has occurred, owing to involvement of the neurovascular bundles. The peripheral autonomic nerves to the genitalia may be injured also by surgical procedures, leading to erectile and ejaculatory dysfunction in men and loss of lubrication in women. The sympathetic thoracolumbar fibers may be injured by retroperitoneal lymph node dissections. Pelvic plexus and cavernosal nerves may be injured by such operations as abdominoperineal resection for carcinoma, hysterectomy, radical prostatectomy, or sphincterotomy, thus significantly impairing the quality of life in patients after otherwise successful surgery (cf. Fig. 30-3). Surgeons are increasingly aware of the need to preserve relevant neural tissue even during radical surgery and have developed "nerve-sparing" operations.

Erectile dysfunction has also been reported after injection of sclerosing agents to treat hemorrhoids and hypersensitive bladder.

Diabetic Polyneuropathy

Diabetes is the most common cause of polyneuropathy in developed countries, and the most frequent type of neuropathy is the distal symmetric sensorimotor variety, in which small nerve fibers may be involved earlier than large fibers. This polyneuropathy is frequently accompanied by autonomic involvement, and dysautonomia is occasionally the predominant clinical presentation, with bladder, bowel, and sexual dysfunction. Hyperglycemia and some glycosylation products promote inactivation of nitric oxide and there seems to be a selective nitrergic neurodegeneration in diabetes. Further discussion of diabetic neuropathy is provided in Chapter 19.

Sexual dysfunction, especially erectile dysfunction, is common in diabetic men. Erectile dysfunction has been reported in 9 percent of diabetic men aged 20 to 29 years, rising to 95 percent of diabetics by age 70. Overall the incidence in a population of 9,500 diabetic men (20 to 70 years old) was 38 percent. Patients had the onset of impotence within the first 10 years of their disease in 50 percent of cases.[14] Men with diabetic polyneuropathy have fewer sleep-related erections, shorter tumescence time, diminished penile circumference increase, and weaker penile rigidity than do nondiabetic men. Erectile dysfunction is usually considered neurogenic when there are other signs of neuropathy, although alternative etiologic possibilities cannot be excluded. There is little correlation with neurophysiologic abnormalities in peripheral nerve function. Although the bulbocavernosus reflex latencies and penile (pudendal) evoked potentials are more often abnormal in impotent than potent diabetic men, neurophysiologic testing of pudendal nerve function is less sensitive in diagnosing neuropathy in impotent diabetics than limb nerve conduction studies.

In patients with cystopathy, retrograde ejaculation is sometimes an additional problem; failure of normal closure of the bladder neck by sympathetic activation during ejaculation leads to semen passing retrogradely into the bladder.

Among women, those with more diabetic complications have greater sexual dysfunction. A correlation in diabetic women of sexual dysfunction with the presence of neuropathy has not been found in all studies. Reduced sexual desire, decreased vaginal lubrication, and decreased capacity to achieve orgasm compared with age-matched controls have been reported.

Chronic Renal Failure

Male patients on hemodialysis have a similar prevalence of erectile dysfunction (approximately 70%) to patients on peritoneal dialysis (80%). Neuropathy is not the only possible cause; primary hypogonadism has been reported, and involvement of the testes also leads to low sperm counts and azoospermia. However, even in nondiabetic men with erectile dysfunction who were undergoing hemodialysis, the etiology is usually neuropathic rather than endocrinologic or vascular. On the whole, there is a tendency for pre-existent erectile dysfunction to improve after transplantation.

Among women with uremia, one-half have decreased desire, and one-third have decreased lubrication; dysfunction improves after transplantation.

Other Acquired Polyneuropathies

Autonomic dysfunction, including erectile dysfunction, occurs in other peripheral neuropathies, including those due to infectious agents, chemical toxins, secondary amyloidosis, prescription or street drugs, and vitamin B_1 or vitamin B_{12} deficiency, or those that are parainfectious or paraneoplastic. Autonomic involvement may lead to erectile dysfunction in the Guillain–Barré syndrome and may also occur in patients with chronic inflammatory demyelinating polyneuropathy. Reversal of erectile dysfunction and penile sensory loss may follow effective treatment.

In persons infected with the human immunodeficiency virus (HIV), peripheral nerve disorders occur commonly and may be accompanied by a dysautonomia. Slowed sural and dorsal penile sensory conduction velocities suggest that neuropathy is important in the genesis of erectile dysfunction in HIV-positive men. Counseling and treatment may be especially important in AIDS patients with sexual dysfunction, since the use of condoms often precipitates the problem, and men are therefore unwilling to use protection.

Hereditary Polyneuropathies

Erectile dysfunction and ejaculatory problems may occur in patients with hereditary sensory neuropathy and Charcot–Marie–Tooth syndrome. Erectile dysfunction also occurs in primary amyloidotic polyneuropathy and adrenoleukodystrophies. Men with hereditary motor and sensory neuropathy and electrophysiologically proven involvement of the pudendal nerves may nevertheless have normal sexual function.

Amyotrophic Lateral Sclerosis

Sexual function is normal in men with amyotrophic lateral sclerosis. Even when severe weakness makes intercourse impractical, erection and ejaculation are possible through partner masturbation, and the sensation of orgasm may be experienced as normal. These factors are highly relevant with regard to the patient's quality of life and may be important in counseling patients and their partners.

Hereditary Neuromuscular Diseases

The early onset and progressive course of certain hereditary neuromuscular diseases may restrict psychosocial and psychosexual development and limit sexual activity. Nevertheless, the capacity for sexual satisfaction remains unaffected in many patients who survive to adulthood and consequently has led to more awareness of the need for appropriate counseling.

In Kennedy syndrome (X-linked bulbospinal muscular atrophy), gynecomastia is common and testicular atrophy, decreased libido, and erectile dysfunction may occur. Hypogonadism, diminished libido, erectile dysfunction, and amenorrhea occur in certain muscular dystrophies (myotonic dystrophy but also others) and in mitochondrial encephalomyopathies.

Adverse Sexual Reactions to Medications

Many medications used in patients with neurologic disorders have adverse effects on sexuality (Table 30-2).

TABLE 30-2 ■ The Effects on Sexual Function of Some Common Medications Used for Neurologic or Related Purposes

Drug	Effects on Sexual Function
Anticholinergics (e.g., for movement disorders, depression, overactive bladder)	Vaginal dryness
Antihypertensives	Erectile dysfunction
Antipsychotics	Erectile dysfunction Reduced libido
Antidepressants	
Selective/nonselective serotonin reuptake inhibitors	Reduced libido Anorgasmia Delayed ejaculation Erectile dysfunction
Duloxetine	Reduced libido Anorgasmia Delayed ejaculation Erectile dysfunction
Trazodone	Priapism
Tricyclic agents (e.g., for depression, pain)	Erectile dysfunction Reduced libido Anorgasmia Delayed ejaculation
Antiparkinsonian agents	
Levodopa, dopamine agonists	Hypersexuality
Amantadine	Reduced libido
Antispasticity agents	
Baclofen	Erectile dysfunction Delayed ejaculation
Dantrolene	Erectile dysfunction Reduced libido
Antiepileptic drugs	
Enzyme-inducing antiepileptic drugs (e.g., phenytoin, carbamazepine, barbiturates)	Erectile dysfunction Reduced libido
Valproate	Erectile dysfunction Reduced libido Anorgasmia
Topiramate	Erectile dysfunction Anorgasmia
Pregabalin	Erectile dysfunction Delayed ejaculation
Oxcarbazepine	Anorgasmia
Levetiracetam	Reduced libido
Lamotrigine	Hypersexuality*

*Improved sexual function has been reported when patients are switched to lamotrigine.

At least until recently, however, the occurrence of sexual dysfunction was rarely monitored in clinical drug trials, and our data are collated from postregistration use, mostly uncontrolled studies and case reports. Further discussion of this aspect is beyond the scope of this chapter.

THERAPY

Sexual dysfunction associated with neurologic disease often increases patients' distress. Discussion with patients and partners about their sexual life should be part of any rehabilitation strategy. In all instances, drug regimens should be reviewed for possible effects on sexual function. Sexual education, counseling, and specific suggestions about therapeutic methods are important, and should be provided by the treating physician. In a limited number of patients, referral to a sexual therapist may be indicated. Methods for sexual rehabilitation in the context of neurologic disorders have been described.[15]

Treatment of Neurogenic Erectile Dysfunction

The development of drug treatments by the oral and intracavernous routes has revolutionized the outlook for men with erectile failure.

In neurogenic erectile dysfunction, part of the problem may be penile sensory loss. Additional vibratory stimulation may help in producing a rigid erection sufficient for vaginal penetration. As a last resort, surgical treatment is also possible.

ORAL AGENTS

Specific phosphodiesterase-5 inhibitors continue to be developed to treat erectile dysfunction; the first was sildenafil. These drugs have already been used by several million men. The selective inhibitors of type 5 cyclic guanosine monophosphate phosphodiesterase augment the nitric oxide-mediated relaxation pathway in penile tissues by increasing available cyclic guanosine monophosphate in the corpus cavernosum. These medications therefore do not cause erection but enhance the response to sexual arousal. Sildenafil taken at bedtime also significantly increases nocturnal erections.

Sildenafil is an effective treatment for erectile dysfunction in men with diabetes, patients on dialysis and after renal transplantation, multiple sclerosis, Parkinson disease, spinal cord injury, spina bifida, and familial amyloidotic polyneuropathy. In men with erectile dysfunction after radical prostatectomy, sildenafil is ineffective when a nerve-sparing procedure was not performed on at least one side, but it is effective if the cavernous nerves were spared, although it may take up to 18 months to obtain the best response. Overall, its efficacy in patients with an organic etiology of erectile dysfunction was reported to be 68 percent, being lower in diabetics (59%) and in nonselected postprostatectomy patients (43%).[16]

Sildenafil (25, 50, or 100 mg) can be taken orally 1 hour before intended sexual activity. (Significant effects have been reported between 30 minutes and 4 to 6 hours after taking the medication.) It should be noted that a meal delays absorption of the drug, and so does slowed gastric emptying such as is seen in Parkinson disease and autonomic neuropathy. Treatment should be begun with 25 or 50 mg, and the same dose taken several times before it is increased. Dose-finding studies have demonstrated a dose-response curve. Sildenafil can be used repeatedly, and if used once or twice per week there should be no fear of tachyphylaxis.

In men with diabetes mellitus or spinal cord injury, vardenafil (5 to 20 mg) and tadalafil (2.5 to 20 mg) have been used with similar efficacy. Tadalafil has a longer half-life and is thus longer acting.

Phosphodiesterase-5 inhibitors are contraindicated in combination with vasodilator drugs of the nitro type and nitric oxide donors, but a cardiologist can change such drug regimens in suitable patients with erectile difficulties requiring treatment. Phosphodiesterase-5 inhibitors should not be used in patients with retinitis pigmentosa. They are contraindicated in men with hypotension (blood pressure below 90/50 mmHg). Care should be taken to identify men with multiple system atrophy who may have erectile dysfunction, atypical parkinsonism, and asymptomatic postural hypotension. In our experience, an intelligent patient can use sildenafil after clear explanation, with careful planning of activity during the several hours after drug intake and performing sexual activity in the recumbent position.

No evidence was found of sildenafil effects on the myocardium or the conduction system. However, evaluation of functional capacity is necessary in patients with coronary artery disease, who need to know the risks of physical (and sexual) activity. Patients who can exercise to 4.5 metabolic equivalents without angina or hypotension can probably use sildenafil safely. Recommendations for the use of sildenafil in patients with cardiovascular disease have been published. In controlled and open-label studies, no increased risk of cerebrovascular events has been reported, although one patient has shown a temporal association of sildenafil use with a transient ischemic attack and then a stroke.

The most common adverse events of sildenafil are headache, flushing, and dyspepsia. Temporary visual symptoms (mainly color-vision disturbances) may occur with higher doses (100 mg), and nonvasculitic anterior optic neuropathy has been described in rare instances. Adverse effects are mostly transitory and of minor intensity.

Treatment with apomorphine sublingually has been tried as another therapeutic option for men with erectile dysfunction, but it has a relatively weaker effect than phosphodiesterase-5 inhibitors, and obnoxious side effects (nausea).

Yohimbine is an ancient aphrodisiac that is produced from the yohimbine tree (*Pausinystalia yohimbine* of the Rubiaceae family), which grows in West Africa. It has little to offer in the presence of modern drugs.

INTRACAVERNOUS INJECTION THERAPY

Intrapenile injections of papaverine have been used extensively in the treatment of erectile dysfunction in men with spinal cord injury, multiple sclerosis, and other neurogenic conditions. Doses do not relate to the level or extent of spinal injury. Prostaglandin E_1, papaverine, and a papaverine-phentolamine mixture all showed an efficacy rate of more than 70 percent. Acute complications such as priapism were, however, lower with prostaglandin (25%) than papaverine (65%) or a papaverine-phentolamine mixture (63%); the risk of local long-term complications was also lower with prostaglandin (8%) than with papaverine (57%) or a papaverine-phentolamine mixture (12.4%).[17]

Prostaglandin E_1 (alprostadil) is now the preferred drug for self-injection therapy in erectile dysfunction. Intracavernous injection should be taught under medical supervision before self-administration is attempted by the patient or his partner. The effect is very rapid and may last for 2 to 4 hours. Its efficacy in diabetic patients with impotence has been confirmed. Local bleeding, pain, and fibrosis may develop in the corpora cavernosa, leading to loss of effectiveness. This treatment is contraindicated in patients taking anticoagulants or with hematologic malignancies.

Long-lasting erections—priapism—as an adverse drug reaction usually have a good prognosis with conservative treatment. Painless priapism of less than 6 hours' duration should be treated at first by cooling. If present for more than 6 but less than 24 hours, intracavernous injection of an α-adrenergic agonist such as metaraminol is recommended. In painful priapism or with failure of conservative methods, penile puncture should be performed, at which time a cavernosal blood sample should be obtained to assess cavernosal hypoxia.

INTRAURETHRAL THERAPY

Intraurethral therapy with alprostadil (prostaglandin E_1) has been introduced as a less invasive alternative; in a study of patients with spinal cord injury, it was found to be of variable effectiveness and less satisfactory than intracavernosal injection therapy.

VACUUM DEVICES

Rigidity adequate for penetration occurs in 90 percent of patients with neurogenic erectile dysfunction when a vacuum device is used. Satisfaction of partners was initially reported as high (70%), but after months of treatment, and despite an increase in sexual activity, only 41 percent of patients were satisfied.[18] Premature loss of rigidity and difficulty in placing and removing the constriction bands are common complaints. The most common complications are bruises, petechiae, and skin edema. The constriction band should not stay in place for longer than 30 minutes; major complications such as penile gangrene, severe erosion, and cellulitis have been associated with prolonged wearing of the band.

The use of a constriction band (on its own) may help patients who can obtain an erection, albeit not a durable one; the same restrictions concerning the duration of application should be observed.

SURGICAL TREATMENT

Penile prostheses (implanted semifirm or inflatable rods) were introduced in the 1970s, but, with the advent of pharmacologic treatment options, have limited utility in neurologic patients. They may still be useful as a last resort, but are not considered further here.

Ejaculatory Dysfunction in Men With Neurologic Disorders

In cases of anejaculation/anorgasmia, vibratory stimulation may be helpful. The presence of functional penile nerves is necessary for orgasm achieved by penile vibratory stimulation. (Interestingly, penile vibration has a significant antispastic effect.)

Diabetes mellitus, retroperineal lymph node resection, and certain pharmacologic agents may render the patient effectively sympathectomized, leading to failure of seminal emission or to retrograde ejaculation. Patients may respond to a variable extent to sympathomimetic pharmacologic agents such as imipramine, phenylpropanolamine, or ephedrine. If retrograde ejaculation persists, sperm retrieval from the bladder is usually all that is required when insemination is contemplated. If unsuccessful, procedures such as surgical sperm retrieval from the testis, epididymis, or vas deferens may be necessary. Such patients are usually poor candidates for the assisted ejaculation procedure of penile vibratory stimulation because the sympathetic innervation necessary for seminal emission is not intact.

Treatment options for insemination in other neuropathic conditions include assisted ejaculation or surgical sperm retrieval. The choice of treatment depends on the patient's ability to respond to methods of assisted ejaculation and on the quantity and quality of sperm in the ejaculate. With surgical methods, the assisted reproductive technology of intracytoplasmic sperm injection will probably be required owing to the low numbers of sperm obtained with these methods. Assisted ejaculation methods generally result in higher numbers of sperm, thus allowing for more assisted reproductive technology options.

Premature (or rapid) ejaculation has been associated with myelopathy and neuropathy, but is nowadays usually considered to be constitutional, with psychogenic contributory mechanisms. Counseling on the use of particular techniques may lead to improvement. Pharmacotherapeutic options include topical anesthetics, antidepressants (selective serotonin reuptake inhibitors such as paroxetine), and phosphodiesterase-5 inhibitors, all used off-label.

Treatment of Abnormalities of Libido

Hormone insufficiency, testosterone in men and estrogens in women, should be corrected. Hyperprolactinaemia should be treated.

For abnormally increased libido, pharmacologic treatment should be checked. Androgen antagonists (cyproterone acetate, medroxyprogesterone acetate) may be effective. In resistant cases, neuroleptics are usually helpful.

Treatment in Women With Sexual Dysfunction

Vibratory stimulation and dildos may be helpful and are routinely advised in patients with genital sensory disturbances and in those with weakness or motor disorders.

Sildenafil has been well-tolerated in women with neurologic disorders causing lack of sexual arousal, such as multiple sclerosis and spinal cord injury, with few benefits or side effects. In multiple sclerosis, there was an effect on lubrication, but quality of life did not improve significantly although some women opted to continue on the drug after conclusion of the study. Clearly sildenafil does not produce the same spectacular results in women as it does in men with disturbed sexual responses related to underlying neurologic disorders.[14]

In women with dysesthetic or painful sensations in the genitalia that are not alleviated by improving lubrication, antiepileptic drugs such as gabapentin, pregabalin, and carbamazepine may help. Women showing signs of estrogen insufficiency should be referred to a gynecologist for hormone replacement therapy.

NEUROLOGIC PROBLEMS ASSOCIATED WITH SEXUAL ACTIVITY

Headache

Headaches related to sexual activity must be treated as potentially serious because subarachnoid hemorrhage may occur during exertion and headaches of other cause may also be exacerbated in the sexual context. Vascular mechanisms are the probable cause of headaches that occur during sexual arousal in patients with unruptured aneurysms, cerebral tumors, and subdural hematomas. Pain due to angina pectoris or myocardial infarction may be referred to the head. Low-pressure postcoital headache, analogous to that following lumbar puncture, may also occur; symptoms are relieved by recumbency.

Regardless of cause, a headache developing for the first time during sexual activity, particularly if it is of sudden onset and occurs at orgasm, is usually alarming; many patients are convinced that they have had a cerebral hemorrhage. Luckily, most sexual headaches are benign and self-limiting.

The benign headache designated before as orgasmic or preorgasmic is a primary headache. It is commonly severe, usually sudden, pulsatile, bilateral, and located occipitally. Its mean duration is 30 minutes, but it may be quite short or last the entire day. A dull, long-lasting, tension-type discomfort can outlast the headache. The headache may be accompanied by nausea, vertigo, and other symptoms. Men are afflicted more often than women; the first peak of occurrence is early in the third decade, with the second late in the fourth decade. Comorbidity with migraine, tension-type headache, and exertional headache is common. The headaches may be recurrent, but spontaneous remission is the rule. Treatment with indometacin or propranolol is recommended.

Migraine may be triggered by sexual activity. Its character is identical to the patient's usual pattern of migraine. On occasion, sexual arousal forms part of the aura of migraine.

Ampoules of amyl nitrite, crushed and inhaled immediately before the event, are sometimes used in an attempt to enhance orgasm. A potent vasodilator, this drug may produce severe vascular headache. More often "sexual activity-associated" headache is nowadays a side effect of the use of phosphodiesterase inhibitors taken for treatment (or sport).

Transient Global Amnesia

Transient global amnesia is sometimes associated with a precipitating event. "Emotional" events predominate in women, "physical" events in men. Sexual intercourse may qualify for both categories and has been regularly reported among provoking events in both sexes.

CONCLUDING COMMENTS

Many questions regarding the neuroanatomy and neurophysiology of sexual function remain to be answered. The fine neural control of human sexual behavior by the cerebral hemispheres, brainstem, and spinal cord is still not elucidated. Tools to define the role of psychosocial and biologic factors (such as endocrine, neurologic, vascular, endothelial, and other factors) in the individual patient with sexual dysfunction are still crude. The options to help patients have nevertheless improved significantly in the last decades. Patients need the interest and support of their physicians in the realm of sexuality; they deserve no less.

ACKNOWLEDGMENTS

ECLAMPSIA AND PRE-ECLAMPSIA

Neurologic disorders may present first during pregnancy, and their investigation and treatment may be complicated by concerns for the safety of the developing fetus. Furthermore, the natural history of certain pre-existing diseases may be affected by pregnancy, and obstetric management may be influenced by the neurologic disturbance. These aspects are considered in this chapter.

Concerns about the use of imaging studies in pregnancy merit comment. In general, fetal exposure to ionizing radiation from computerized tomography (CT) is small, especially when the fetus is not in the imaged region. Magnetic resonance imaging (MRI) does not expose patients to ionizing radiation and may be necessary when the findings may influence clinical management during the pregnancy. Iodinated

contrast may be administered during pregnancy when necessary for maternal care, but thyroid function tests should then be performed in the neonate in the first week of life. Gadolinium contrast passes into the placenta and may harm the fetus, so its use should be avoided when possible; otherwise, the smallest possible dose is given when required for maternal care.

EPILEPSY

Birth rates are lower and maternal mortality during pregnancy, delivery, or the postpartum period are higher among women with epilepsy that among nonepileptic women. Pregnancy may affect the natural history and management of patients with epilepsy in several ways. In addition, antiepileptic management may affect the developing fetus and obstetric management. Many pregnancies are unplanned, so that regular counseling of women with epilepsy during the reproductive years is important.

Effect of Pregnancy on Maternal Seizures

An increase in seizures occurs during pregnancy in 23 to 75 percent of cases depending on the series; seizure control is unchanged in between 53 and 67 percent. It is not possible to predict in advance whether or how seizure frequency will be altered during pregnancy, but certain general points can be made. Seizure frequency is more likely to increase in poorly controlled epileptic patients than in those with infrequent seizures, and in those with focal seizures; any increase is most likely to occur during the first trimester. Any change in seizure frequency usually reverses after the birth of the infant, although occasional patients whose seizures increase during pregnancy remain more difficult to control thereafter. For patients without seizures for at least 9 months prior to conception, the likelihood of remaining seizure-free during pregnancy ranges between 84 and 92 percent in different series.[1] The influence of a particular pregnancy cannot be predicted by the outcome of previous pregnancies, any relationship between seizures and the menstrual cycle, or maternal age. Seizures may occur for the first time during or immediately after pregnancy and in some instances occur only in relation to pregnancy. Even in patients with such true gestational epilepsy, however, it is not possible to predict the course of subsequent pregnancies from the occurrence of seizures during one pregnancy.

Status epilepticus may complicate pregnancy and sometimes occurs before there is any other evidence that seizures have become more difficult to control. It may take the form of tonic-clonic (major motor) or nonconvulsive status. The former is easy to recognize, but a transient alteration in mental status and level of arousal may not be attributed to nonconvulsive status epilepticus unless an electroencephalogram is performed. As in the nonparous woman, it is important to obtain control of the seizures rapidly, but therapeutic termination of pregnancy is usually unnecessary. There is no evidence that anticonvulsant drugs administered intravenously to treat status epilepticus affect the fetus adversely.

The reason that seizure frequency sometimes increases during pregnancy is not clear, but a change in drug requirements during the gestational period may sometimes be responsible. Pregnancy probably causes an increase in the clearance and a decrease in the blood concentrations of, for example, lamotrigine, levetiracetam, phenytoin, and, to a lesser extent, carbamazepine, and of the active oxcarbazepine metabolite, the monohydroxy derivative.[2] Zonisamide serum concentration may decline by more than 40 percent during pregnancy, especially in the last trimester, but there is much interindividual variability. Evidence of a change in clearance or blood level of phenobarbital, valproate, primidone, and ethosuximide is inadequate to permit a definite conclusion to be reached.[2] Other possible reasons for the increased dose requirements of anticonvulsants during pregnancy include poor compliance with the drug regimen, changes in drug absorption and excretion, and the dilutional effects of increasing plasma volume and extracellular fluid volume. Changes in drug absorption may relate to nausea, vomiting, or reduced gastric motility. Antacids are frequently prescribed during pregnancy and are known to adsorb to medications, preventing absorption. An increased metabolic capacity of maternal liver and metabolism of part of the anticonvulsant dose by the fetus, placenta, or both may also be important. Folic acid therapy (which may reduce the risk of major congenital malformations when taken preconceptionally[2]), prescribed routinely by many obstetricians, sometimes lowers the plasma phenytoin level.

Whether hormonal factors contribute to an increase in seizure frequency during pregnancy is unclear, but estrogens are epileptogenic in animals, and progesterone is said to have both convulsant and anticonvulsant properties. Finally, fatigue and sleep deprivation may influence seizure frequency during pregnancy.

The reason that seizure frequency decreases in some epileptic patients is also unclear, but improved compliance with the anticonvulsant drug regimen may be responsible.

Effects of Maternal Epilepsy on the Fetus

SEIZURES

A major concern in the management of epileptic women during pregnancy is the possible effect of the seizure disorder and of anticonvulsant drugs on the developing fetus. It is difficult to determine the precise risk that a seizure disorder will develop in the offspring of epileptic parents. The risk depends in part on whether the parental epilepsy is idiopathic (constitutional) or acquired; such risk appears to be increased among the offspring of epileptic mothers but not when only the father is epileptic. The reason for the increased risk is unclear, but genetic factors may be important, as may the consequences of maternal seizures or anticonvulsant drugs taken during pregnancy.

FETAL MALFORMATIONS

For many years, concern has existed that anticonvulsant drugs are teratogenic. Epidemiologic studies are difficult to interpret because epilepsy occurs for different reasons, varies in severity between patients and in the same patient at different times, may itself increase the risk of fetal malformation, and is treated by many drugs in different doses and combinations; environmental and genetic factors also bear on the development of fetal malformations and are difficult to control. Nevertheless, numerous reports suggest that certain anticonvulsant drugs are indeed teratogenic in humans, and the risk of malformation among the offspring of epileptic women is approximately double that for nonepileptic women. A greater teratogenic risk exists with polypharmacy, but specific antiepileptic drugs in the regimen may actually be more important than whether multiple drugs are taken.

The older antiepileptic drugs taken during the first trimester of pregnancy are probably all teratogenic to some extent, especially when taken in combination.[3] However, it cannot be determined whether the increased risk relates to all or to only some antiseizure medications. Trimethadione, which is now rarely used and should be avoided during pregnancy, is particularly dangerous and causes fetal malformations and mental retardation in more than 50 percent of exposed infants. The absolute risk of major congenital malformations is also especially marked for valproate,[3] which is associated with a high (1%) rate of neural tube defects and may also cause cleft lip or palate, polydactyly, hypospadias, craniosynostosis, atrial or ventricular septal defect, developmental delay, and other disorders; it is also associated with cognitive impairment and autism spectrum disorder. Its teratogenicity is dose dependent. Other antiepileptic drugs have different teratogenic risks. Phenytoin, phenobarbital, carbamazepine, and topiramate have been associated variously with cardiac anomalies and cleft palate, and carbamazepine with neural tube defects.[3–5] A longitudinal, prospective cohort study showed that the risks of major congenital malformation are lowest with lamotrigine and levetiracetam. Gabapentin, oxcarbazepine, and zonisamide are not associated with an increased risk, but the data concerning these medications are limited.[4] There are no or very limited data for newer drugs such as eslicarbazepine, lacosamide, perampanel, and brivaracetam. Vagal nerve stimulation therapy has not been associated with teratogenicity. These findings should guide the rational selection of medication in women with epilepsy, taking into account comparative risks and treatment alternatives.[6]

A specific syndrome has been described among some of the offspring born to mothers taking phenytoin, phenobarbital, or carbamazepine during pregnancy and bears some resemblance to the fetal alcohol syndrome. It is characterized by prenatal and postnatal growth deficiency, microcephaly, a dysmorphic appearance, hypoplasia of the distal phalanges, and mental deficiency. A characteristic facial phenotype in children exposed to valproic acid or sodium valproate in utero has also been described. Some of these children may have educational difficulties.

The mechanisms involved in teratogenesis of anticonvulsant drugs are not known but may include folate deficiency or antagonism and production of toxic intermediary metabolites during biotransformation of the parent compound. Specific oxidative intermediates such as epoxide, for example, have been suggested as the ultimate teratogen in patients receiving phenytoin.

BLEEDING DISORDERS

A clinical or subclinical bleeding disorder may occur in neonates exposed to anticonvulsant drugs in utero, without evidence of coagulopathy in the mothers. Although a number of anecdotal cases have been reported, the evidence is insufficient to determine whether the risk is, in fact, substantially increased in the newborns of women with epilepsy.[2] Bleeding has usually occurred within 24 hours of birth, sometimes in unusual sites (e.g., the pleural or abdominal cavities). Bleeding has also been reported to occur in utero, leading to stillbirth. However, it has been questioned whether maternal use of antiseizure medication leads to a coagulopathy at all, and certainly the evidence is insufficient to support or refute this association.[2] In any event, the routine intramuscular administration of vitamin K_1 (1 mg) to all newborns (regardless of maternal epilepsy) is sufficient to reduce the incidence in infancy of late vitamin K deficiency bleeding (previously designated hemorrhagic disease of the newborn), with its high morbidity and mortality.

WITHDRAWAL SYMPTOMS

Maternal use of certain anticonvulsants may be associated with withdrawal symptoms in the neonate, with restlessness, irritability, tremulousness, difficulty in sleeping, and vasomotor instability, usually beginning a few days after birth.

BREAST-FEEDING

Although certain anticonvulsant drugs (primidone, ethosuximide, gabapentin, lamotrigine, levetiracetam, topiramate, and zonisamide) taken by the mother may be present in breast milk, there is no evidence that these have symptomatic effects on the newborn or affect development.[2] Breast-feeding therefore need not be discouraged on this account; however, when obvious sedation develops in an infant that could relate to anticonvulsants in the maternal milk, breast-feeding should be discontinued and the child observed for signs of drug withdrawal. There is no evidence that phenobarbital, phenytoin, valproate, and carbamazepine penetrate the breast milk in a clinically important amount.[2]

Management of Epilepsy

Little or no information is available in the published literature to guide decision-making with regard to certain management issues in women with epilepsy. Epilepsy must be managed during pregnancy, as at other times, by prophylactic anticonvulsant drugs. Management should be by monotherapy whenever possible, with selection of the anticonvulsant that is most appropriate for seizure type. As indicated earlier, lamotrigine and levetiracetam seem to have the least teratogenic risk, and women of childbearing age should be managed on one of these drugs when feasible, depending on seizure type. There is little point in substituting one anticonvulsant drug for another after the first 2 to 3 months of pregnancy because major fetal malformations will probably have occurred already if they are going to occur at all. Folate supplementation may help, however, to reduce the risk of teratogenicity and of certain malformations (such as neural tube defects), although the optimal dose is unclear. Some prescribe 0.4 mg folate daily for all women of childbearing age from a month before conception to the end of the first trimester, whereas others prescribe 4 mg daily for 3 months before and after conception for those at particular risk because of family and past medical (including spousal) history, a previous baby with a neural tube defect, or because they are taking valproate or carbamazepine. Folate supplementation is followed by routine prenatal vitamin supplementation for the remainder of the pregnancy and during lactation.

Anticonvulsant drug treatment should be monitored during pregnancy by serial (monthly) measurement of plasma drug levels, depending on the drug that is being taken, as discussed earlier. Patients should be seen monthly, and as the pregnancy continues the dose of medication may need to be increased to maintain plasma concentrations at previously effective levels. If increases are made during pregnancy, dose reductions will be necessary at some point after delivery to prevent toxicity, but at a time that must be determined individually based on clinical evaluation and plasma drug levels. In general, lamotrigine and levetiracetam can be tapered over 2 to 3 weeks, and other antiseizure medications over about a month or longer, beginning 3 or 4 days after delivery.

If patients inquire, it is appropriate to indicate that there is a slightly increased risk of fetal malformation due either to the seizure disorder itself or to the drugs used in its treatment. Nevertheless, there is still a very good chance (90 to 95%) that offspring will be normal. It must also be emphasized that the risks to both mother and fetus of noncompliance with anticonvulsant drug regimen are considerable, in that an increased seizure frequency or even status epilepticus may occur, with its associated morbidity and mortality.

Obstetric Management

Most women with epilepsy will have a normal pregnancy and delivery. It is rare for seizures to occur during labor and delivery, but when they do occur it is usually in women who have continued to have seizures during the pregnancy.

Increased incidences of vaginal hemorrhage and toxemia and an increased stillbirth rate have been reported in epileptic women by some authors but not others. For those taking antiepileptic medication, the risk of cesarean delivery or late-pregnancy bleeding is increased but is less than double the expected risk, while the risk of premature contractions or premature labor and delivery is increased only mildly.[1] The increase in cesarean deliveries has been attributed to uncertainty in guiding the delivery of epileptic women and the misperception of an increased risk of complications. An increased incidence of neonatal death has sometimes been reported, perhaps owing to an increased incidence of congenital malformations, iatrogenic neonatal hemorrhage, the metabolic or toxic effects of seizures or anticonvulsant drugs, or socioeconomic factors.

Targeted ultrasonography can be used to diagnose most neural tube defects at 12 to 22 weeks of pregnancy as well as other major structural abnormalities.

Interactions Between Oral Contraceptives and Anticonvulsants

Certain anticonvulsants (including phenytoin, carbamazepine, felbamate, topiramate, oxcarbazepine, eslicarbazepine, perampanel, phenobarbital, and primidone) may alter the effectiveness of oral contraceptives, leading to unwanted pregnancy. Thus, the risk of contraceptive failure in patients taking these anticonvulsants should be discussed in advance and documented in the patient's records; in some instances, use of an additional backup contraceptive method should be considered, such as a condom, intrauterine device, or depot injection. The incidence of breakthrough bleeding is also increased in women taking these anticonvulsants and concurrent oral contraceptives, and such bleeding may point to the possibility of contraceptive failure. Oral contraceptives may also affect seizure frequency or blood levels of anticonvulsant medication (e.g., lamotrigine).

MIGRAINE

Migraine is more common in women than men and is often influenced by pregnancy. Most commonly, the frequency and severity of attacks improve after the first trimester, but occasionally migraine worsens or occurs for the first time during pregnancy. Occasionally, attacks are changed so that auras occur without headache. The influence of pregnancy on migraine does not depend on any relationship of migraine to the menstrual cycle. Similarly, it does not relate to the sex of the fetus or to differences in plasma progesterone levels, although there may be some relationship to changes in the pattern of circulating estrogens. The association between migraine and oral contraceptive preparations is discussed in Chapter 20.

Acute Treatment

Treatment of migraine during pregnancy is similar to that at other times, with emphasis on the avoidance of precipitating factors together with the use of simple analgesics as necessary. However, acetaminophen should be used in preference to aspirin because there is some evidence that aspirin use in large dosages in the later stages of pregnancy may prolong labor, increase the incidence of stillbirth, impair neonatal hemostasis, and cause premature closure of the ductus arteriosus. Nonsteroidal anti-inflammatory drugs (NSAIDs) also are best avoided. Some but not other studies in animals suggest that they may lead to congenital malformations and miscarriage when given in early pregnancy; after 30 weeks, they may cause premature closure of the ductus arteriosus and other adverse fetal outcomes.

Although early studies showed that sumatriptan in extraordinarily high doses led to death or malformations in fetal rats and rabbits, later retrospective studies and meta-analyses in humans provided no evidence either for teratogenicity or for prematurity or spontaneous abortions.[7] When acute treatment for migraine is required during pregnancy, sumatriptan (unless contraindicated for other medical reasons) is best taken by nasal spray or injection as nausea and gastric stasis might well limit the utility of oral administration. The safety of other triptans in pregnancy is less clear.

Partial opioid agonists may be used on a limited basis if the response to other medications is inadequate. Prochlorperazine may help both nausea and headache.

Ergot-containing preparations should be avoided because of possible teratogenicity and the effect this drug may have on the gravid uterus.

Preventive Treatment

Preventive measures can usually be discontinued during pregnancy as migraine tends to improve spontaneously, but they may be required for women who experience frequent, prolonged, and severe attacks that respond poorly to treatment. Patients should avoid known precipitants of attacks, eat regular meals, use relaxation techniques, and maintain good sleep hygiene.

Memantine is well tolerated, appears to be safe during pregnancy, and may be effective for migraine prophylaxis. Propranolol is also effective for migraine prophylaxis but should be avoided during pregnancy when possible or used in the lowest effective dose. This is because animal studies have shown that it may impair fetal growth and that β-adrenergic blockade may inhibit the normal responsiveness of the fetus to asphyxia or other stresses. Other reported complications in neonates include prematurity, respiratory depression, hypoglycemia, and hyperbilirubinemia.[8]

Topiramate and valproic acid, which are effective for migraine prophylaxis, are not recommended during pregnancy because of their teratogenic effects, discussed in an earlier section.

The tricyclic antidepressant amitriptyline is sometimes used in low dose (25–50 mg daily) and seems to be safe during pregnancy. It is best discontinued during the third trimester because of possible effects on the fetus (respiratory distress, drowsiness, hypoglycemia).

Many women, often with a past or family history of migraine, experience mild bifrontal headaches in the week after delivery, sometimes accompanied by photophobia, nausea, and anorexia. These headaches usually respond to simple analgesics or to sumatriptan and settle spontaneously.

Treatment During Lactation

Acetaminophen, NSAIDs (especially ibuprofen), and sumatriptan can be used safely during lactation.

TUMORS

Although any type of intracranial tumor occasionally presents during pregnancy, pituitary adenomas, meningiomas, neurofibromas, hemangioblastomas, and certain vascular malformations sometimes exhibit relapses during pregnancy, with partial or complete remission occurring after delivery. The basis of this relationship is unclear, but it seems likely that pregnancy produces a slight increase in tumor size. The enlargement of certain pituitary adenomas during pregnancy may be due to the trophic effects of increased circulating estradiol. Similarly, an increase in size of meningiomas may relate to a direct trophic effect of gonadal hormones on tumor cells; sex steroid–binding sites have been found in human meningiomas, but there are marked differences in their reported prevalence and concentration. Tumors with symptoms that show a consistent temporal relationship to pregnancy are usually so situated that significant neurologic involvement, with the development of new symptoms or signs, occurs with only slight expansion of the underlying lesion. Thus, spinal meningiomas are more likely than convexity meningiomas to show a relationship of symptoms to pregnancy. Visual field defects are unlikely to develop during pregnancy in patients with pituitary microadenomas, but may certainly occur with larger tumors.

Patients with suspected intracranial neoplasms should be managed during pregnancy as at other times. MRI is generally the best noninvasive means of establishing the diagnosis and does not involve exposing the fetus to irradiation. Essential operative treatment should not be delayed. However, surgery for pituitary adenomas or other benign tumors diagnosed toward the end of pregnancy can often be delayed until after delivery, provided that the patient is followed closely. Radiation therapy or chemotherapy may be required during pregnancy. Radiation therapy is associated with a risk of fetal loss or teratogenicity depending on the level of fetal exposure, especially if administered during the first trimester; in later pregnancy it carries an increased risk of childhood cancer or leukemia. However, tumors of the brain or head and neck can usually be irradiated satisfactorily without dangerous fetal exposure. Therapeutic abortion may need to be considered in some patients with malignant brain tumors, depending on the therapy required and especially when it cannot be delayed to the latter half of pregnancy or postponed until after delivery, or when significant symptoms, such as uncontrollable seizures, complicate the pregnancy.

The pregnancy itself can usually be managed normally in patients with intracranial tumors. Concerns that vaginal delivery may exacerbate any existing increase in intracranial pressure due to the tumor are usually misplaced, especially if adequate regional anesthesia is employed and low forceps are used, if necessary, to shorten the second stage of labor.

The long survival associated with low-grade gliomas suggests that some women with such tumors may wish to become pregnant after the diagnosis has been established. Such decisions need to be made on an individual basis, but patients with these lesions may certainly go through pregnancy without further complications.

Choriocarcinoma may develop after a normal pregnancy or follow a molar, ectopic, or terminated pregnancy. Intracranial metastases are common, and hemorrhage may occur into the cerebral lesions. Early diagnosis and treatment are important for survival.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension has a clear association with pregnancy and is especially likely to occur during the first trimester or postpartum. It therefore seems sensible that women with this disorder should defer pregnancy until their disease is controlled and important that all pregnant patients with new-onset headaches be examined funduscopically to exclude the diagnosis. Headache and visual disturbances due to papilledema may be accompanied by diplopia from sixth nerve palsy. Investigations reveal no space-occupying lesion, but the cerebrospinal fluid (CSF) pressure is increased. The disorder is self-limiting, but it may not remit for weeks after delivery, and there may be recurrences during subsequent pregnancies. Treatment, as in the nonpregnant woman, consists of measures to lower the intracranial pressure to prevent secondary optic atrophy. It may require the use of acetazolamide, furosemide, corticosteroids, repeated lumbar punctures, or a surgical shunting procedure. Topiramate is also effective but should be avoided during pregnancy. Optic nerve decompression and early delivery of the fetus may have to be considered if the intracranial pressure remains high despite these measures. There are no specific obstetric complications, and a normal birth can be expected.

Intracranial venous sinus thrombosis may simulate pseudotumor cerebri and is discussed later.

CEREBROVASCULAR DISEASE

A significant number of pregnancy-related maternal deaths result from stroke. An increased incidence of stroke has been associated particularly with the puerperium. The highest risk for thrombotic stroke is in the first 6 weeks postpartum and this probably relates at least in part to various hormonal changes.

Sex steroids can affect several physiologic and metabolic factors that predispose to cerebral thromboembolic or venous infarction, as discussed in Chapter 20. The association of stroke with oral contraceptives is well recognized. Estrogens increase blood coagulability and platelet aggregation. Sex hormones may also predispose to aneurysm formation or rupture, as suggested by observations that early menarche or oral contraceptive use is associated with an increased risk of subarachnoid hemorrhage, that the risk of hemorrhage is greatest in the perimenstrual period, and that premenopausal women are at reduced risk of subarachnoid hemorrhage. Whether pregnancy influences intracranial arteriovenous malformations (AVMs) is unclear, but it may certainly aggravate spinal arteriovenous fistulas (p. 587). Eclampsia or pre-eclampsia is the most common cause of stroke during pregnancy, and the microangiopathic syndromes of pre-eclampsia, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome are considered on p. 599 and in Chapter 25.

Occlusive Arterial Disease

Most cases of nonhemorrhagic hemiplegia developing during pregnancy or the postpartum period are due to arterial occlusion. As in nonpregnant patients, this may relate to thrombus formation on an atheromatous plaque; inflammatory disorders such as arteritis or meningovascular syphilis; hematologic disorders such as polycythemia and sickle cell disease; and cardiac disorders such as a cardiomyopathy, rheumatic or ischemic heart disease, intracardiac shunts, cardiac dysrhythmias, subacute bacterial endocarditis, use of prosthetic heart valves, and cardiac myxoma. It may be associated with diabetes, cigarette smoking, and migrainous headaches. During pregnancy, in addition, stroke may be predisposed to by anemia, hormonal factors, changes in blood coagulation factors (see Chapter 25), increased platelet aggregation, hypertension, and puerperal septicemia, and by pre-eclampsia or eclampsia (discussed later).

A variety of cardiovascular changes occur during pregnancy: plasma volume increases, a hemodilutional anemia develops, and there is a progressive increase in heart rate and cardiac output as pregnancy advances. The blood pressure declines, however, as systemic vascular resistance drops in early pregnancy, reaching a nadir at around the end of the second trimester. There is thus a relative venous stasis that is enhanced by compression of the inferior vena cava by the enlarging uterus and by diminished physical activity in late pregnancy and the postpartum period. These circulatory changes may bear in part on the development of stroke.

The blood is in a hypercoagulable state during pregnancy; there is a rise in all procoagulant factors except XI and XIII, and increased thrombin activity. Circulating inhibitors of coagulation, such as protein C and protein S, are reduced during normal pregnancy, and antithrombin III may be reduced, as is discussed in Chapter 25. The activity of the fibrinolytic system is also reduced during pregnancy. These various changes predispose pregnant women to stroke. Hemoglobinopathies may also lead to significant maternal morbidity during pregnancy. Thus, women with sickle cell disease are especially likely to experience crises, usually vaso-occlusive, during pregnancy. Sickle cell disease is also associated with an increased incidence of obstetric complication—including abortion, growth retardation, preterm birth, fetal anomalies, pre-eclampsia, eclampsia, and stillbirth—although fetal wastage has been reduced considerably by improved prenatal care.

The presence of circulating antiphospholipid autoantibodies (discussed in Chapters 11 and 25) is similarly associated with a high rate of maternal arterial and venous thrombotic events and transient ischemic attacks (TIAs), as well as with obstetric complications such as an increased rate of spontaneous abortion and of early-onset, atypical pre-eclampsia. Pregnancy may represent an especially high risk of thromboembolic disease in patients with these antibodies. Treatment recommendations are limited by a lack of clinical evidence but may involve low-dose aspirin, unfractionated heparin, or low-molecular-weight heparin.

Hypertensive disorders of pregnancy are associated with ischemic stroke. These disorders include gestational hypertension, which typically resolves within 3 months after delivery, pre-eclampsia and eclampsia, and the HELLP syndrome (hemolysis, elevated liver enzymes, low platelets). Hypertensive disorders of pregnancy are more common in African-Americans than in other segments of the population, and are associated with a significant number of deaths, particularly in developing countries. They are associated with an increased incidence of premature births and stillbirths.

A peripartum cardiomyopathy may occur during the last trimester of pregnancy or the puerperium, especially in the presence of twinning, toxemia, or postpartum hypertension; it sometimes presents with embolic phenomena necessitating anticoagulation. Its precise cause is unclear, but nutritional, hormonal, viral, and immunologic mechanisms have been suggested.[9] Subsequent pregnancies are associated with a significant reduction in left ventricular function and may lead to clinical deterioration and death.[10]

A reversible cerebral vasoconstriction syndrome may occur during an otherwise normal pregnancy or the postpartum period (postpartum cerebral angiopathy) and lead to a fatal outcome.[11] It has been associated with hypertension and use of vasoconstrictive drugs and may be mistaken for cerebral vasculitis. Presentation is commonly with thunderclap headache; focal deficits and seizures may also occur. Cerebral infarction, intracranial bleeding, or vasogenic edema may be associated. The disorder follows a self-limiting course. Treatment is with calcium-channel blockers, but benefit is uncertain. The outcome is variable; full recovery occurs in many patients, but in others the disorder has a fulminant course and may have a fatal outcome or lead to residual deficits.[11]

A reversible intimal hyperplasia of the cerebral vasculature during pregnancy has been described as a rare cause of stroke or TIA during the gestational period, but such cases are poorly documented and hard to interpret. There are rare reports of arterial occlusion by paradoxical embolization from a pelvic vein through a patent foramen ovale. Fat, air, or amniotic fluid embolism may also occur during childbirth but usually presents with dyspnea, shock, and acute encephalopathy. Amniotic fluid embolism is an important cause of stroke and maternal death. Hemodynamic collapse and disseminated intravascular coagulopathy may lead to focal neurologic signs from cerebral hypoperfusion or hemorrhage.

As in nonpregnant women, transient cerebral ischemic attacks may precede occlusion of one of the major intracranial arteries. Neurologic investigation and management should not be influenced by the pregnancy, but special shielding during radiologic studies may help to protect the developing fetus. MRI is the imaging procedure of choice. MR angiography can help to define the vasculature, and diffusion-weighted imaging to detect acute cerebral ischemia. However, gadolinium contrast should not be used if possible—it passes into the placenta and may be harmful to the fetus.

Treatment of thrombotic stroke with tissue plasminogen activator (tPA) is contraindicated during pregnancy and the postpartum period, because safety and efficacy have not been established in these circumstances, but tPA does not cross the placenta, is not teratogenic in animal models, and has not caused problems in published case reports. Hemorrhagic complications are more likely, especially in the first few days after delivery. Angiographic delineation of degenerative atherosclerotic disease in a localized arterial segment that is surgically accessible may permit disobliterative surgery, especially when stenosis is severe (70 to 99% in the internal carotid artery). If surgery is decided against or there is more widespread atherosclerotic disease, treatment is with low-dose aspirin. A cardiac source of emboli usually necessitates treatment with warfarin (as also do certain hypercoagulable states or venous occlusive disease). This drug is associated with risks of teratogenicity and fetal wastage when used during the first trimester, and it crosses the placenta, thereby increasing the risk of hemorrhagic complications. The newer direct-acting anticoagulants also cross the placenta and there is little information on their safety during pregnancy and lactation. Accordingly, patients requiring anticoagulation during pregnancy are best maintained on subcutaneous heparin, which is discontinued with the onset of labor and restarted approximately 12 hours after vaginal delivery (or 24 hours after cesarean section). Hypertension may require treatment (e.g., with nifedipine or methyldopa). Statin drugs are best avoided during pregnancy and lactation.

The optimal management of labor and delivery in patients who have had a stroke during pregnancy is unclear. In most cases, vaginal delivery assisted by forceps is probably satisfactory. The blood pressure needs to be monitored closely, however, to avoid excessively high or low levels.

Occlusive Venous Disease

Aseptic intracranial venous thrombosis may occur during pregnancy, during the puerperium, or with the use of oral contraceptives for reasons that are unclear. It has been attributed to coagulation abnormalities, changes in the constituents of peripheral blood, and intimal damage to dural sinuses (see Chapter 25). The extent to which it relates to hormonal changes is unknown, but such changes probably have an important etiologic role, as discussed in Chapters 11 and 20. In many instances there is no evidence of thrombosis in the pelvic or leg veins. Inherited prothrombotic states associated with intracranial venous thrombosis include protein C, protein S, antithrombin III, and factor V Leiden deficiency, and hyperhomocyteinemia (see Chapter 25); the antiphospholipid antibody syndrome and systemic malignancy may also be associated, and thus require exclusion.[12]

Intracranial venous thrombosis (Fig. 31-1) occurs most commonly during the third trimester of pregnancy or the postpartum period, sometimes in relation to preeclampsia. Although it may, in fact, occur at any time during a normal pregnancy, when it develops during the first trimester it usually is in relation to some complication such as spontaneous or therapeutic abortion. It is characterized clinically by headache, seizures, obtundation, confusion, and sometimes focal neurologic disturbances. Examination commonly reveals papilledema, and there may be signs of meningeal irritation from subarachnoid bleeding secondary to cortical infarction and of focal or multifocal deficits. CSF pressure is often increased, and its protein or cell content may be increased. Imaging procedures, particularly MRI and MR

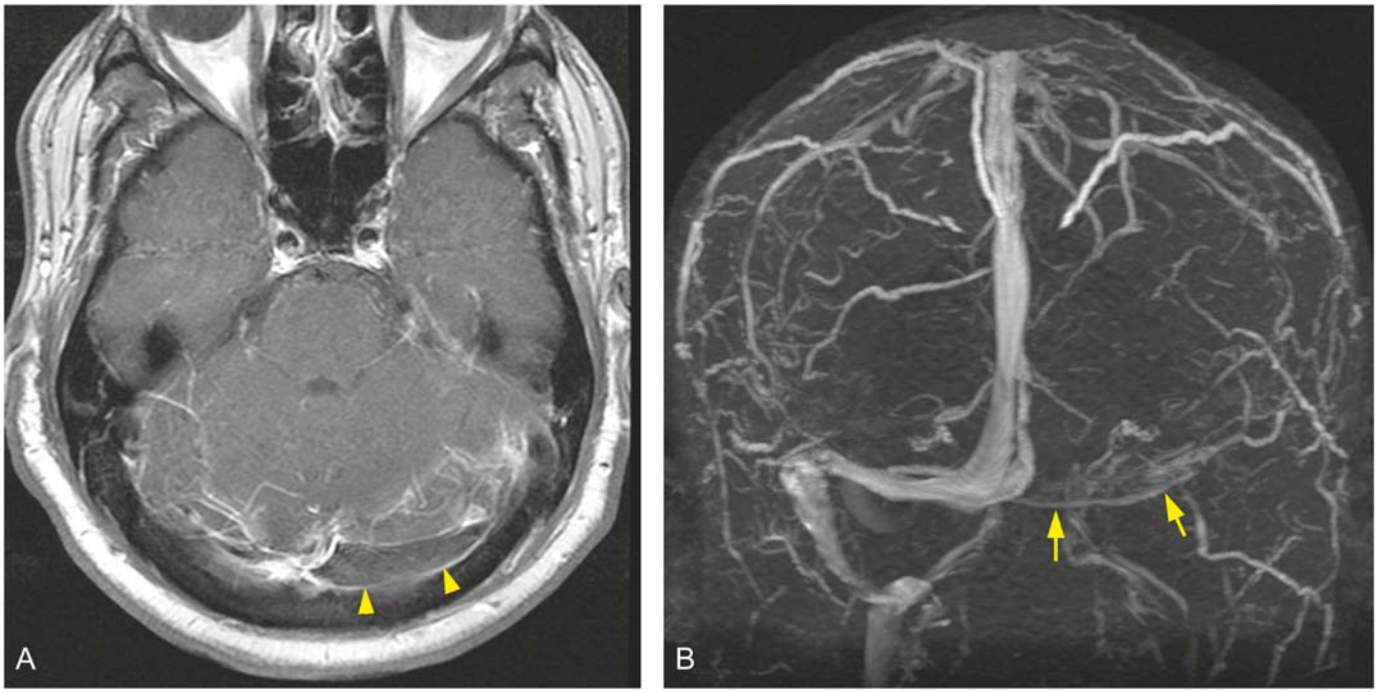

FIGURE 31-1 ■ Thrombosis of the left transverse sinus. *A*, Axial postcontrast T1-weighted MR image shows a filling defect within the left transverse sinus consistent with thrombosis *(arrowheads)*. *B*, Coronal MR venogram confirms thrombosis of the left transverse sinus *(arrows)*. venography or computed tomography (CT) and CT venography, confirm the diagnosisand help to exclude arterial disease.

Treatment of intracranial venous thrombosis is controversial. Anticonvulsant drugs and antiedema agents may be helpful. Anticoagulation with subcutaneous low-molecular-weight heparin is worthwhile despite the risk of provoking hemorrhagic complications and should be continued for the remainder of the pregnancy and the puerperium, followed by anticoagulation with warfarin for at least 3 to 6 months. The heparin is discontinued 24 hours before induction of labor or cesarean section, or with the onset of spontaneous labor, and restarted approximately 12 hours after vaginal delivery or 24 hours after cesarean section. (Many obstetricians replace low-molecular-weight heparin with unfractionated heparin at 36 to 37 weeks, or earlier if preterm delivery is likely because of obstetric complications.) The role of thrombolytic therapy to prevent extension of the thrombus in pregnant or postpartum women is not clear. Different mortality rates have been reported in various series, but a rate of 15 percent is based on the pooled outcomes in a number of studies.[12] Survivors may experience recurrence of thrombosis in subsequent pregnancies. Accordingly, prophylactic low-molecular-weight heparin should be given throughout subsequent pregnancies and the puerperium.

Cesarean section may be necessary if venous thrombosis has occurred before or during labor. If it occurs early in the pregnancy, labor can generally be allowed to commence spontaneously, with forceps-assisted delivery if necessary.

Women with a previous cerebral venous thrombosis should avoid contraceptives containing estrogens.

Pituitary Infarction or Hemorrhage

Acute infarction or hemorrhage of the pituitary gland, especially around the time of delivery, is a well-recognized complication that leads to hypopituitarism if the patient survives the acute event. The disorder may occur in patients with pre-existing diabetes or in those who experience such obstetric complications as postpartum hemorrhage with vascular collapse. It may also occur in patients with coagulopathies or a pituitary adenoma. The extent of pituitary damage governs the severity of pituitary hypofunction. The initial symptom may be failure of lactation. Emergency treatment with corticosteroids and trans-sphenoidal decompression of the intrasellar content may need to be considered to preserve life and vision. Management otherwise is with hormone replacement therapy.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) may occur in patients with a variety of obstetric complications. It is discussed in detail in Chapter 25 and further consideration here is unnecessary.

Subarachnoid Hemorrhage from Intracranial Vascular Anomalies

Subarachnoid hemorrhage may occur during pregnancy from an aneurysm or cerebral AVM (Fig. 31-2). The morbidity and mortality rates are greater with the former. It is unclear whether intracranial AVMs are

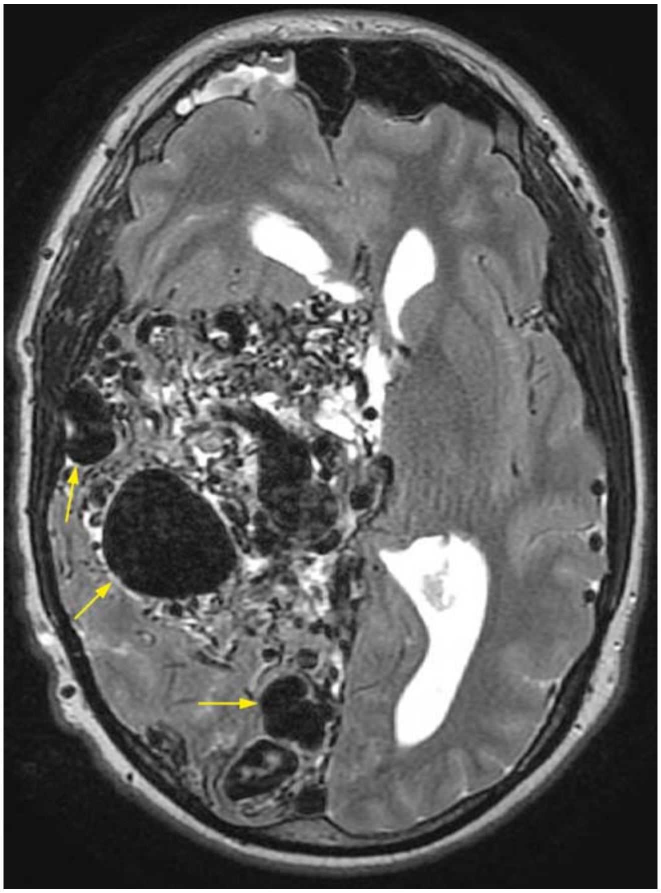

FIGURE 31-2 ■ Axial T2-weighted MR scan showing a large mass of flow voids involving the thalamus, typical of an arteriovenous malformation. The large flow voids *(arrows)* are venous varices, indicating possible outflow obstruction and increased risk of hemorrhage. Midline shift of the lateral ventricle is evident. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

more likely to bleed during pregnancy, but recent data suggest otherwise.

Symptoms and signs of subarachnoid hemorrhage are as in nonpregnant patients. The hemorrhage may be the first indication of the underlying lesion. An AVM is somewhat more likely than an aneurysm to be responsible if subarachnoid hemorrhage is accompanied by a major focal neurologic deficit (suggesting an intracerebral hematoma). CT scan or MRI of the head detects subarachnoid or intracerebral bleeding and may permit the causal lesion to be identified and localized but, as mentioned earlier, gadolinium contrast should be avoided if possible. Arteriography confirms the identity of the lesion and provides information about its anatomic characteristics that is especially important in planning operative treatment. All of the major intracranial vessels should be opacified because feeders to AVMs sometimes arise from the contralateral side and aneurysms may be multiple. Special shielding during radiologic studies is necessary for pregnant women to protect the developing fetus.

The management of subarachnoid hemorrhage is as for nonpregnant women. Because of the high risk of rebleeding in survivors of a ruptured aneurysm, operative or endovascular treatment should not be delayed because of pregnancy if the clinical and arteriographic findings indicate its feasibility. Treatment of stable unruptured aneurysms can usually be delayed until after childbirth, but enlarging unruptured aneurysms may require more immediate management. Although ruptured AVMs may also bleed again, this may not be for months or years after the initial hemorrhage, and neurosurgical treatment can often be postponed until the pregnancy is over.

The obstetric management of survivors of a subarachnoid hemorrhage is controversial. In patients with aneurysms that have been successfully treated by surgery or in whom rupture occurred before the last trimester, pregnancy and delivery can generally be permitted to continue normally. In patients with unoperated or incompletely obliterated aneurysms that ruptured during the last trimester of pregnancy, either instrumental delivery with regional anesthesia or cesarean section at 38 weeks' gestation is appropriate, depending on obstetric considerations. Some have suggested delivery by cesarean section at 38 weeks for women with AVMs, but this measure seems difficult to justify.

Intracranial hemorrhage during pregnancy or the postpartum period may also occur in association with eclampsia or pre-eclampsia, hypertension, vasculitis, various hematologic disorders, mycotic aneurysms, cocaine abuse, and moyamoya disease and as a manifestation of choriocarcinoma. Treatment is of the underlying cause.

The relationship of oral contraceptive use to intracranial hemorrhage is considered in Chapter 20.

Intracranial Dural Arteriovenous Fistulas

Dural arteriovenous fistulas may present during pregnancy, after abortion, or during the postpartum period. Some are developmental anomalies, but others are acquired in adult life, occasionally following trauma. The anomalous arteriovenous shunt may involve either the anterior-inferior group of dural sinuses (cavernous, intercavernous, sphenoparietal, superior and inferior petrosal, and basilar plexus) or the superior-posterior group (superior and inferior sagittal, straight, transverse, sigmoid, and occipital). Anomalies involving the former group lead typically to unilateral orbital or head pain, diplopia, a proptosed or red eye, tinnitus, or some combination of these symptoms. Malformations involving the superior-posterior dural sinuses may lead to subarachnoid hemorrhage, increased intracranial pressure, tinnitus, seizures, or focal neurologic deficits due to cerebral ischemia. In either case, there may be papilledema, and a bruit is often present either over the eye (with involvement of the anterior-inferior sinuses) or about the mastoid region or ear (superior-posterior sinuses involved).

Arteriography is necessary to localize the shunt with certainty and determine its anatomic features. With shunts to the anterior-inferior dural sinuses, embolization of feeding vessels may help preserve vision or relieve intolerable symptoms. Ligation or embolization of feeding vessels is often helpful in relieving symptoms from shunts to the superior-posterior dural sinuses, and a direct surgical approach is also sometimes feasible.

Spinal Arteriovenous Fistulas and Malformations

Spinal fistulas and AVMs are usually either dural or intradural in location. They may lead to spinal subarachnoid hemorrhage or to a myeloradiculopathy that can either present acutely or develop insidiously. Symptoms usually are progressive. At least one-half of the survivors of subarachnoid hemorrhage from these spinal lesions have further episodes of bleeding, and one-half of the subsequent survivors bleed again unless the underlying lesion is treated. Similarly, once there is any functional impairment in the legs due to the myeloradiculopathy, disability is likely to worsen, so that 50 percent of patients become unable to walk at all or require two sticks or crutches to do so, within 3 years. Spinal cord or root symptoms may show a characteristic relationship to exercise or posture and occasionally to pregnancy or the menstrual cycle.

Typically, examination reveals a mixed upper and lower motor neuron deficit in the legs, often with an associated sensory disturbance that occasionally has a radicular distribution. There may be a co-existing cutaneous malformation that sometimes relates segmentally to the spinal lesion. A spinal bruit may be present.

Unruptured dural arteriovenous fistulas and spinal AVMs probably produce symptoms by causing venous hypertension. Although they are usually extramedullary, their draining veins connect with veins draining the spinal cord. The increased venous pressure leads to a reduction in the arteriovenous pressure gradient across the cord and thus to a reduction in spinal blood-flow. Pressure on pelvic or abdominal veins by the gravid uterus could aggravate symptoms of caudally situated dural arteriovenous fistulas and AVMs by obstructing venous return to the heart, thereby reducing still more the arteriovenous pressure gradient across the cord. Whether anemia and hemodilution are also partly responsible for exacerbations of symptoms during pregnancy is unclear, and it is not known whether sex hormones exert direct trophic influences on these lesions.

Advances in imaging procedures have revealed that the nidus of many spinal vascular lesions is situated durally. Spinal MRI is an excellent screening procedure (Fig. 31-3); if the findings suggest an arteriovenous fistula, spinal angiography is performed to determine its anatomy, the anatomy of the spinal circulation, and the precise level of the abnormal fistula. Treatment of dural lesions is indicated in patients with progressive symptoms, functional incapacity, or a history of hemorrhage, and consists of embolization, surgical excision, or both. Treatment is clearly more difficult for vascular anomalies located anteriorly or within the spinal cord, but in some of these, also, the actual nidus of the lesion is dural and thus operable.

INFECTIONS

A variety of organisms may infect the nervous system, as discussed in later chapters. Pregnancy may interfere with resistance to specific infectious agents, thereby endangering maternal health. Treatment of various infections may also be complicated during pregnancy because of the need to avoid certain antimicrobial agents if possible. When infection occurs during pregnancy, it may pose risks to the developing fetus from the infective organism and the drugs used in its treatment. Obstetric management may be complicated.

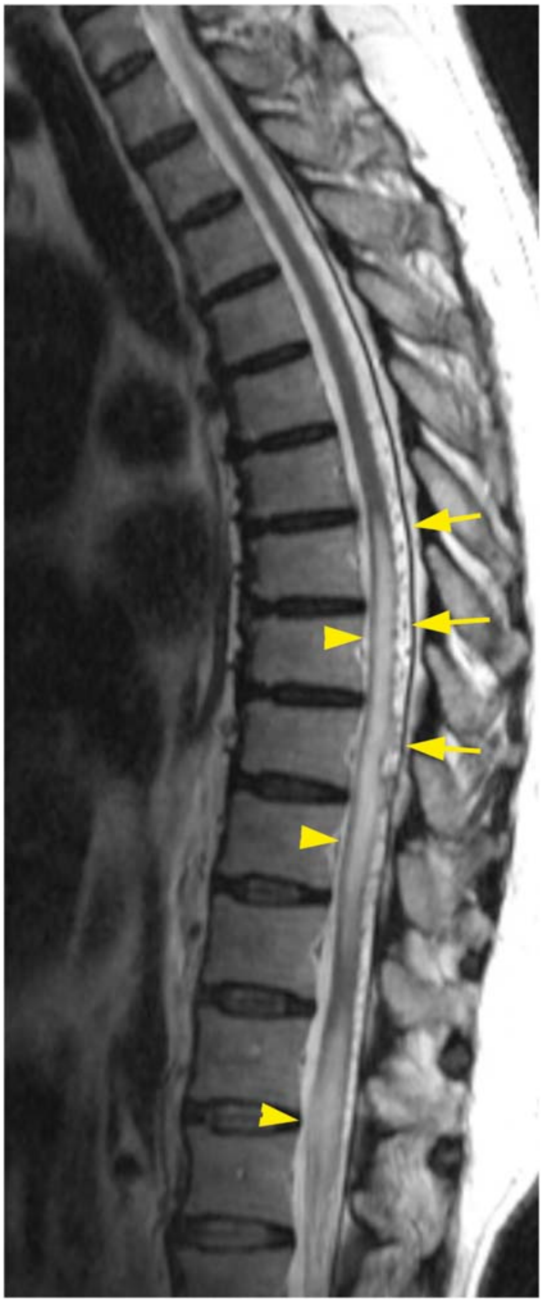

FIGURE 31-3 ■ Sagittal T2-weighted MR scan of the thoracic spine illustrates edema of the central spinal cord *(arrowheads)* and enlarged flow voids posteriorly *(arrows)*. The findings are typical of a spinal dural arteriovenous fistula. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

Retroviral Infections

Children born to women with *acquired immunodeficiency syndrome* (AIDS) are at risk of developing the disease after an interval that varies from several months to several years. Those infected transplacentally with human immunodeficiency virus (HIV) may be born with congenital AIDS. Infection with HIV may occur not during fetal development but at birth or from breast milk. Neurologic manifestations are particularly frequent in infected children and are due to a progressive encephalopathy that leads to developmental delay or regression, with evidence of cortical atrophy on neuroimaging studies. Calcification of the basal ganglia also occurs. Other manifestations of the disease include failure to thrive, interstitial pneumonitis, hepatosplenomegaly, and increased susceptibility to bacterial infections. Secondary opportunistic infections of the immunocompromised mother are potentially a risk to the fetus or child.

The availability of effective antiretroviral agents and access to infant formula (to prevent postnatal transmission through breast milk) have reduced the incidence of perinatal infections with HIV in developed countries. Combination antiretroviral therapy of infected pregnant women (regardless of CD4 cell count) and nevirapine therapy with or without zidovudine for 6 or 12 weeks for neonates (depending on the infant's risk of infection and method of feeding) are helpful in preventing mother-to-child transmission without an increase in fetal adverse events. Compared with no antiretroviral treatment or monotherapy, combination therapy does not seem to be associated with increased risks of prematurity or other adverse outcomes of pregnancy.

Management of delivery is based on obstetric considerations alone in patients with a low viral load (<1,000 copies/mL) and receiving combination antiretroviral therapy. Cesarean section at 38 weeks to reduce the risk of fetal infection is often preferred for those with higher viral loads or who are untreated.

Because some of the antiviral agents used to treat HIV infection may be teratogenic (in many instances no pharmacokinetic or safety data related to pregnancy are available), infants born of mothers treated with them during pregnancy may theoretically have nervous system abnormalities from the virus itself, from the medications used in its treatment, or both. The virus invades endothelial cells, causes a vasculitis, and leads to microinfarcts in the fetal brain; its effects depend upon the developmental stage of the fetus when it is exposed to the virus, but even late gestational exposures may affect brain development.

Children of women infected with *human T-cell leukemia virus*, type I (HTLV-I) may acquire the infection through breast-feeding and develop a resulting myelopathy in adult life. This is considered further in Chapter 43.

Poliomyelitis

Pregnancy increases the susceptibility of women to clinical poliomyelitis, but it is not clear whether this is because pregnant women are more susceptible to the initial viral infection or to invasion of the nervous system. Weakness tends to be more severe and widespread when poliomyelitis develops during the late stages of pregnancy. Poliomyelitis affects the course of pregnancy. During the first trimester, spontaneous abortion may occur with apparently mild nonparalytic attacks of the disease or in conjunction with a febrile reaction in its acute phase. Abortion or fetal loss may also occur during later stages of pregnancy, but usually in conjunction with severe poliomyelitis. Successful pregnancy may occur, however, even in patients who are dependent on continuous noninvasive positive-pressure ventilation. The uterine muscle is not paralyzed in women with poliomyelitis, and labor can usually be managed as in normal women unless there are specific obstetric indications for cesarean section or induction of labor. Normal offspring can be anticipated, although neonatal poliomyelitis may occur. Neonatal involvement within the first 5 days of life is generally assumed to follow transplacental transmission of the virus and is associated with a 50 percent or greater mortality rate.

Tetanus

Tetanus is an important complication of abortion or delivery, especially in developing countries, and is associated with a high mortality rate. In addition to treating the tetanus, any retained products must be evacuated from the uterus, and hysterectomy is sometimes necessary. Neonatal tetanus results from contamination of the umbilical cord, and in some areas the mortality rate is a high (but uncertain and geographically variable) proportion of all births. Infants are usually diagnosed within 10 days; the history is typically that of increased irritability for up to 48 hours, followed by cessation of sucking and crying, accompanied by convulsions and often by fever. Improved maternity facilities and the active immunization of women who are pregnant or of childbearing age are important public health measures to counter this disorder.

Other Infections

Maternal infection with *Listeria monocytogenes* may lead to abortion or stillbirth as well as to a number of other manifestations including meningitis; in neonates it leads to either an early-onset, predominantly septicemic infection or a late-onset, predominantly meningitic or meningoencephalitic infection. The bacteriologic and serologic findings suggest the diagnosis, and treatment is with appropriate antibiotics.

Maternal *rubella*, especially during the first trimester, may lead to congenital fetal malformations. Ocular abnormalities, seizures, mental retardation, deafness, focal neurologic deficits, and other abnormalities, including cardiac anomalies, occur in a variety of combinations. Much more rarely, a panencephalitic illness has been reported during the second decade of life in patients with congenital rubella and leads to pyramidal and extrapyramidal signs, seizures, and dementia. High antibody titers to rubella virus occur in the blood and CSF, and the virus may be isolated from the brain.

Congenital *toxoplasmosis* causes meningoencephalitis, chorioretinitis, obstructive hydrocephalus, and cerebral calcification. Pregnant women should therefore be advised to keep away from cat feces and to avoid ingestion of raw or undercooked meat or eggs.

Fetal infection with *cytomegalovirus* may lead to a variety of somatic manifestations. Neurologic involvement may be manifested by cerebral malformation, microcephaly, mental retardation, seizures, obstructive hydrocephalus, cerebral calcification, deafness, chorioretinitis, or some combination of these disorders.

Neonatal infection with *herpes simplex virus* leads primarily to visceral involvement. When there is neurologic involvement, manifestations may include seizures, irritability, increased intracranial pressure, depressed level of consciousness, and motor deficits.

Maternal *syphilis* is important to recognize and treat. It is associated with an increased rate of spontaneous abortion and increased perinatal mortality. Offspring of affected mothers may have symptomatic congenital syphilis. Infection may also occur at birth if infants come into contact with an infective lesion. The clinical features of congenital neurosyphilis are similar to those of neurosyphilis in adults. They may become apparent at any time after the first few weeks of life, or they can be delayed for several years. Treatment is of the underlying infection, penicillin being the drug of choice. Fetal infection usually occurs in the second half of pregnancy. Thus, treatment at an early stage of pregnancy generally prevents fetal involvement, emphasizing the importance of serologic testing during antenatal care. Details of treatment are provided in Chapter 39.

Tuberculous meningitis may occur during pregnancy and is then associated with higher mortality and neurologic morbidity rates than otherwise. Its treatment is discussed in Chapter 40.

METABOLIC AND TOXIC DISORDERS

In parts of the world where malnutrition is common, many pregnant women have a deficient intake of diverse nutrients including proteins, vitamins, and minerals. The incidence of malformed fetuses is high in this circumstance, but it is generally not possible to recognize the specific deficiency that is responsible. Fetuses exhibit intrauterine growth retardation, and organ development, including that of the brain, is sometimes affected.

Clinical presentation of the neurologic manifestations of *vitamin B_{12} deficiency* (myelopathy, polyneuropathy, mental changes, optic neuropathy) does not differ during pregnancy, but any accompanying megaloblastic anemia may be obscured by folic acid supplements. As in the nonpregnant patient, treatment is with parenteral vitamin B_{12} to arrest progression and correct reversible neurologic deficits. Maternal vitamin B_{12} deficiency during pregnancy may lead to similar deficiency in neonates, exacerbated in breast-fed infants by the reduced content of vitamin B_{12} in maternal milk. Clinically, such infants exhibit apathy, developmental delay or regression, involuntary movements, cutaneous pigmentation, and megaloblastic anemia. Treatment is with vitamin supplementation.

Phenylketonuria, with its autosomal-recessive inheritance, is an important cause of mental retardation. Neonatal screening programs can identify affected infants so they can be treated before intellectual function deteriorates. Affected women have a high rate of spontaneous abortion. Offspring of untreated women have a high incidence of facial dysmorphism, developmental delay, microcephaly, and congenital heart disease. Family planning and preconception counseling are important, as dietary treatment before conception or as soon as possible thereafter may prevent or lessen some of these features. To ensure that the diagnosis is not missed, antenatal screening for maternal phenylketonuria or testing at the first antenatal visit of women with a positive family history, low intelligence of uncertain cause, or a history of microcephalic offspring is justifiable. The homozygous offspring of an affected mother requires a diet low in phenylalanine, but the most appropriate nutritional management of heterozygotes is less certain. In any event, the affected mother should avoid breast-feeding because of the high concentration of phenylalanine in her milk.

Many *toxins* and *drugs* are teratogenic and may affect the developing nervous system. The teratogenic effects of antiepileptic drugs taken during pregnancy were considered earlier. Excessive maternal alcohol intake may lead to the fetal alcohol syndrome, in which intrauterine growth retardation and dysmorphic facies are common, but cerebral abnormalities (cortical changes, hypoplasia or agenesis of the corpus callosum, and microcephaly) may lead to seizures, mental deficiency, and motor deficits. Excessive vitamin A intake early in gestation may be teratogenic (cleft palate, spina bifida). Many other agents that are seemingly innocuous to the mother may affect the fetus, and the topic is too extensive to be reviewed here. Most drugs are not labeled for use in pregnancy, and there are few or no data on human fetal effects at the time of marketing. The use of medication or recreational agents during pregnancy should therefore be as limited as possible.

MOVEMENT DISORDERS

Movement disorders of any type may occur during pregnancy, as at other times. Comment here is restricted to those related more specifically to pregnancy or posing obstetric problems.

Chorea

CHOREA GRAVIDARUM

Chorea gravidarum occurs most often in primigravidas, frequently without evidence of preceding streptococcal infection, as a variant of Sydenham chorea. Approximately two-thirds of patients have a history of chorea or rheumatic fever, and most of the others have signs of rheumatic heart disease. Symptoms usually begin early in pregnancy; they remit after delivery but may recur during subsequent pregnancies. Altered patterns of circulating sex hormones during pregnancy may account for the chorea by their effects on previously damaged basal ganglia (Chapter 20). The chorea improves after delivery or abortion, as sex hormone levels return to prepregnancy values. The prognosis generally relates to cardiac complications, but there are rare case reports of rhabdomyolysis and a fatal outcome. The neurologic disorder generally benefits from bed rest and sedation, and other treatment is usually unnecessary. In the rare circumstance that symptomatic treatment is required after the first trimester, haloperidol is often preferred because of its less severe maternal side effects. The disorder is not an indication for termination of pregnancy, and there are no specific obstetric complications.

OTHER CAUSES OF CHOREA

Chorea developing for the first time during pregnancy does not necessarily represent a variant of Sydenham chorea. Huntington chorea may occasionally present during pregnancy, and chorea may also develop at this time as a result of systemic lupus erythematosus, polycythemia vera rubra, thyrotoxicosis, hypocalcemia, encephalitis, cerebrovascular disease, or Wilson disease, or as a drug-induced reaction. Further discussion is provided in Chapter 58.

Chorea may be induced by oral contraceptives, sometimes in women with pre-existing abnormalities of the basal ganglia. It usually begins approximately 3 months after contraceptives are started, tends to evolve subacutely, may be asymmetric or unilateral, and settles with discontinuation of the causal agent. Its pathophysiologic basis is unknown, but vascular mechanisms, immunologic mechanisms, and a hormone-dependent alteration in central dopaminergic activity have been proposed.

Restless Legs Syndrome

The restless legs syndrome is about three times more prevalent in pregnant than nonpregnant women, usually developing during the latter part of pregnancy. Unpleasant creeping sensations occur in the legs and occasionally the arms, usually at night or during relaxation, leading to a compelling need to move about and to chronic sleep deprivation. The cause is unknown. Neurologic examination reveals no abnormalities. Treatment of co-existing anemia or iron deficiency may improve symptoms, and treatment with low-dose clonazepam (0.25–1 mg before retiring at night) is sometimes worthwhile. Other drugs that may be helpful include carbidopa-levodopa (Sinemet), dopamine agonists, gabapentin, pregabalin, and opiates, but these drugs are usually best avoided during pregnancy. Symptoms generally resolve spontaneously in the first few weeks postpartum but may recur in subsequent pregnancies. When the syndrome develops during pregnancy, it may also recur unrelated to pregnancy in later life.

Dystonia

When acute dystonia develops during pregnancy, the most probable cause is use of a dopamine antagonist antiemetic or neuroleptic, such as metoclopramide. In patients with long-standing dystonia of either the idiopathic or secondary variety, pregnancy sometimes influences the neurologic outcome, but in an unpredictable manner. In occasional patients, dystonia worsens during pregnancy, but in others remission occurs. There are several reports of dystonia occurring without recognizable cause during pregnancy and resolving before delivery or within a few weeks thereafter; the term "dystonia gravidarum" has been used to refer to such cases. Pregnant patients with dystonia should be offered genetic counseling if the disorder has a hereditary basis. The conduct of labor depends on the severity and nature of the abnormal posturing.

Essential Tremor

Essential tremor is a common disorder, but the published data concerning its occurrence and management during pregnancy are limited. Its pharmacologic treatment is best avoided during pregnancy whenever possible, but disabling tremor may require treatment. Propranolol, discussed earlier, may affect fetal growth and blunt the fetal response to asphyxia. Only low levels of propranolol are found in breast milk and are unlikely to cause any adverse effects in breastfed infants. Primidone also was discussed earlier, in relation to epilepsy.

Parkinson Disease

Parkinson disease may develop in women who are still young enough to bear children. The incidence of obstetric complications or fetal defects is not increased. Concerns are sometimes expressed about the possible effects of pregnancy on the neurologic disorder. There is no consistent effect on overall parkinsonian disability, although some patients may show a worsening of their neurologic symptoms despite continuing on pharmacologic treatment. Deterioration may occur at any time or throughout the pregnancy, but whether this reflects the natural progression of the disease, a pregnancy-related alteration in pharmacodynamics, physical or psychologic stress, hormonal changes, or other factors is unclear. The safety of antiparkinsonian medication during pregnancy is also not known, but levodopa has not been associated with teratogenicity, spontaneous abortion, or birth complications.[13] Amantadine should not be prescribed during pregnancy as it is teratogenic.

The extent to which antiparkinsonian medications are secreted in breast milk, and the effect of these medications on infants, is not clear. Patients are therefore advised not to breastfeed while taking antiparkinsonian drugs.

Tourette Syndrome

The tics of Tourette syndrome may complicate pregnancy but are usually not aggravated by pregnancy. Unless the tics are disabling, medication can be reduced or withdrawn during or prior to pregnancy. When tics cause disability, treatment with neuroleptics (haloperidol or pimozide) is best introduced after the first trimester. The limited available evidence suggests that maternal haloperidol in doses up to 10 mg daily produces low levels in milk that usually do not affect the breastfed infant.

Wilson Disease

Untreated Wilson disease, an autosomal-recessive disorder, is associated with a high miscarriage rate, but pregnancy poses no special problems in patients receiving adequate chelation treatment. Penicillamine therapy may be associated with mesenchymal birth defects, but a number of reports document an uneventful pregnancy with birth of a normal infant in patients treated with penicillamine or zinc sulfate.[14]

MULTIPLE SCLEROSIS

The classic, unpredictable relapses and remissions that occur in multiple sclerosis (MS) make it difficult to determine whether pregnancy influences the disorder. However, several epidemiologic studies have suggested that the relapse rate is reduced during pregnancy but increased during the 3 to 6 months immediately after childbirth. The postpartum increase in relapse rate may relate to fatigue, stress, or a reduction in antenatal immunosuppression. Neither pregnancy itself nor the number of pregnancies affects the degree of subsequent neurologic disability. In some studies MS did not seem to influence the course of pregnancy or childbirth, but in others it was associated with smaller babies for age and more frequent deliveries involving the use of forceps, vacuum extractors, or cesarean section than in controls. Obstetric management may need to be modified for women with significant disability (such as severe spasticity), but MS should otherwise not influence the mode of delivery in most instances.

There is uncertainty about the safety and teratogenicity of many of the medications used in MS, especially the newer disease-modifying agents. Discontinuing them during pregnancy, however, may lead to disease activation especially in the puerperium, when the risk of relapse is already increased. There is limited information to guide decision-making. A consensus statement outlining the position of the Association of British Neurologist has attempted to clarify some of the issues. It urges that at or soon after diagnosis, all women with MS of childbearing age should have prepregnancy counseling, repeated at regular intervals. Patients considering pregnancy should discuss this with their physician before trying to conceive, and the safety of all drug treatments during pregnancy should be reviewed. Disease-modifying drug treatment does not need to be deferred because of a wish to have children. Any relapses during pregnancy or the puerperium can be treated with corticosteroids. The following comments are based largely on those of the UK Consensus Statement.[15]

Glatiramer acetate can be used safely throughout the pregnancy. β-Interferon preparations are probably safe when taken throughout the pregnancy—there is no evidence of fetal teratogenicity. Patients receiving β-interferon therapy when they became pregnant had a higher rate of fetal wastage (miscarriages or stillbirths) and of low-birth-weight babies in some, but not other studies. It has been suggested that patients should stop β-interferon therapy before becoming pregnant; failure to do so, however, does not necessarily imply a bad outcome, and most patients will produce a healthy infant. If stopped during pregnancy, it will take several months for full efficacy to be restored once restarted, so that cover of the puerperium, when the relapse rate is highest, will be incomplete. Thus, the benefits of continuing treatment generally outweigh the risks of treatment.

There may be an increased risk of spontaneous abortion and lower birth weight associated with natalizumab treatment, but it is not clearly teratogenic. Exposure late in pregnancy has been associated with minor, self-limiting hematologic abnormalities in infants. To minimize fetal exposure, it has been suggested that the last dose during pregnancy is given at approximately 34 weeks and the medication restarted soon after birth, ideally within 8 to 12 weeks from the last dose if possible to avoid rebound disease activity.[15] Natalizumab passes into breast milk and the amount increases with time; some therefore advise against breast feeding, despite its advantages and benefits.

There is limited information about the safety of fingolimod in pregnancy and women with MS should be advised to use effective contraception while taking it. Those planning to become pregnant should stop fingolimod at least 2 months before conception and discuss alternative treatments. They should stop fingolimod immediately in the event of an unplanned pregnancy. Pregnancies in women on fingolimod should be treated as high risk and patients referred for a fetal scan. Fingolimod should not be taken while breastfeeding

Teriflunomide is teratogenic in animals at equivalent doses to those given to humans. Women should use effective contraception while taking it and for 2 years after stopping unless they have undergone the accelerated elimination procedure. Those wishing to conceive should switch to another disease-modifying drug, stop teriflunomide, and undergo an accelerated elimination procedure. They should continue to use contraception for at least 6 weeks after serum drug concentrations are less than 0.02 mg/L on two occasions at least 14 days apart. Women who become pregnant while on teriflunomide should undergo a fetal scan.

There is only limited information about the safety of dimethyl fumarate in pregnancy. Women treated with it should use effective contraception and if they do become pregnant they should only continue treatment if the potential benefit justifies the potential risk to the fetus. If a woman taking dimethyl fumarate wishes to become pregnant, the use of alternative treatments should be discussed.

Ocrelizumab, a monoclonal IgG antibody, crosses the placenta, and fetal exposure is likely if the drug is given during pregnancy. The data regarding the use of ocrelizumab in pregnancy are limited. No B-cell count data have been collected in infants exposed to it, and the potential duration of B-cell depletion in infants is unknown. Accordingly, infants should be monitored for B-cell depletion, and inoculation with live and live-attenuated vaccines should be postponed until the infant's B-cell count has recovered. Breast feeding should be discouraged.

Women with MS should not be treated with alemtuzumab during pregnancy or while breastfeeding. The manufacturers recommend that women use effective contraception for 4 months following a course of alemtuzumab. If pregnancy does occur within a month of treatment, increased obstetric monitoring is advised. For 4 years after a cycle of alemtuzumab, women are at risk of autoimmune thyroid disease, immune thrombocytopenic purpura, and other autoimmune diseases. These may occur during pregnancy and affect both the mother and fetus. The women's obstetric team should be informed of these risks.

Cladribine is teratogenic and, given its potential for serious risk to the fetus, the manufacturers recommend that women using hormonal contraception should also use a barrier method of contraception during cladribine treatment and for at least 4 weeks after the last dose in each treatment year. Women should be advised not to become pregnant for at least 6 months after a course of cladribine.

Pregnant women with MS are often concerned about development of the disease in their offspring. Although MS may indeed show a familial incidence, this association is uncommon and tends to involve siblings rather than different generations, so that firm reassurance can generally be given. Pregnancy and parenthood should not be discouraged unless the patient is incapable of coping with the demands involved. Neurologic management during pregnancy is as at other times, but patients with sphincter disturbances or a paraparesis may pose particular problems. The method of delivery should be guided by obstetric factors alone.

OPTIC NEURITIS

Optic neuritis of any type may occur fortuitously during pregnancy. Optic nerve involvement is a rare complication of hyperemesis gravidarum, and uncontrollable vomiting may necessitate termination of pregnancy. Optic nerve involvement may occur during pregnancy or the postpartum period in patients with MS or tumors that enlarge slightly during the gestational period. Genetic counseling is important if there is a history of hereditary optic atrophy.

TRAUMATIC PARAPLEGIA

When spinal injury occurs during pregnancy, the patient must be investigated and managed with her own best interests in mind. Despite concerns that radiologic studies might affect the developing fetus, such studies should not be postponed if indicated neurologically.

Patients with established paraplegia should be educated about (1) the importance of avoiding urinary infection by ensuring a minimal amount of residual urine after micturition, and (2) the best means of avoiding pressure sores. Unless a paraplegic woman has a gross impairment of renal function, however, she need not be discouraged from pregnancy if she wishes to have a family. Care should be taken to prevent anemia during pregnancy.

The conduct of labor is complicated in paraplegic women. With complete cord lesions above T10, onset of labor is unrecognized and labor is painless. For this reason, the cervix is usually examined at each antenatal visit after approximately the 26th week of pregnancy; patients are hospitalized if the cervix is dilated, or routinely after about 32 weeks of pregnancy. With cord lesions below T10, uterine contractions are accompanied by normal pain sensations.

Complete cord lesions above T5 or T6 may be associated with *autonomic hyperreflexia*. Headache, sweating, nasal congestion, hypertension, reflex bradycardia, and cutaneous vasodilation and piloerection above the level of the lesion are often conspicuous during the uterine contractions of labor, becoming especially marked just before delivery. If unrecognized, the disorder is sometimes mistaken for pre-eclampsia. Symptoms have been attributed to release of catecholamines. Treatment in the past has included reserpine (to deplete catecholamines from sympathetic nerve terminals), atropine, clonidine, glyceryl trinitrate, or hexamethonium. Continuous lumbar epidural anesthesia can block or prevent autonomic hyperreflexia.

Cesarean section is not necessarily indicated by the paraplegia itself but may be required if there is bony deformity of the spine or pelvis. Forceps delivery may be necessary to compensate for paralysis of muscle involved in the expulsive efforts of the second stage or to shorten delivery time because of severe hypertension. Paraplegic and even quadriplegic patients have a normal milk ejection reflex during suckling and can breast-feed their infants.

ROOT AND PLEXUS LESIONS

Low back pain is common during pregnancy. There is usually no serious underlying neurologic cause, so that management is generally conservative. Acute *prolapse of a lumbar intervertebral disc*, for example, is rare during pregnancy and must be distinguished from conditions simulating it. This may require imaging. MRI during pregnancy is without known adverse effects on the fetus, but the use of contrast agents is best avoided if possible. Compressive injuries of the lumbosacral plexus may occur during labor and can be difficult to distinguish from an acutely prolapsed lumbar intervertebral disc. However, disc prolapse is associated with tenderness and rigidity of the lumbar spine, sciatica, and signs of root tension. Electrophysiologic studies may also clarify the diagnosis, depending on whether there is evidence of involvement of the paraspinal muscles (which are supplied proximally from the nerve roots). Management of lumbar disc prolapse during pregnancy is generally conservative, with surgery considered primarily for patients with significant progressive neurologic deficits or cauda equina syndrome. The optimal method of delivery for women with significant lumbar disc herniation is unclear because straining may worsen the herniation; cesarean section is often advocated in this circumstance.

Lumbosacral plexus lesions result from compression by the fetal head or obstetric forceps of the roots of the sciatic nerve. This injury is especially likely when there is minor disproportion or when midforceps are used during delivery because of malpresentation. Anatomic features of the pelvis that predispose to this complication include a straight sacrum; a flat, wide posterior pelvis; posterior displacement of the transverse diameter of the inlet; wide sacroiliac notches; and prominent ischial spines. Symptoms are usually unilateral and develop immediately after delivery. There is often predominant involvement of fibular (peroneal) fibers, as reflected by the distribution of motor and sensory findings. With mild injuries, the prognosis for recovery is excellent, but recovery may be prolonged and incomplete if axonal degeneration has occurred. Electrophysiologic studies therefore assist in determining prognosis. Treatment of severe cases with calipers and a night cast prevents contractures.

Despite an obstetric lumbosacral plexus palsy, delivery in subsequent pregnancies need not be by cesarean section. However, cesarean section is appropriate if the infant is large or there are premonitory symptoms suggesting nerve compression with attempted engagement of the fetal head during the last 4 weeks of pregnancy.

Maternal brachial plexopathy may be idiopathic or occur on a familial basis (also known as hereditary neuralgic amyotrophy). In some of the reported cases there has been a clear association of attacks with pregnancy or the puerperium; inflammation, probably immune-based, appears pathogenic at least in some instances. Pain in the shoulder or arm occurs and may last for several weeks, followed by wasting and weakness of muscles in the affected area. Reflex and sensory changes also occur. Mutations or duplications in the *SEPT9* gene on 17q25, inherited in an autosomal-dominant manner, are involved in many familial cases. A hereditary basis is suggested by recurrent episodes, especially postpartum, a positive family history, involvement of nerves beyond the brachial plexus, and the presence of mild dysmorphic features such as hypotelorism, epicanthic folds, low-set ears, and a small mouth. Early treatment with corticosteroids may be helpful.

PERIPHERAL NERVE DISORDERS

Entrapment Neuropathies

Two entrapment neuropathies are especially likely to occur during pregnancy. *Carpal tunnel syndrome* occurs often, possibly because of fluid retention. Nocturnal pain and paresthesias in the hand disturb sleep. Weakness of the thenar muscles occurs in more advanced cases. The clinical and electrophysiologic features of the disorder do not require description here. When the syndrome develops during pregnancy, it most often does so in the third trimester (although it may present earlier), and typically settles within approximately 3 months of delivery, often within 2 weeks; however, symptoms with onset in early pregnancy are less likely to improve after delivery. Treatment should be conservative. The use of a nocturnal wrist splint is often helpful for alleviating symptoms; the splint should maintain the wrist in a neutral or slightly flexed position. Salt restriction, local injection of corticosteroids into the carpal tunnel, or treatment with diuretics sometimes helps. The patient should be reassured about the benign nature of her symptoms. Surgical division of the anterior carpal ligament is usually unnecessary unless symptoms become intolerable or continue to progress in the weeks after delivery. In some instances, carpal tunnel syndrome develops in the puerperium; it may then relate to the position of the hand and wrist during breast-feeding. Treatment is conservative, but the wearing of wrist splints at such a time may be difficult.

Entrapment of the lateral femoral cutaneous nerve is also common during pregnancy, especially in its later stages, and leads to the syndrome of *meralgia paresthetica.* Pain, paresthesias, and numbness occur about the outer aspect of the thigh, usually unilaterally, and are sometimes relieved by sitting. Clinical examination reveals no abnormality except in advanced cases, when cutaneous sensation may be disturbed in the affected area. Symptoms generally settle spontaneously within a few weeks of delivery, and the patient can therefore be reassured. In rare instances, however, the pain has reportedly been so severe that labor has been induced early. Local injection of hydrocortisone about the region where the nerve lies medial to the anterior superior iliac spine may provide temporary benefit. Symptomatic relief may also follow treatment with low-dose tricyclic antidepressants. Anticonvulsant drugs such as carbamazepine should be avoided during pregnancy. The safety of treatment with lidocaine patches during pregnancy has not been established.

Traumatic Mononeuropathies

A number of isolated nerve lesions may occur as a complication of various obstetric maneuvers. Lower-limb nerve injury has been associated with nulliparity and a prolonged second stage of labor. The *obturator nerve* may be injured when the patient is in the lithotomy position because of angulation as the nerve leaves the obturator foramen. It may also be compressed between the fetal head and the bony pelvic wall. Similarly, an isolated *femoral neuropathy* may occur by angulation and pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as when anesthetized patients are placed in the lithotomy position; stretch of the nerve by excessive hip abduction and external rotation may also occur. The *saphenous nerve* is sometimes injured by pressure from leg braces when the patient is improperly suspended in the lithotomy position. The most common cause of *sciatic nerve* palsy is a misplaced deep intramuscular injection, but this nerve can also be injured by stretch when a patient is placed in stirrups on the obstetric table. To avoid such injury, the knee and hip joints should be well flexed and extreme external rotation of the hip avoided. The *common fibular (peroneal) nerve* may be injured in the region of the head of the fibula by pressure from the leg braces of the obstetric table, especially in anesthetized women. The clinical features of all these neuropathies are well known and are not recapitulated here.

Damage during labor and delivery to the innervation of the sphincter muscles in the pelvic floor may be responsible for stress incontinence of urine or feces, as discussed in Chapter 29.

Bell Palsy

Idiopathic lower motor neuron facial palsy is common and shows a definite association with pregnancy, attributed by some to fluid retention, a viral inflammatory reaction, or pregnancy-related change in immune function. Approximately 85 percent of cases occurred during the third trimester of pregnancy or the puerperium. The onset of Bell palsy during pregnancy has been related to hypertensive disorders, implying that patients who develop Bell palsy during pregnancy should be monitored closely for hypertension or preeclampsia. Diabetes should be excluded. Although most patients with Bell palsy recover completely without treatment, such recovery may be less likely for women with a complete palsy developing during pregnancy than for the general population. Despite questions concerning its efficacy, treatment with corticosteroids is generally prescribed for Bell palsy, especially if a poor prognosis is anticipated because of severe pain or a clinically complete palsy and if patients are seen within the first week of the disorder. However, corticosteroids are perhaps best avoided during the first trimester, at least in those with a good prognosis, because incomplete evidence suggests they may increase the risk of oral clefts. Antiviral therapies are probably not effective. In patients with a complete facial palsy, protection of the cornea should be ensured. Electrodiagnostic evaluation after the first week provides a guide to prognosis.

Polyneuropathies

There is no specific polyneuropathy of pregnancy, but any type may occur during the gestational period. *Nutritional deficiency* is probably the most likely cause in patients from one of the developing nations or in those with hyperemesis. There may be evidence of peripheral nerve involvement in patients with hyperemesis gravidarum complicated by Wernicke encephalopathy and sometimes by Korsakoff syndrome. Diagnosis is confirmed by finding a marked reduction in blood transketolase activity and a marked thiamine pyrophosphate effect. As in nonpregnant women, treatment is with thiamine, 100 mg being given once intravenously and then intramuscularly for several days until a satisfactory diet is ensured. Vitamin B_{12} deficiency was discussed earlier (see p. 590).

Guillain–Barré syndrome may occur during any stage of pregnancy or in the puerperium. It may be associated with antecedent infections such as with *Campylobacter jejuni* or cytomegalovirus. Its course is not influenced by pregnancy. Approximately 3 percent of patients have one or more relapses, sometimes several years after the initial illness, and they occasionally occur in relation to pregnancy. There has been a case reported of a mother with cytomegalovirus-related acute inflammatory neuropathy that developed approximately 10 weeks before delivery of a healthy infant who, in turn, developed a neonatal inflammatory neuropathy after several days.

Serial ultrasonographic fetal monitoring has sometimes been performed but usually reveals normal fetal movement, even when paralysis is severe in the mother. Early ventilatory support may be helpful in preventing fetal hypoxia. Hypotensive episodes due to autonomic involvement may necessitate volume expansion to ensure adequate placental perfusion. The maternal outcome appears unaffected by early delivery. The Guillain–Barré syndrome is treated as in nonpregnant women; experience with plasmapheresis or intravenous immunoglobulin therapy is more limited in this circumstance but both have been used safely during pregnancy. Delivery may require forceps or assisted extraction devices because of weakness of the abdominal muscles, which may reduce the ability to increase the intra-abdominal pressure voluntarily; uterine contractions are normal.

When relapse of *chronic inflammatory demyelinating polyneuropathy occurs* during pregnancy, it is usually late in pregnancy or in the puerperium. There are no specific fetal complications. Treatment is as in nonpregnant women, but concerns regarding plasmapheresis and intravenous immunoglobulin merit reiteration; there is further concern about the use of azathioprine, cyclosporine, and cyclophosphamide, which may retard fetal growth and have other adverse effects, including potential teratogenicity. *Multifocal motor neuropathy* with conduction block may be exacerbated during pregnancy but responds to intravenous immunoglobulin therapy; after pregnancy, power commonly reverts to its previous level.

Pregnancy may lead to acute exacerbations in the hepatic type of *porphyria*. The usual neurologic manifestation is a polyneuropathy that is predominantly motor but sometimes has pronounced autonomic accompaniments. Cerebral manifestations may also occur. In many patients with hepatic porphyria, however, pregnancy is well tolerated. Relapses may occur at any time, but are most likely during early pregnancy and may then lead to spontaneous abortion. Patients with this disorder who are contemplating pregnancy must therefore understand the implications and uncertain outcome, and they must be monitored closely during the gestational period. Caution must also be exercised in the medications used during and after labor because they may provoke exacerbations.

MYASTHENIA GRAVIS

Myasthenia gravis, an autoimmune disorder of neuromuscular transmission, is associated most commonly with antibodies against muscle nicotinic acetylcholine (ACh) receptors; in seronegative cases, antibodies against muscle-specific kinase are often present. Exacerbations of myasthenia gravis may occur in relation to the menstrual period. The disorder may be influenced in an unpredictable manner by pregnancy, and the effect of pregnancy may vary in the same patient on different occasions. Pregnancy does not worsen the long-term outlook. The severity of the myasthenia at the time of the pregnancy does not predict the occurrence of exacerbation or remission. Remission occurs during pregnancy in approximately 30 percent of cases, relapse in between 30 and 50 percent, and no change in the remainder. A significant additional number of relapses occur in the postpartum period, when they tend to be particularly severe; these may relate in part to postpartum infection. Relapses may occur at any time during the pregnancy. Severe relapse of the disorder may suggest the need for termination of pregnancy, but termination does not necessarily lead to clinical benefit. The myasthenia must be treated effectively but, as indicated earlier, the safety (to mother or fetus) of cholinesterase inhibitors, immunosuppressive agents, plasmapheresis, and intravenous immunoglobulins during pregnancy is not completely clear; the potential risks of such treatment, however, must be balanced against the risks to both mother and fetus of myasthenic crisis. Evidence suggests that mycophenolate mofetil is best avoided in pregnancy because it is teratogenic and has been associated with first-trimester pregnancy loss. There have also been concerns about the possible teratogenicity of azathioprine in animal studies, and fetal malformations have occurred in humans that possibly related to the drug. Both plasmapheresis and intravenous immunoglobulin therapy have been used safely and effectively in myasthenic patients during pregnancy.

Myasthenia gravis has little effect on pregnancy itself, unless it leads to maternal respiratory inadequacy; weakness of the respiratory muscles may be exacerbated by a restriction of diaphragmatic excursions by the growing fetus. There is sometimes a marked contrast between the strength of uterine contractions during the second stage of labor and the severity of skeletal muscle weakness. Enemas should not be given because they may precipitate a myasthenic crisis. Cesarean section is best reserved for patients in whom it is indicated for obstetric reasons. Regional anesthesia rather than general anesthesia is desirable, and the use of muscle-relaxant drugs should be avoided if possible. Magnesium sulfate should not be used in myasthenic patients with toxemia because of its effects on neuromuscular transmission. In a population-based cohort study, no significant differences were found in perinatal mortality, mean gestational age, or birth weight between the offspring of myasthenic and nonmyasthenic women.[16] Breast-feeding is not contraindicated.

Neonatal myasthenia, a transient disorder that may relate to placental transfer of maternal antibodies against ACh receptors, occurs in approximately 10 to 15 percent of the newborn infants of myasthenic women, regardless of the duration or severity of the maternal illness or ACh receptor antibody titer. Infants of myasthenic mothers should therefore be watched carefully for clinical signs of the disorder: a poor cry, respiratory difficulties, weakness in sucking, feeble limb movements, and a weak Moro reflex. Symptoms generally become apparent within the first 3 days of birth but are not usually evident immediately after birth. The neonatal disorder can be treated with anticholinesterase drugs if necessary, and it usually subsides within 6 weeks of delivery. Its occurrence in one child does not imply that subsequent children born to the same mother will have the disorder.

The transient neonatal form of myasthenia is distinct from congenital myasthenia, which is rare, occurs in children born to healthy mothers, and is a life-long disorder that varies in type with age of onset, severity, and pathogenesis.

MYOTONIC DYSTROPHY

The weakness and myotonia of myotonic dystrophy type 1 may worsen during pregnancy, and the course of the disorder sometimes appears to accelerate during the gestational period. Women with early-onset myotonic dystrophy are more likely to experience a complicated pregnancy than those with later onset. A number of obstetric complications have been reported, including threatened, spontaneous, and habitual abortion; ectopic pregnancy; preterm labor; and placenta praevia. Perinatal loss (stillbirths or neonatal deaths) is increased and has been related to congenitally affected fetuses and associated complications of the pregnancy. Premature onset of labor in patients with myotonic dystrophy has sometimes been attributed to abnormalities of uterine muscle. The uterus may fail to contract normally during labor, so that the first stage is prolonged, and retention of the placenta and postpartum hemorrhage may occur. Skeletal muscle weakness may also lead to difficulties during the second stage of labor. If anesthesia is required for obstetric reasons, depolarizing muscle-relaxant drugs should be avoided because they may cause myotonic spasm, and nondepolarizing drugs are given in reduced dosage to patients who are taking quinine for their myotonia. Electrocardiographic monitoring facilitates the early recognition of cardiac arrhythmias, to which patients with myotonic dystrophy are prone, and which may require a pacemaker. General anesthetics may lead to marked respiratory depression, and regional analgesia is the preferred method of management.

Type 2 myotonic dystrophy (CCTG expansion in intron 1 of the *ZNF9* gene on chromosome 3q 21.3) may first become manifest during pregnancy, with worsening occurring in subsequent pregnancies, for uncertain reasons. When initial symptoms occur before or during pregnancy, marked improvement often follows delivery, with a recurrence of symptoms in subsequent pregnancies. In one series, preterm labor occurred in 50 percent of pregnancies and was more likely in women who developed the first symptoms or a deterioration of the myotonic dystrophy during pregnancy compared with those in whom an influence of gestation on the disease course was inapparent. No increased obstetric risk was found, and early pregnancy loss rate was normal.[17]

Myotonic dystrophy type 1 (expanded CTG repeat in the *DMPK* gene) may occur congenitally among the offspring of mothers with the disease. An affected mother is more likely to have a child with congenital myotonic dystrophy in a first pregnancy if she has multisystem disease when pregnant, age at onset is less than 30 years, her father is the affected parent, and CTG expansion is more than 1 kb; however, even subclinically affected women with low repeat sizes can have congenitally affected offspring. Recurrence risk to further children is high if an affected woman has given birth to one child with congenital myotonic dystrophy. There may be a history of hydramnios or reduced fetal activity during late pregnancy. Affected infants may die within hours or a few days of birth. Clinical features of the disorder in such infants include facial diplegia, hypotonia, respiratory distress, feeding difficulties, delayed motor development, and mental retardation. Talipes is also common. Myotonia is absent clinically in neonates with the congenital form of myotonic dystrophy but is uniformly present in children 10 years or older. Myotonic dystrophy type 2 has not been reported in congenital form.

In congenital myotonic dystrophy, transmission is generally via the mother. The data suggest that the disorder results from the combination of the gene responsible for the disorder in adults, with some additional maternally transmitted factor.

The gene causing myotonic dystrophy type 1 is on chromosome 19q13.2-q13.3 and has variable penetrance; increasing numbers of triplet repeat expansions govern development of clinical disease. Genetic counseling is an important consideration for women with myotonic dystrophy who are contemplating pregnancy. Counseling and planning of pregnancy may be difficult in patients with mild cognitive impairment or behavioral disturbances. Prenatal detection of the disorder provides the opportunity for abortion of an affected fetus.

ECLAMPSIA AND PRE-ECLAMPSIA

Reference has not been made in this chapter to eclampsia (defined as the occurrence of seizures or coma in a patient with pre-eclampsia, i.e., the onset of hypertension and proteinuria during the second half of pregnancy), which is usually treated by obstetricians rather than neurologists. The neurologic manifestations of pre-eclampsia or eclampsia include headache, tinnitus, diplopia, visual blurring, scotomas, and transient blindness that may arise cortically. The pathophysiologic basis of the seizures or coma that occur in patients with eclampsia is unclear, but the cerebral dysfunction has been attributed to a number of factors, including intensive vasoconstriction, endothelial damage, cerebral edema, and DIC in the cerebral microcirculation. The relationship between hypertension, seizures, and cerebral dysfunction is unclear and unpredictable, but a further increment in the previously elevated blood pressure or an exacerbation of headache may be noted. Imaging (CT scans or MRI) may reveal cerebral edema, ischemia, infarction, or hemorrhage, and angiographic evidence of vasospasm is sometimes found; the radiologic findings resemble those in hypertensive encephalopathy. Treatment generally consists of controlling hypertension, preventing convulsions, and reducing cerebral edema. In extreme cases, termination of pregnancy may be necessary. In general, seizures can be controlled with intravenous diazepam, with the addition of phenytoin if necessary. Many obstetricians prefer to use magnesium sulfate to control eclamptic seizures, and some justification exists for this approach, which may be superior in this context to phenytoin or diazepam. A common regimen is to administer 10 g intramuscularly followed by 5 g intramuscularly every 4 hours, depending on renal output. The aim is to achieve a serum magnesium level of 5 to 8 mEq/L. Other therapeutic approaches reflect obstetric management and include prompt delivery, and need not be recapitulated here. Low-dose aspirin (81 mg/day) after 12 weeks of gestation may reduce the risk of pre-eclampsia in women with a past history of the disorder.

Pre-eclampsia (hypertension, proteinuria, and edema, occurring between the twentieth week of gestation and 48 hours postpartum) may present with a variety of manifestations due to involvement of such different organs as the kidney, liver, heart, central nervous system, or blood-clotting system. It may be clinically impossible to distinguish between pre-eclampsia and either thrombotic thrombocytopenic purpura or the hemolytic-uremic syndrome. Hematologically, however, pre-eclampsia is characterized by DIC and reduction of plasma antithrombin III activity, in contrast to thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome. The so-called HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), probably a variant of pre-eclampsia, frequently has major neurologic consequences such as intracerebral hemorrhage.

The *posterior reversible leukoencephalopathy syndrome* (PRES) is sometimes considered to be indicative of eclampsia, even when there are no other features of eclampsia (proteinuria, hypertension). It is characterized by the gradual onset of headache, confusion or an impairment of consciousness, visual changes, and seizures, associated with edema of the posterior cerebral (parieto-occipital) white matter on imaging studies. The MRI findings consist most often of punctate or confluent areas of increased signal on proton density and T2-weighted images (Fig. 31-4). Treatment is as for pre-eclampsia or eclampsia. PRES also occurs in hypertensive crisis or with cytotoxic immunosuppressive therapy, with acute or chronic renal disease (see Chapter 16), in various vasculitic disorders, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura, after organ transplantation, with sepsis, and in many other clinical settings. Treatment is focused on control of the blood pressure.

Thrombotic thrombocytopenic purpura is characterized by fever, Coombs-negative hemolytic anemia, thrombocytopenic purpura, fluctuating neurologic involvement, and renal disease, and it may simulate pre-eclampsia. Its neurologic features are discussed in Chapter 25. Thrombotic thrombocytopenic purpura may develop during the antepartum period, often before approximately 24 weeks of gestation, and may result in infant death, although successful treatment may permit prolongation of the pregnancy. Treatment is by plasma exchange or

Dillon, MD, University of California, San Francisco.)

infusion. Platelet transfusions should be avoided because they may trigger an exacerbation. Antiplatelet agents (such as aspirin or dipyridamole) usually are not effective, but treatment with corticosteroids may be helpful. Postpartum *hemolytic-uremic syndrome* is similar to thrombotic thrombocytopenic purpura, and many consider it within the same spectrum.

Adverse drug reactions are a common and important cause of morbidity and hospital admission and are a major burden on the healthcare budget. Drug reactions commonly involve the nervous system, causing a variety of disorders that may be serious and even life-threatening, and may mimic naturally occurring neurologic disorders. Unlike many of these, most drug-induced disorders are readily reversible if the

offending agent is identified early and withdrawn. It is therefore essential that the possibility of an iatrogenic condition should be considered in any patient presenting with neurologic symptoms, and a full drug history should always be obtained with this in mind. The spectrum of drug-induced disorders is diverse, as discussed in this chapter.

HEADACHE

Drugs can cause headache through a number of different mechanisms, such as by inducing cerebral vasodilation or vasoconstriction, raised intracranial pressure, or aseptic meningitis. Moreover, medication may exacerbate a pre-existing headache disorder such as migraine or tension-vascular headache.

Vascular Headaches

Many drugs cause headaches by inducing vasodilation or reversible cerebral vasoconstriction. These include sympathomimetics, amyl nitrate, nitroglycerin, antihistamines, nicotinic acid, pentoxifylline, nifedipine, theophylline, aminophylline, terbutaline, and dipyridamole. Headache may also occur during treatment with cyclosporine, bromocriptine, dopamine, and nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., naproxen, ketoprofen, diclofenac, alclofenac, ibuprofen), and in patients taking H_2-receptor antagonists (e.g., cimetidine and ranitidine) and proton pump inhibitors (e.g., omeprazole and lansoprazole).

Headache is common during intravenous immunoglobulin infusions, which may induce reversible cerebral vasoconstriction, and may also occur with the use of illicit drugs such as amphetamines, cannabis, cocaine, and lysergic acid diethylamide (LSD). Selective serotonin reuptake inhibitors (SSRIs), serotonin-noradrenaline reuptake inhibitors (SNRIs), α-sympathomimetics, nasal decongestants, triptans, ergot alkaloid derivatives, nicotine patches, and herbal medications such as ginseng have also been implicated.

Medication Overuse Headache

Medication overuse headache is one of the most common causes of disabling headache in clinical practice and often goes unrecognized.[1] A paradoxical increase in headache frequency commonly occurs in migraine or cluster headache patients consuming excessive quantities of ergotamine preparations or triptans on a regular basis. Treatment involves gradual withdrawal of the offending drugs and commencement of an alternative prophylactic medication. Chronic analgesic dependency may have a similar effect in chronic tension-vascular headache sufferers, leading to rebound headaches and contributing to the syndrome of chronic daily headache.

Idiopathic Intracranial Hypertension

A number of drugs may cause the idiopathic intracranial hypertension syndrome, characterized by headache, papilledema, diplopia, and visual impairment. These include oral contraceptives, estrogens and progestational agents, growth hormone, anabolic steroids, antibiotics (e.g., tetracyclines, minocycline, ampicillin, nalidixic acid, nitrofurantoin), nonsteroidal anti-inflammatory medications (e.g., naproxen, ibuprofen, indomethacin), vitamin A and retinoids (isotretinoin, etretinate), danazol, amiodarone, thyroxine, ketamine, nitrous oxide, and corticosteroids or corticosteroid withdrawal.

Aseptic Meningitis

Aseptic meningitis may be caused by a variety of drugs including NSAIDs and cotrimoxazole, particularly in patients with systemic connective tissue diseases, and occasionally by other antimicrobials such as sulfasalazine, penicillin, amoxicillin, ciprofloxacin, and cephalosporins; and by carbamazepine and pentoxifylline. Aseptic meningitis may also develop after intravenous immunoglobulin therapy and treatment with other immunomodulatory agents such as infliximab, leflunomide, azathioprine, and monoclonal antibodies such as muromonab-CD3. Intrathecal anesthetics, contrast media, methylprednisolone, methotrexate, and cytarabine may also cause aseptic meningitis.

STROKE

Women taking oral contraceptives have an increased risk of ischemic stroke and cerebral venous thrombosis, but the absolute risk is small in healthy young women without other stroke risk factors who are on low-dose estrogen-progestin preparations. The risk of ischemic stroke is higher in women with migraine and high blood pressure and in smokers and those taking higher-dose contraceptive pills. Oral contraceptives are not thought to increase the risk of hemorrhagic stroke, but have been implicated in subarachnoid hemorrhage, particularly in smokers. The risk of stroke may also be increased by postmenopausal hormone replacement therapy, particularly if commenced more than 5 years after the menopause.[2] Women with breast cancer treated with tamoxifen have an increased risk of ischemic stroke and of other types of stroke including venous sinus thrombosis. There is also a modest increase in the risk of ischemic stroke and myocardial infarction in men on testosterone replacement therapy, particularly in the first 2 years of treatment.[3]

Overmedication with antihypertensive drugs is an important potential cause of iatrogenic ischemic stroke, especially in the elderly and in patients with severe cerebrovascular disease. Patients taking anticoagulants have an increased risk of intracerebral and other forms of intracranial hemorrhage, particularly with long-term or poorly controlled therapy; and there is an increased risk of ischemic stroke in patients with heparin-induced thrombocytopenia. The use of aspirin and other antiplatelet drugs for primary or secondary stroke prevention is also a risk factor for intracerebral hemorrhage.

Intracerebral or subarachnoid hemorrhage may occur following intravenous, oral, or intranasal administration of amphetamines and related compounds that cause acute blood pressure elevation. Recreational use of methamphetamine is an important risk factor for intracerebral hemorrhage and is associated with a fivefold increase in the risk of hemorrhagic stroke, which can occur at an earlier age and has a poorer outcome than in nonusers.[4] Intracranial hemorrhage may also occur in patients taking diet pills, decongestants, and stimulants containing phenylpropanolamine or pseudoephedrine. Intracerebral hemorrhage or ischemic stroke may occur in individuals taking high doses of ephedrine-containing preparations or taking cocaine, amphetamines, methylphenidate, or heroin. These drugs, as well as phenylpropanolamine, pseudoephedrine, oxymetazoline, allopurinol, penicillin, and ergot alkaloids, have also been implicated in causing cerebral vasculitis in some patients.

SEIZURES

Many drugs can induce seizures in healthy individuals, and especially in those with pre-existing epilepsy or a low seizure threshold (Table 32-1). It has been estimated that up to 6 percent of new-onset seizures are drug related and that approximately 10 percent of cases of status epilepticus presenting to an emergency department result from drug toxicity.[5] Some drugs are more likely than others to cause seizures, particularly those that cross the blood–brain barrier and those administered in high doses intravenously or intrathecally. The following classes of drugs have been reported repeatedly to induce seizures, in decreasing order of frequency: antidepressants, stimulants, anticholinergics, and other medications such as baclofen, antihistamines, antipsychotics, naproxen, meperidine, local anesthetics, isoniazid, propoxyphene, methylphenidate, lithium, cyproheptadine, acetylsalicylic acid, and glipizide. With a number of the drugs listed in Table 32-1, seizures have been reported only rarely and the association therefore remains circumstantial.

A number of factors predispose to drug-induced seizures, including a family history of epilepsy and a genetically determined low seizure threshold. Penicillin-induced seizures are more likely to occur with high-dose

TABLE 32-1 ■ Drugs Associated with the Occurrence of Seizures

Antidepressants	Tricyclics, monoamine oxidase inhibitors, SSRIs
Antipsychotics	Phenothiazines, butyrophenones, lithium, clozapine, olanzapine
Analgesics	Fentanyl, alfentanil, morphine, meperidine, pentazocine, propoxyphene, mefenamic acid
Local Anesthetics	Lidocaine, mepivacaine, procaine, bupivacaine
General Anesthetics	Ketamine, halothane, enflurane, methohexital, propofol, isoflurane
Antimicrobials	Penicillins, ampicillin, cephalosporins, imipenem, metronidazole, nalidixic acid, isoniazid, cycloserine, pyrimethamine, acyclovir, ganciclovir, foscarnet
Antineoplastics	Chlorambucil, vincristine, methotrexate, cytarabine, misonidazole, carmustine
Bronchodilators	Aminophylline, theophylline
Sympathomimetics	Ephedrine, terbutaline, phenylpropanolamine
Other Drugs	Antihistamines, anticholinergics, anticonvulsants, chloroquine, baclofen, cyclosporine, azathioprine, β-adrenergic blockers, flumazenil, disopyramide, bromocriptine, domperidone, phencyclidine, amphetamines, methylphenidate, famotidine, isotretinoin, ondansetron, allopurinol, oxytocin, erythropoietin

intravenous or intrathecal administration, and in patients with impaired renal failure who have high blood levels of the drug. Other drugs that may cause seizures when they accumulate as a result of reduced renal excretion include meperidine, imipenem, nalidixic acid, cephalosporins, cimetidine, lithium, and erythropoietin. Seizures have also been reported in patients treated with cyclosporine, especially in renal or liver transplant patients who have high blood levels of the drug.

A number of therapeutic agents such as oxytocin, carbamazepine, and the SSRIs can cause seizures by inducing hyponatremia. Withdrawal of benzodiazepines, barbiturates, tricyclic antidepressants, alcohol, or baclofen is another important cause of seizures, particularly if the withdrawal is too abrupt. Withdrawal of anticonvulsant drugs in epileptic patients is also an important cause of seizures or even status epilepticus, and should always be gradual.

Conversely, excessively high doses and serum concentrations of certain anticonvulsants may aggravate epilepsy or induce new seizure types or even status epilepticus. Carbamazepine may aggravate absences and myoclonic or atonic seizures. Benzodiazepines may induce tonic seizures and status epilepticus in patients with the Lennox–Gastaut syndrome. Valproic acid and vigabatrin may occasionally induce status epilepticus. Gabapentin may have an adverse effect on myoclonic epilepsy, as may topiramate on focal epilepsy, and tiagabine may induce nonconvulsive status epilepticus.

The convulsant effects of certain drugs, such as isoniazid, aminophylline, local anesthetics, phencyclidine, and meperidine, are dose related, but other drugs may cause seizures even with therapeutic doses and blood levels. These include theophylline, tricyclic antidepressants, and phenothiazines. The aliphatic phenothiazines chlorpromazine, promazine, and prochlorperazine are more likely to induce seizures than the piperazine group, such as fluphenazine and trifluoperazine. Seizures have also been reported with the atypical neuroleptics clozapine, olanzapine, risperidone, and sertindole. Most classes of antidepressant may induce seizures, including SSRIs, SNRIs, tricyclics, bupropion, mirtazapine, reboxetine, and trazodone, although the risk is low. Lithium-induced seizures are well known and generally occur when plasma levels exceed 3.0 mEq/L.

ENCEPHALOPATHY

Certain drugs such as lithium and acyclovir may cause a diffuse disturbance of cerebral function leading to tremor, asterixis, myoclonus, seizures, ataxia, confusion, and obtundation. Such a syndrome may be caused by lithium toxicity, but it sometimes occurs even when blood levels of the drug are within the recommended therapeutic range.

A severe diffuse encephalopathy with associated focal neurologic features has recently been recognized in patients with various forms of malignancy undergoing chimeric antigen receptor T-cell therapy.[6]

High doses of penicillin and cephalosporins may also cause an acute encephalopathy, particularly in patients with impaired renal function, as may a variety of other drugs including lidocaine, tocainide, benzodiazepines, vigabatrin, valproic acid, phenytoin, carbamazepine, baclofen, isoniazid, levodopa, mefloquine, sulfonamides, podophyllin, L-asparaginase, thymidine, 5-fluorouracil, carmustine (BCNU), mechlorethamine, *N*-phosphonacetyl-L-aspartic acid (PALA), cytarabine, fludarabine, doxorubicin, and intrathecal metrizamide. In the past, a myoclonic encephalopathy was recognized in patients with prolonged exposure to bismuth-containing preparations or with aluminum toxicity in those undergoing hemodialysis ("dialysis encephalopathy"), and with carisoprodol overdosage.

A progressive leukoencephalopathy characterized by dementia, dysarthria, ataxia, and paralysis, at times followed by seizures, coma, and death, may occur in patients treated with high-dose intrathecal, intraventricular, or intravenous methotrexate, particularly after cranial or craniospinal radiotherapy. A posterior leukoencephalopathy with headache, seizures, cortical blindness, and parieto-occipital lesions has been increasingly recognized in patients treated with cyclosporine (Fig. 32-1). The condition is often associated with hypertension and high blood drug levels and is usually reversible. Other drugs that have been associated with the development of a leukoencephalopathy include capecitabine, cisplatin, cytarabine, 5-fluorouracil, fludarabine, ifosfamide, amphotericin B, interferons, interleukin-2, levamisole, tacrolimus, melarsoprol, and bevacizumab, as well as heroin, synthetic cannabinoids, and other drugs of addiction.

There is increasing awareness of the higher risk of developing the JC virus–associated disorder progressive multifocal leukoencephalopathy (PML) in individuals treated with immunomodulatory biologics such as natalizumab (anti-α4-integrin) and rituximab (anti-CD20).

DRUG-INDUCED COMA

Drugs are a common and important cause of coma resulting from accidental or self-administered overdosage. The drugs can be classified into those that have a direct

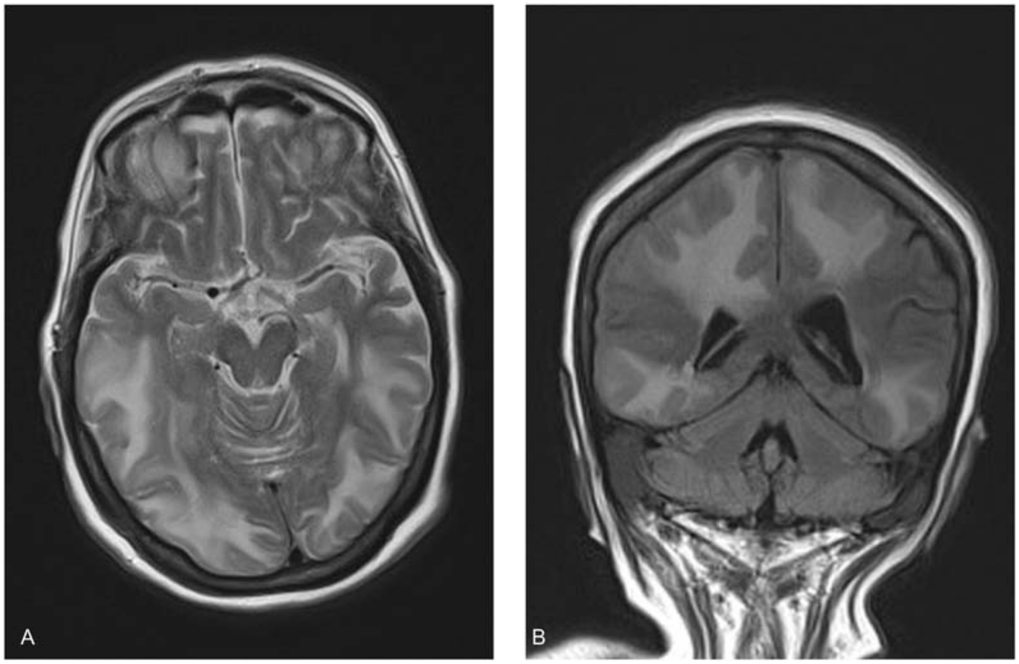

FIGURE 32-1 ■ Axial (*A*) and coronal (*B*) T2-weighted MRI of the brain showing findings of posterior reversible encephalopathy syndrome in a patient with mixed connective tissue disease receiving cyclosporine.

depressant effect on the brain such as hypnotics, sedatives, antidepressants, analgesics, or various drug combinations, and those that cause coma through indirect effects, such as insulin, antihypertensives, and antiarrhythmics. Other drugs that may cause depression of consciousness include phenothiazines, salicylates, acetaminophen (which can cause severe hepatic damage), paraldehyde, acyclovir, and valproic acid.

Certain neurologic findings are characteristic of drug-induced coma. The pupils are typically small and reactive, but may be dilated and fixed in severe barbiturate intoxication or pinpoint in opiate poisoning. The corneal reflexes are preserved but may be lost in profound drug-induced coma. Both spontaneous and reflex eye movements are depressed early, particularly with barbiturate, tricyclic, and phenytoin intoxication, with the eyes being fixed and divergent, without spontaneous roving eye movements, and with impaired or absent oculocephalic and oculovestibular reflexes. Muscle tone is often reduced and the tendon reflexes are depressed, with flexor plantar responses, but there may be hypertonia, hyperreflexia, decerebrate posturing, and extensor plantar responses, particularly if there has been superadded cerebral hypoxia. Muscle twitching, choreoathetosis, myoclonus, and seizures may all occur in coma caused by tricyclic agents or lithium toxicity.

The electroencephalogram (EEG) can sometimes provide a clue to identifying the causative drug. In drug-induced coma it usually shows diffuse slowing, but with barbiturate or benzodiazepine intoxication there is typically a predominance of beta activity ("beta coma"). Alpha-pattern coma, or mixed alpha and beta rhythms, may also occur with benzodiazepine or with chlormethiazole intoxication.

NEUROPSYCHIATRIC DISORDERS

Psychiatric adverse drug reactions are common in clinical practice and may take various forms.

Behavioral Toxicity

A variety of nonspecific symptoms including drowsiness, insomnia, irritability, restlessness, anxiety, mood changes, vivid dreams and nightmares, and increased sensitivity to light and sound may occur with a wide range of medications and may be the prelude to a more florid delirious state, but usually subside with withdrawal of the drug or dose reduction. Such symptoms are encountered most frequently with tricyclic agents, lithium, amphetamines, phenothiazines, barbiturates, glucocorticoids, cholinergic drugs, levodopa, antihistamines, and acetylcholinesterase inhibitors, as well as some anticonvulsants. Similar symptoms may also occur following withdrawal of certain medications such as benzodiazepines and SSRIs.

Delirium and Confusional States

Drugs are an important cause of delirium and confusional states, particularly in the elderly. Various drugs may cause such reactions, including sedatives, tranquilizers, hypnotics, narcotics, antihistamines, and anticholinergics. Other important causes include antiparkinsonian drugs and antidepressants, in particular the SSRIs and SNRIs, which have been associated with the serotonin syndrome (discussed later), as well as interactions between serotonergic drugs and monoamine oxidase inhibitors or tricyclic agents and other drugs. Abrupt withdrawal of SSRI drugs may also precipitate a confusional or delirious state with associated twitching, hypertonia, and sensory symptoms. Less frequent causes of drug-induced delirium include cephalosporin and macrolide and fluoroquinolone antibiotics. Delirious states with associated motor hyperactivity have also been reported frequently with the influenza antiviral agent oseltamivir.

Mood Disorders

Drug-induced depressive reactions are common. Reserpine and α-methyldopa were among the first drugs recognized to cause depression, but depression is uncommon with the newer generations of antihypertensive agents. Mood disturbance with manic features is the most common psychiatric side effect of corticosteroids, and depression is the most common psychiatric symptom in patients taking levodopa. Depression may also occur in patients on a variety of other medications, including oral contraceptives, anabolic steroids, tetrabenazine, digoxin, indomethacin, naproxen, disulfiram, sulfonamides, cycloserine, retinoids, antineoplastics, antiepileptics, baclofen, barbiturates, benzodiazepines, phenothiazines, butyrophenones, and interferons. It may also follow benzodiazepine, amphetamine, or fenfluramine withdrawal.

Although euphoria is a common drug-induced side effect, manic or hypomanic reactions are uncommon. Such reactions may however occur with a variety of drugs including glucocorticoids, corticotropin, anabolic steroids, thyroxine, captopril, chloroquine, isoniazid, ranitidine and cimetidine, dopaminergic agents, baclofen, opiates, pentazocine, monoamine oxidase inhibitors, tricyclic agents, iproniazid, cyclosporine, sympathomimetic amines, amphetamines, benzodiazepines, procyclidine, phenylpropanolamine, and hallucinogens. Antidepressants may also induce mania, especially in individuals with bipolar disorder. Increased risk of a manic episode has been reported with tricyclic antidepressants and monoamine oxidase inhibitors, but not with standard doses of SSRIs.

Psychoses

Various drugs have been reported to cause paranoid or schizophreniform psychotic reactions characterized by delusions, hallucinations, and emotional and thought disorder, particularly in the elderly. Although these drug-induced disorders closely resemble the naturally occurring psychoses, such individuals do not appear predisposed to develop a psychotic disorder subsequently.

Hallucinatory States

Various drugs can cause hallucinations without other features of delirium or psychosis. The hallucinations usually tend to be visual, extremely vivid and colored, and often of animals, sometimes having microptic or Lilliputian dimensions. The most common causative drugs are tricyclic agents, benzodiazepines, vigabatrin, bromides, methylphenidate, atropine and other anticholinergic drugs after parenteral or even topical administration into the eye, ephedrine, amantadine, bromocriptine, pergolide, levodopa, digoxin, diltiazem, prazosin, captopril, disopyramide, pentazocine, buprenorphine, indomethacin, salicylates, cimetidine, aminophylline, acyclovir, and cyproheptadine, as well as cannabis and LSD. Auditory and less often visual hallucinations are also a feature of withdrawal from alcohol, barbiturates, benzodiazepines, and baclofen.

Cognitive Impairment

Various drugs may cause transient memory impairment, including baclofen, pregabalin, benzhexol, isoniazid, propranolol, antidepressants (SSRIs and tricyclics), and statins. More severe, but reversible, cognitive impairment, which may mimic dementia, can also develop with chronic intake of benzodiazepines, barbiturates, bromides, and chlorpromazine, with anticonvulsant overdosage, and with glucocorticoid and interleukin administration. These medications may also aggravate cognitive functions in patients who already have mild cognitive impairment and should therefore be administered with caution.

A number of antiepileptic drugs may adversely affect cognitive functions. Early studies suggested that such effects were less frequent with carbamazepine or sodium valproate than with phenytoin or phenobarbital. However, more recent studies have shown that, at therapeutic serum concentrations, the adverse effects are comparable for these drugs. The newer antiepileptics gabapentin, lamotrigine, vigabatrin, tiagabine, remacemide, topiramate, and levetiracetam have fewer cognitive effects.

Several lines of evidence, including pretrial safety and tolerability testing, postmarketing surveillance, and multiple case reports have linked statins to short-term reversible cognitive impairment, particularly in relation to short-term memory. However, this was not confirmed in a systematic review and meta-analysis of randomized controlled trials.[7] In spite of this, it does appear that memory impairment can occur in a small proportion of people taking statins and that the risk may be greater in individuals on the more potent lipophilic statins, atorvastatin and simvastatin. Further prospective studies are required to determine whether certain subpopulations of statin users are at greater risk and to identify other patient-specific factors that may allow such individuals to be identified.[7]

MOVEMENT DISORDERS

Several drugs, in particular dopamine-receptor blocking antipsychotics and antiemetics, may induce involuntary movements or abnormalities of movement, posture, or gait that may resemble naturally occurring extrapyramidal disorders.[8] These same drugs may also aggravate pre-existing extrapyramidal disorders such as Parkinson disease and should therefore be used with caution in such patients. There is marked individual variability in the susceptibility to these reactions, some patients developing side effects even with small doses of a drug, whereas others on much higher doses are unaffected. Sex, age, and genetic factors may all play a part in determining individual susceptibility.

Akathisia

Akathisia is a state of motor restlessness characterized by an uncontrollable urge to move about, pace, or even run incessantly. The condition typically occurs in patients taking dopamine-blocking agents such as phenothiazine derivatives and less frequently with butyrophenones, benzodiazepines, tricyclic agents, SSRIs, levodopa, lithium, monoamine oxidase inhibitors, and vigabatrin. The reported incidence of akathisia with antipsychotic drugs ranges from 20 to 75 percent and is less frequent with the atypical antipsychotics. It usually remits within days or weeks of withdrawal of the neuroleptic drug, but may persist for several months and is occasionally permanent.

The most effective treatment for akathisia is to withdraw or lower the dose of the causative drug. Benztropine or diphenhydramine is usually effective in controlling akathisia when given intramuscularly or intravenously, and propranolol, clonazepam, and amantadine may also be beneficial.

Acute Dystonic-Dyskinetic Reactions

Acute dystonic reactions are a well-recognized side effect of antipsychotic or antiemetic drugs, in particular the phenothiazines (fluphenazine, prochlorperazine) and butyrophenones (haloperidol), metoclopamide, and, less frequently, promethazine, tricyclic antidepressants and SSRIs, phenytoin, carbamazepine, propranolol, ondansetron, flunarizine, and cinnarizine. The onset is usually within the first few days of starting treatment, but can be almost immediate, and may be quite abrupt. The dystonia may be confined to the head and neck, causing facial grimacing, jaw spasms and trismus, abnormal tongue movements, blepharospasm, oculogyric crises, orofacial dyskinesias, and torticollis or retrocollis. In some cases the dystonia is more generalized, with slow writhing movements or prolonged tonic spasms of the limb and axial muscles resulting in carpopedal spasm, opisthotonos, lordosis, tortipelvis, and a bizarre gait. Rarely laryngospasm may occur. Because of their bizarre and protean nature, the movements can be mistaken for hysteria. The differential diagnosis also includes hyperventilation, tetany, tetanus, strychnine poisoning, and epilepsy. Despite their dramatic and at times alarming nature, the acute dystonic reactions are self-limiting and will usually remit once the drug is withdrawn. Severe reactions can be terminated by intravenous or intramuscular benztropine or promethazine, or intravenous diazepam.

Tardive Dyskinesia and Other Tardive Syndromes

Tardive dyskinesia and other tardive syndromes may occur in patients treated with a variety of dopamine antagonists.[8] They are most commonly seen in patients with schizophrenia or schizoaffective or bipolar disorder treated with antipsychotic medications for long periods, but may also occur with prolonged administration of metoclopramide, chlorpromazine, thioridazine, promethazine, prochlorperazine, amoxapine, perphenazine, trifluoperazine, flunarizine, cinnarizine, and antidepressants. Early studies found tardive dyskinesia in up to 50 percent of patients treated with the older antipsychotic drugs, but the frequency has declined since the introduction of the second- and third-generation antipsychotics. Tardive dyskinesia usually develops after more than 12 months of continuous therapy, although it has been reported with periods as short as 3 months. It may present after cessation of therapy. The condition is more common and is often more severe in the elderly, in whom it is less likely to remit.

The dyskinesia typically takes the form of an orobuccal dyskinesia with lip smacking and pursing; sucking; jaw opening and closing; protruding, side-to-side, or writhing movements of the tongue; and facial grimacing. The movements tend to be stereotyped and may interfere with speaking and swallowing. In some cases more generalized choreoathetotic movements of the limbs and trunk and repetitive foot-tapping movements are present, at times resembling Huntington chorea. Less frequently, dystonic posturing of the neck and myoclonic jerking of the distal extremities are present as well. Akathisia or parkinsonism may also occur.

Tardive dystonia is less common and tends to occur in younger individuals, particularly men. It is distinguished from tardive dyskinesia by the more sustained abnormal movements and postures, which may be focal or more generalized and may involve the jaw, neck, limbs, or trunk. Tardive dystonia is often more disabling than tardive dyskinesia. Other tardive syndromes include akathisia, chorea, myoclonus, tremor, tics, and oculogyric crises.

The severity of tardive dyskinesia is variable and it may remit in up to 40 percent of cases, even on continued therapy. Occasionally remission may occur even several years after withdrawal of antipsychotic medications. Interruption of therapy when dyskinesia first develops may be beneficial, but there is some evidence that repeated interruptions may actually increase the risk of persistence.

The treatment of tardive dyskinesia is problematic.[8] Many medications have been used in the past, including dopaminergic agents (tetrabenazine, bromocriptine, and levodopa) and drugs with a cholinergic action, such as choline and deanol. Other drugs reported to be beneficial include amantadine, clonazepam, baclofen, propranolol, diazepam, tocopherol, *Ginkgo biloba*, levetiracetam, and calcium-channel blockers. None has been consistently effective. More recently, the VMAT2 inhibitors deutetrabenazine and valbenazine have become established as evidence-based therapies for tardive syndromes.[8]

In cases of focal or segmental tardive dystonia or orobuccal dyskinesia, botulinum toxin injections may be effective. Deep brain stimulation may need to be considered in medically refractory cases.

Levodopa-Induced Dyskinesias

Choreoathetotic dyskinetic reactions involving the face, tongue, limbs, and trunk are common in patients with Parkinson disease treated with levodopa and other dopaminergic agents, developing in about 50 percent of patients after 4 to 5 years of treatment, usually starting on the side of the body that is more affected by the disease. Levodopa-induced dyskinesias are thought to be due to nonphysiologic phasic stimulation of dopamine receptors in the striatum and are dose-dependent.[9] In some patients they develop early during treatment with levodopa or dopamine agonists and usually respond to a reduction in drug dose. With prolonged treatment, dyskinesias become an increasing problem, tending to occur at times of peak response to levodopa (peak-dose dyskinesia) but sometimes occurring as blood levels decline (biphasic dyskinesia) and alternating with periods of akinesia and severe rigidity (the so-called on–off phenomenon). The administration of smaller, more frequent doses of levodopa, or a reduction in overall dose and the introduction of a dopamine agonist is often helpful in alleviating this common complication of prolonged levodopa therapy. Other medications that can be beneficial include amantadine and leviracetam, and a number of novel pharmacologic approaches are under development.[9] However, severe and disabling dyskinesias are usually an indication for deep brain stimulation.

Chorea and Choreoathetosis

A number of drugs may cause chorea, which is characterized by multifocal, nonstereotyped, "fidgety" or jerky movements and may co-exist with the slower movements of athetosis or with dystonia. Chorea or choreoathetosis has been reported with many drugs

including anticonvulsants in high doses (e.g., phenytoin, ethosuximide, valproic acid, carbamazepine, phenobarbital), clonazepam withdrawal, anticholinergic drugs (e.g., high doses of benzhexol), tricyclic agents, fluoxetine, amphetamines, methylphenidate, amoxapine, pemoline, cimetidine, theophylline, aminophylline, lithium, methadone, antihistamines, cyclosporine, oxymetholone, intrathecal baclofen, and certain oral contraceptives. Chorea has also been well described with cocaine use ("crack dancing").

Tics

A condition resembling Gilles de la Tourette syndrome has been reported in children after the administration of dextroamphetamine, methylphenidate, or pemoline. Other antipsychotic drugs as well as opiates, clonazepam, carbamazepine, phenobarbital, and fluoxetine have also been reported to cause tics.

Myoclonus

Drug-induced myoclonus may occur particularly in patients treated with antipsychotic and tricyclic antidepressant drugs or lithium carbonate and has also been reported with a variety of other drugs including propofol, clozapine, vigabatrin, phenytoin, fluvoxamine, chlorambucil, opioids, antibiotics (e.g., penicillin, ticarcillin, carbenicillin, imipenem, cephalosporins), and calcium-channel blockers. Reversible multifocal myoclonus may also occur with gabapentin or pregabalin treatment, particularly in patients with renal insufficiency. A clinical picture resembling Creutzfeldt–Jakob disease with myoclonus, tremor, cerebellar and extrapyramidal manifestations, cognitive impairment, and periodic sharp-wave EEG complexes has been reported in patients with lithium toxicity.

Tremor

Many drugs may cause or aggravate tremor. These include β_2-adrenergic agonists (e.g., salbutamol, salmeterol); sympathomimetic drugs (e.g., ephedrine, pseudoephedrine, phenylpropanolamine); antiseizure agents (e.g., sodium valproate); antidepressants and mood stabilizers (e.g., tricyclic drugs, SSRIs, lithium); neuroleptic agents (e.g., phenothiazines, butyrophenones); antiarrhythmics (amiodarone, procainamide, mexiletine); chemotherapeutic agents (e.g., doxorubicin, cytarabine, thalidomide); and some immunosuppressants (e.g., cyclosporine, tacrolimus), as well as thyroxine, glucocorticoids, hypoglycemic agents, levodopa, amphetamines, theophylline, and aminophylline.

A postural tremor of the hands, head, and trunk resembling essential tremor is not uncommon in patients treated with sodium valproate. This usually develops over a period of several months and remits when the drug is stopped or the dose is reduced. Treatment with propranolol or amantadine may alleviate the tremor. Postural or action tremor is also an early manifestation of lithium intoxication and is common even with therapeutic doses. A postural tremor has been reported in up to 40 percent of patients on cyclosporine.

A "flapping" tremor (asterixis) may occur in patients treated with various drugs including phenytoin, phenobarbital, carbamazepine, sodium valproate, methyldopa, ceftazidime, lithium, and tocainide.

Parkinsonism

Drug-induced parkinsonism is probably the most common drug-induced movement disorder. It can occur at any age, but is more common in the elderly. Although it may closely resemble idiopathic Parkinson disease, early differentiation is important in view of the markedly different prognosis in the two conditions.[8,10] Bradykinesis is usually the most prominent clinical feature, with associated facial masking, rigidity, tremor, and altered gait. Unlike idiopathic Parkinson disease, the symptoms are usually, but not always, bilateral from the outset, and the incidence of tremor is lower.

The drugs most commonly implicated are neuroleptics and antipsychotic medications with central dopamine-blocking actions, including phenothiazines (e.g., chlorpromazine, fluphenazine, cyamemazine), butyrophenones (e.g., haloperidol, droperidol), benzamides (e.g., sulpiride, amisulpride, tiapride), and other atypical antipsychotics (e.g., clozapine, olanzapine, risperidone, quetiapine). Other drugs that have been implicated include antidepressants (SSRIs and tricyclics); calcium-channel blockers (flunarizine, cinnarizine); antiemetics (metoclopramide, prochlorperazine); and anticonvulsants (valproic acid, phenytoin) (Table 32-2). These drugs may also aggravate the symptoms of early idiopathic Parkinson disease or lead to the development of signs in the premotor or prodromal stages of the disease.

Drug-induced parkinsonism is usually reversible, with most patients improving gradually following drug

TABLE 32-2 ■ Major Causes of Drug-Induced Parkinsonism[8,10]

Antipsychotics (typical)	Haloperidol, droperidol, chlorpromazine, fluphenazine, cyamemazine, loxapine, pimozide, flupenthixol, zuclopenthixol
Antipsychotics (atypical)	Amisulpride, sulpiride, tiapride, clozapine, olanzapine, quetiapine, risperidone, aripiprazole, ziprapisone
Antidepressants	Citalopram, paroxetine, fluoxetine, fluvoxamine, escitalopram, sertraline, venlafaxine, mirtazapine, amitriptyline, clomipramine, phenelzine
Calcium-Channel Blockers	Flunarizine, cinnarizine, verapamil, diltiazem
Antiemetics	Prochlorperazine, metoclopramide, domperidone
Miscellaneous	Lithium, tetrabenazine, valproic acid, donepezil, pyridostigmine, amiodarone, captopril, cyclosporine, tacrolimus, rifampicin, acyclovir, vincristine, trimetazidine, H_1-antihistamines, meprobamate, reserpine

withdrawal or dose reduction. In some cases, spontaneous improvement occurs even if the causative medication is continued. However, tremor may persist after drug withdrawal and sometimes there is continued deterioration in motor signs, suggesting that the medication may have unmasked the symptoms of idiopathic Parkinson disease. Administration of an anticholinergic agent, such as benzhexol or benztropine, may reduce or reverse the parkinsonian symptoms, but dopaminergic medication may be required in some cases. In patients who need to continue on neuroleptic therapy, switching to a lower risk medication such as quetiapine or clozapine is usually recommended.

CEREBELLAR SYNDROMES

Various drugs may cause ataxia, incoordination, and other manifestations of cerebellar dysfunction. These drugs include sedatives and tranquilizers such as barbiturates, benzodiazepines, chloral hydrate, and paraldehyde, as well as anticonvulsants such as phenytoin, carbamazepine, and primidone whose effects are usually dose dependent. Individual tolerance to these drugs varies considerably, but in general symptoms are more likely to develop with higher doses, and if dose escalation is too rapid, although with pregabalin and gabapentin symptoms may develop even at relatively low doses. Signs of cerebellar dysfunction are caused more rarely by phenothiazines, monoamine oxidase inhibitors, reserpine, thioxanthenes, and lithium. Lithium may cause an isolated cerebellar ataxia or more diffuse encephalopathy, even with blood levels within the therapeutic range. A cerebellar syndrome has also been reported in bone marrow and liver transplant recipients treated with cyclosporine; in patients with leukemia or lymphoma on high doses of cytarabine; in cancer patients treated with high- or low-dose fluorouracil; and in patients with impaired renal function taking nitrofurantoin or perhexiline.

These disorders are usually reversible when the causative agent is withdrawn or the dose is adjusted, but there are reports of permanent cerebellar dysfunction and cerebellar atrophy in some patients treated with lithium or phenytoin.

NEUROLEPTIC MALIGNANT SYNDROME

The neuroleptic malignant syndrome is a serious and potentially lethal complication of treatment with antipsychotic and antiemetic medications that reduce dopaminergic transmission. It is characterized clinically by hyperpyrexia, severe generalized muscular rigidity, and an elevated serum creatine kinase (CK) level (which are considered major diagnostic criteria); tachycardia, abnormal blood pressure, tachypnea (autonomic manifestations); and altered consciousness, diaphoresis, and leukocytosis (which are the minor diagnostic criteria). Three major criteria, or two major and four minor criteria are considered very suggestive of the diagnosis in the right clinical context. Other less frequent motor abnormalities include tremor, myoclonus, dystonia, opisthotonos, trismus, and chorea.

The drugs most frequently implicated are haloperidol, fluphenazine and other phenothiazines, thioxanthenes, or combinations of these drugs with each other or with lithium, metoclopramide, loxapine, or tricyclic agents. Clozapine and olanzapine have also been implicated. Risk factors include high drug doses, rapid dose increases, parenteral administration, and switching from one potentially causative drug to another. The condition may occur with both high and low doses of either high- or low-potency neuroleptics and may develop after neuroleptic therapy is begun, after an increase in dose, or after the introduction of a second more potent drug. The current view is that neuroleptic malignant syndrome is due to profound dopamine receptor blockade in the striatum and in thermoregulatory and vasomotor centers in the hypothalamus.

In mild cases, complete recovery may occur within days or weeks of stopping the causative drug, but in severe cases rhabdomyolysis, myoglobinuria, metabolic acidosis, renal failure, coagulation defects, respiratory failure, shock, seizures, and coma may develop and there is a mortality rate of approximately 6 percent even in the modern era.[11] Treatment involves discontinuation of the causative drug together with rapid cooling, control of agitation with parenteral benzodiazepines, restoration of fluid and electrolyte balance, and management of any other complications. Specific medications that are beneficial in reversing rigidity and hyperthermia and hastening recovery include dantrolene, bromocriptine, amantadine, levodopa, or a combination of these drugs.

A disorder resembling neuroleptic malignant syndrome may also occur after abrupt levodopa or dopamine agonist withdrawal in patients with Parkinson disease, and after withdrawal of intrathecal baclofen.

SEROTONIN SYNDROME

The serotonin syndrome is a closely related disorder that sometimes is difficult to distinguish from neuroleptic malignant syndrome and which can also be life-threatening in severe cases. It can occur after initiation, increase in dose, or overdose of one of the SSRI or SNRI antidepressants, or with combination therapy. Other drugs that have been implicated less frequently include other classes of antidepressants such as tricyclics, monoamine oxidase inhibitors, and bupropion; opioids, triptans, lithium, antinausea medications, and dextromethorphan-containing cough suppressants; as well as some herbal supplements (e.g., St John's wort and ginseng) and recreational drugs (e.g., LSD, ecstasy, cocaine, and amphetamines).

The features of the serotonin syndrome include high fever, tachycardia, labile blood pressure and autonomic instability, confusion, agitation, tremor, myoclonus, shivering, seizures, piloerection, hyperreflexia, and incoordination. Muscular rigidity and hyperthermia tend to be less severe than in the neuroleptic malignant syndrome; some of the other typical features, such as prodromal nausea, vomiting, and diarrhea, and shivering, hyperreflexia, myoclonus, and ataxia are uncommon in neuroleptic malignant syndrome.

Cessation of the causative drug is critical if the diagnosis is suspected. Although mild cases may recover rapidly within a few days, patients with suspected serotonin syndrome should be hospitalized for observation and treatment. Key aspects of management include maintenance of hydration with intravenous fluids, sedation and control of seizures with benzodiazepines, and administration of cyproheptadine to block serotonin production.

OTOTOXICITY

More than 150 drugs are known to have ototoxic effects, causing cochlear or vestibular damage to the inner ear.[12] Tinnitus is usually the first symptom of cochleotoxicity and, when persistent, is the forerunner of impending hearing loss. Vestibulotoxicity results in vertigo, oscillopsia, and balance impairment, particularly in subdued light.

The most important ototoxic drugs are the aminoglycoside antibiotics, which may cause irreversible inner ear damage after parenteral, oral, or even topical administration. Since these agents are excreted through the kidneys, ototoxicity is more likely to develop in individuals with renal insufficiency. All the aminoglycosides can cause cochlear or vestibular toxicity. Some (e.g., neomycin, kanamycin, amikacin, and vancomycin) are principally cochleotoxic, whereas others (e.g., gentamicin and streptomycin) are preferentially vestibulotoxic, and tobramycin is both vestibulotoxic and cochleotoxic.

Vertical oscillation of the surroundings on movement ("bobbing oscillopsia") is highly characteristic of the vestibulopathy caused by the aminoglycoside antibiotics. Hearing loss affects the high frequencies initially and is usually irreversible. It may develop within a few days of commencing treatment, but more often is delayed and may even develop after the drug is stopped. As a group, the aminoglycosides cause degeneration of the sensory hair cells of the cochlea, the outer hair cells being most severely affected, accounting for the preferential loss of higher frequencies, whereas gentamycin selectively destroys the vestibular hair cells. It is essential to have a high level of awareness of this serious complication, to monitor blood levels of the drug, to avoid prolonged courses of gentamycin, and to discontinue the drug if early symptoms of vestibulotoxicity develop. However, some patients may still develop irreversible vestibulotoxicity even when blood levels are maintained within the recommended range, and the onset of symptoms may be delayed.

Other ototoxic antibiotics include minocycline (which is almost exclusively vestibulotoxic), colistin, polymyxin

B, erythromycin (which may cause reversible deafness after oral or intravenous administration), metronidazole, vancomycin, and rarely, procaine penicillin, cephalexin, and chloramphenicol.

The loop diuretics furosemide, ethacrynic acid, and bumetanide are also ototoxic, especially in patients with renal or hepatic impairment or those also taking an aminoglycoside antibiotic. Salicylates, in particular aspirin, may cause tinnitus, deafness, and vertigo when the serum concentration approaches 300 mg/L. Quinine may cause tinnitus and reversible low-tone hearing loss in a small proportion of patients taking the drug and an idiosyncratic mechanism seems to be involved. Prolonged high-dose administration of chloroquine may cause irreversible tinnitus and perceptive deafness. A number of cytotoxic drugs including cisplatin, vincristine, misonidazole, bleomycin, and mustine hydrochloride may cause hearing loss. Cisplatin causes a high incidence of tinnitus and high-tone hearing loss; recording of brainstem auditory evoked potentials is helpful in detecting early involvement of the auditory pathway.

Other ototoxic drugs include quinidine, deferoxamine, and sildenafil. Practolol caused combined sensorineural deafness and conductive hearing loss due to serous otitis media when it was in use. There are also rare reports of hearing loss or vestibular dysfunction in patients taking propoxyphene, naproxen, indomethacin, sulindac, metoprolol, nortriptyline, propylthiouracil, flecainide, and both interferon-alpha and beta.

VISUAL DISORDERS

Drug-induced visual disorders may result from effects on the pupil, refractive mechanisms, retina, optic nerve, and central visual pathways.

Pupillary Changes

Parasympathomimetic drugs such as carbachol and neostigmine cause miosis, as may morphine, chloral hydrate, and phenothiazines. Mydriasis is more often drug-induced and potentially more serious as it may precipitate acute angle-closure glaucoma in susceptible individuals. Drugs that may cause mydriasis and cycloplegia with blurring of near vision include anticholinergics, antihistamines, monoamine oxidase inhibitors, tricyclic antidepressants, chlorpropamide, indomethacin, hexamethonium, fenfluramine, oral contraceptives, amphetamines, and LSD.

Refractive Changes

In addition to the drugs mentioned earlier that may cause cycloplegia and induced hypermetropia, certain drugs cause a transient myopia as a result of fluid shifts between the lens and the aqueous humor. These include oral diuretics (chlorothiazide, hydrochlorothiazide, chlorthalidone, and acetazolamide), tetracyclines, sulfonamides, corticosteroids and corticotropin, stilbestrol, phenytoin, thiamine, bromocriptine, and arsenicals, as well as insulin and oral hypoglycemic agents.

Retinopathy

Chloroquine, hydroxychloroquine, mepacrine, and amodiaquine may cause a pigmentary maculopathy and retinopathy with central and peripheral field defects and impairment of central vision after prolonged administration. Patients on these drugs should have regular neuro-ophthalmic examinations, electroretinography, and electro-oculography to detect early signs of retinopathy. Phenothiazines in high doses may produce a progressive choroidoretinopathy; cardiac glycosides, methylphenidate, and cephaloridine have also been reported to cause pigmentary retinopathy. Macular edema has been reported with fingolimod, a new oral therapeutic agent for multiple sclerosis, and normally resolves on cessation of treatment. It may rarely also be caused by chlorothiazide, acetazolamide, and oral contraceptives.

Other drugs that may interfere with vision through retinal effects include indomethacin, quinine, tamoxifen, ethambutol, diethylcarbamazine, and vigabatrin, which has been found to cause symptomatic, or more often asymptomatic, visual field constriction.

Optic Neuropathy

A number of antimicrobial agents including linezolid, chloramphenicol, isoniazid, paraminosalicylate, streptomycin, ethambutol, sulfonamides, griseofulvin, and dapsone can cause a toxic optic neuropathy. Other drugs implicated in causing optic neuropathy include amiodarone, chlorpropamide, chlorambucil, cisplatin, 5-fluorouracil, vincristine, interferon-alpha, penicillamine, disulfiram, nonsteroidal anti-inflammatories, monoamine oxidase inhibitors, morphine, retinoids, organic arsenicals, cardiac glycosides, dideoxyinosine, omeprazole.

Certain drugs, such as sildenafil (Viagra) and tadalafil (Cialis) used for erectile dysfunction, and ergotamine may all precipitate an acute ischemic optic neuropathy, particularly in individuals with a high arteriosclerotic risk profile.

There have also been case reports of the tissue necrosis factor alpha (TNF-α) inhibitors infliximab, adalimumab, and etanercept causing optic neuritis, with enhancement of the optic nerve on MRI in some cases; some patients have associated cerebral demyelinating lesions.

In the past, optic neuropathy and optic atrophy were also part of the subacute myelo-opticoneuropathy (SMON) syndrome associated with the antifungal/antiprotozoal drug clioquinol, when it was used for the treatment of enteric infections.

Disorders of Color Vision

Disturbances of color vision may result from the effects of various drugs on retinal cone receptors or from optic nerve dysfunction. Xanthopsia (yellow vision) may occur with sulfonamides, streptomycin, methaqualone, barbiturates, digitalis derivatives, thiazide diuretics, and the anthelmintic drug santonin. Sildenafil (Viagra) and tadalafin (Cialis) can cause blue vision, which is reversible. Other drugs that may cause altered color vision include nalidixic acid, oral contraceptives, cannabis, LSD, and the older anticonvulsants troxidone and paramethadione.

Cortical Blindness

Cortical blindness may rarely occur after episodes of severe hypotension during anesthesia or after treatment of hypertension. It has also been reported as a complication of chemotherapy during childhood and of excessive doses of salicylates or barbiturates. It may also occur as part of a posterior reversible encephalopathy syndrome in patients treated with cyclosporine (Fig. 32-1).[7]

Diplopia

Certain drugs commonly cause diplopia by leading to breakdown of a latent squint. These include benzodiazepines, tricyclic antidepressants, anticonvulsants, indomethacin, quinine, methaqualone, and fenfluramine. Rarely, diplopia may be due to an extraocular muscle palsy, gaze palsy, or internuclear ophthalmoplegia.

Nystagmus

Drug-induced nystagmus is common in hospital practice. Horizontal vestibular nystagmus may be seen in patients taking high doses of barbiturates, benzodiazepines, anticonvulsants, or other sedative and hypnotic drugs. It is a useful early sign of toxicity in patients on anticonvulsant therapy and may occur even with therapeutic doses of some of these drugs. Other drugs reported to cause nystagmus rarely include monoamine oxidase inhibitors, salicylates, gold, neostigmine, chlordiazepoxide, fenfluramine, and amitriptyline, as well as the ototoxic antibiotics and a number of other medications. Downbeat nystagmus may also be drug-induced and has been associated with administration of lithium, amiodarone, and lamotrigine, and with phenytoin toxicity.

DISORDERS OF TASTE AND SMELL

Drug-induced disorders of taste and smell are common. Many drugs cause metallic, bitter, or salty taste sensations (phantogeusia) or other distortions of taste. These include biguanides, ethambutol, vitamin D, gold, allopurinol, penicillin, metronidazole, tinidazole, lincomycin, clindamycin, terbinafine, aspirin, and phenindione. A number of other drugs may also cause a reduction or loss in taste, the perception of sweetness being most often affected, including D-penicillamine (which causes marked hypogeusia in up to 30% of patients, corrected by the administration of copper), levodopa, captopril, enalapril, etidronate, oxyfedrine, methimazole, carbimazole, thiouracil, phenylbutazone, amphotericin B, griseofulvin, terbinafine, azathioprine, salazosulfapyridine, chlormezanone, carbamazepine, and baclofen.

Distortion or loss of the sense of smell (anosmia) has been associated with many different drugs including amoxicillin/clavulanic acid, doxycycline, erythromycin, captopril, intranasal steroids, and others. In most cases the sense of taste or smell recovers with the passage of time, but in some instances the impairment is irreversible. For most of the drugs just mentioned, disturbances of taste and smell will be listed as potential adverse effects in the product information, but this will not necessarily be the case with more recently introduced therapeutic products.

SPINAL DISORDERS

An acute ischemic myelopathy can occur in heroin addicts due to vasculitis and has also been reported following accidental injection of penicillin into the superior gluteal artery. Acute cord compression may result from hemorrhage into the extradural space in patients on anticoagulants. Spinal cord compression has also been reported as a result of hyperplastic extradural adipose tissue in patients on prolonged corticosteroid therapy.

A syndrome of myeloneuropathy with sensory loss in the hands and feet, Lhermitte sign, leg weakness, spasticity, ataxia, and sphincter disturbances can occur as a result of prolonged occupational or recreational exposure to nitrous oxide, particularly in the dental profession. The condition resembles subacute combined degeneration of the spinal cord and is thought to be due to the inhibitory effects of nitrous oxide on vitamin B_{12} utilization. Recovery usually occurs after exposure to nitrous oxide is discontinued and treatment is provided with vitamin B_{12} and folate supplements. A posterior column myelopathy may also occur following intrathecal administration of methotrexate.

Spinal anesthesia can be followed by headache, nausea, vomiting, and transient neurologic symptoms such as urinary retention and pain or sensory symptoms in the lower limbs. More serious complications such as radiculopathy or cauda equina syndrome due to damage to the spinal nerve roots, and epidural hematoma or abscess can also occur, but are rare.

Intrathecal injection of methylprednisolone (Depo-Medrol) can cause an acute meningeal reaction due to the polyethylene glycol detergent in the preparation, and may present with an acute cord syndrome. Other drugs that can be toxic when administered intrathecally include baclofen, lidocaine, morphine, chymopapain, methotrexate, cytarabine, and radiologic contrast agents. Epidural injections are not usually associated with such reactions unless there is inadvertent dural puncture.

AUTONOMIC DISORDERS

Postural Hypotension

Many drugs may cause postural hypotension, resulting in dizziness, falls, or syncope; focal cerebral ischemic events sometimes occur in patients with severe cerebrovascular disease. The drugs most frequently implicated are antihypertensives, vasodilators, diuretics, tricyclic antidepressants, and levodopa.

Bladder Dysfunction

Anticholinergic drugs may cause urinary retention by inhibiting parasympathetic postganglionic cholinergic neurons, particularly if there is bladder outflow obstruction due to prostatic hypertrophy. These drugs include atropine, hyoscine, propantheline, benzhexol, benztropine, methixene, orphenadrine, dicyclomine, and belladonna derivatives. Tricyclic antidepressants and phenothiazines may also precipitate acute urinary retention because of anticholinergic effects. Other drugs that may cause urinary retention include monoamine oxidase inhibitors, disopyramide, ephedrine, salbutamol, terbutaline, and theophylline.

A number of other drugs may also interfere with control of micturition and cause urinary incontinence. These include prazosin, metoprolol, benoxaprofen, depot phenothiazines, clonazepam, phenoxybenzamine, and methyldopa.

Sexual Dysfunction

Many drugs interfere with normal sexual function, causing loss of libido, impotence, impaired ejaculation, or orgasmic dysfunction. The most common are antihypertensives, tricyclic antidepressants, monoamine oxidase inhibitors, SSRIs, major tranquilizers, antihistamines, and anticholinergics, as well as baclofen, cimetidine, clofibrate, disopyramide, dopamine agonists, and levodopa.

PERIPHERAL NEUROPATHIES

Drug-induced neuropathies account for only a small proportion of cases of peripheral neuropathy, but their importance lies in the fact that they are potentially reversible if the causative agent is identified early and withdrawn before irreversible axonal damage occurs.

Various drugs may adversely affect peripheral nerve function and cause an axonal or demyelinating neuropathy (Table 32-3). The risk of drug-induced neuropathy is higher in individuals with diabetes mellitus, alcoholism, renal or hepatic insufficiency, or a preexisting neuropathy, or those treated with more than one neurotoxic drug ("synergistic neurotoxicity"). Some drugs principally affect sensory nerve function, causing paresthesias and sensory loss whereas others, such as dapsone and gold, cause a predominantly motor neuropathy with inconspicuous or absent sensory changes. Most drugs, however, produce a mixed sensorimotor neuropathy usually manifesting initially

TABLE 32-3 ■ Drugs Associated With Development of Peripheral Neuropathy

Antineoplastics	Vinca alkaloids: vincristine, vinblastine
	Taxanes: paclitaxel, docetaxel, cabazitaxel
	Platinum compounds: cisplatin, carboplatin, oxaliplatin,
	Epothilones: eribulin, ixabepilone
	Proteasome inhibitors: bortezomib, carfilzomib, ixazomib
	Others: cytarabine, thalidomide, misonidazole, podophyllin
Antimicrobials	Isoniazid, ethambutol, ethionamide, streptomycin, fluoroquinolones, chloramphenicol, dapsone, metronidazole, voriconazole, fluconazole, stibogluconate, suramin
Antirheumatics	Chloroquine, hydroxychloroquine, etanercept, infliximab, adalimumab, colchicine, D-penicillamine
Immune Therapies	Tacrolimus, leflunomide, interferon-alpha and beta, immune checkpoint inhibitors
Cardiovascular Drugs	Amiodarone, perhexiline, simvastatin, atorvastatin, disopyramide, hydralazine, flecainide, enalapril, captopril
Psychotropics/Sedatives	Phenelzine, lithium, tricyclics, perazine, glutethimide, methaqualone
Other Drugs	Levodopa, disulfiram, pyridoxine, dichloroacetate, phenytoin, streptokinase

with sensory symptoms, followed by motor symptoms later if the drug is continued. In addition to paraesthesias, myalgia and cramps are early symptoms in some cases. The tendon stretch reflexes are preserved in the early stages but are usually depressed or lost in more advanced cases.

Antineoplastic Drugs

Chemotherapy-induced peripheral neuropathy is an important complication of treatment particularly with the vinca alkaloids, platinum compounds, and taxanes, which cause dose-dependent (and dose-limiting) neurotoxicity.[13] Vincristine and other vinca alkaloids, which bind β-tubulin and prevent its polymerization into microtubules, are particularly neurotoxic. Most patients treated with these drugs for long enough will develop a sensorimotor polyneuropathy with early loss of tendon reflexes and sometimes autonomic symptoms. Muscle cramps may be prominent in the early stages, and some patients also develop a painful proximal myopathy. Recovery may occur if the drug is stopped or the dose is reduced, but mild sensory symptoms and areflexia often persist. In some patients treated with these drugs, symptoms of neuropathy may not develop until after the treatment is completed or may progress despite cessation of treatment, a phenomenon referred to as "coasting."

The platinum compounds are all potentially neurotoxic as well as ototoxic, and cause a painful sensory neuropathy with proprioceptive impairment and sensory ataxia. Cisplatin and carboplatin cause a dorsal root ganglion neuronopathy rather than a dying-back axonopathy. Oxaliplatin, which interferes with axonal ion conductance, causes transient sensory symptoms after intravenous administration, but a persisting neuropathy may develop after repeated infusions.

The taxanes (paclitaxel, docetaxel, and cabazitaxel), which lead to aggregation of microtubules, can cause a predominantly sensory or sensorimotor axonal neuropathy and principally affect large-diameter myelinated sensory and motor fibers. Coadministration of other neurotoxic drugs such as cisplatin further increases the risk of neuropathy. The recently introduced epothilone group of drugs, which also affect microtubules, may also cause peripheral neuropathy. Eribulin and ixabepilone, which are used to treat breast cancer, can both cause an axonal sensorimotor peripheral neuropathy.

The proteasome inhibitor bortezomib, which is used to treat multiple myeloma, presents with a painful length-dependent predominantly axonal sensory neuropathy in about 30 percent of patients, with an associated autonomic neuropathy in 10 to 15 percent of cases. The neuropathic effects of bortezomib can be reduced by subcutaneous administration and may be reversed with cessation of the drug or dose reduction. A small proportion of patients develop a severe polyradiculoneuropathy, which is thought to be immune mediated. The newer generation proteasome inhibitors, carfilzomib and ixazomib, appear to be less neurotoxic and have a lower incidence of neuropathy.

Long-term treatment with thalidomide, which is used for the treatment of myeloma, can cause a predominantly sensory peripheral neuropathy thought to be due to the antiangiogenic effects of the drug. Newer formulations of the drug, lenalidomide and pomalidomide, appear to be less neurotoxic.

Misonidazole and other compounds related to metronidazole are used as radiosensitizing agents in cancer therapy and may induce a sensory neuropathy. Podophyllin derivatives, which have been used to treat disseminated malignancy and are also constituents of certain laxative preparations and topical agents, may cause a peripheral neuropathy or myeloneuropathy. A severe demyelinating peripheral neuropathy has also been reported after high-dose cytarabine therapy in leukemia patients.

Antimicrobial Agents

Historically, the best-known examples of antimicrobial-induced neuropathy are the mixed sensorimotor neuropathy caused by isoniazid, which interferes with pyridoxine metabolism and can be prevented by coadministering vitamin B_6 supplements, and the sensory or sensorimotor neuropathy or optic neuropathy caused by ethambutol. Ethionamide and streptomycin can also rarely cause a peripheral neuropathy, but this is less frequent than the ototoxic effects of streptomycin. Peripheral neuropathy was a recognized complication of sulfonamide treatment in the past, but none of the drugs in current use have this effect. A sensorimotor or motor peripheral neuropathy is a well-documented complication of treatment with nitrofurantoin, especially in patients with renal insufficiency. There have been reports of a reversible neuropathy in patients on prolonged metronidazole therapy. The risk of peripheral neuropathy is increased with oral intake of fluoroquinolone antibiotics, particularly in elderly men, but not with amoxicillin-clavulanate.[14]

The triazole antifungal agents voriconazole and itraconazole have been reported to cause a sensorimotor neuropathy in conjunction with neurotoxic chemotherapy, and in the treatment of invasive aspergillosis and fluconazole-resistant *Candida* infections. This has also been described in leukemia patients not receiving neurotoxic chemotherapy.

Dapsone, used in the treatment of leprosy and certain dermatologic conditions, may cause a predominantly motor neuropathy after prolonged high-dose therapy. Suramin, when used to treat trypanosomiasis or onchocerciasis, may cause a dose-related axonal sensorimotor neuropathy with lamellar inclusions in dorsal root ganglia and Schwann cells, and may mimic the Guillain–Barré syndrome clinically. Sodium stibogluconate has also been associated with the development of peripheral neuropathy when used in the treatment of leishmaniasis.

Antirheumatic Drugs

Peripheral neuropathy is a well-recognized complication of gold therapy in rheumatoid arthritis. Motor involvement is usually prominent and sensory symptoms are inconspicuous. The onset may be abrupt and the progression rapid, and in some cases may mimic Guillain–Barré syndrome, particularly in patients who develop facial diplegia and elevated cerebrospinal fluid protein levels. A sensory or mixed neuropathy has also been reported in patients with rheumatoid arthritis treated with leflunomide.

Chloroquine may cause a mild sensorimotor neuropathy or more severe neuromyopathy. A neuropathy may occur rarely in patients treated with D-penicillamine, and Guillain–Barré syndrome has been reported to occur. A mixed sensorimotor neuropathy sometimes develops in patients treated with colchicine for long periods and is often associated with a proximal myopathy.

Several types of neuropathy have been described with the TNF-α inhibitors etanercept and infliximab, including Guillain–Barré syndrome, Miller Fisher syndrome, chronic inflammatory demyelinating neuropathy, multifocal motor neuropathy with conduction block, mononeuritis multiplex, and axonal sensory or sensorimotor polyneuropathy. The pathogenesis is thought to involve a T-cell and humoral immune attack against peripheral nerve myelin antigens, inhibition of axonal signaling functions, and vasculitis-induced ischemia. Adalimumab may also be associated with a peripheral neuropathy; multifocal motor neuropathy with conduction block and acute bilateral phrenic neuropathy have been reported.

Cardiovascular Drugs

A demyelinating sensorimotor polyneuropathy is well documented in patients treated with the antiarrhythmic agent amiodarone and in the past also occurred in patients treated with the coronary vasodilator perhexiline, which is no longer in clinical use. Streptokinase has been associated with the development of Guillain–Barré syndrome. Peripheral neuropathy has also been reported rarely with disopyramide, hydralazine, flecainide, enalapril, and captopril.

Cholesterol-Lowering Agents

Although peripheral neuropathy was not detected in the initial large statin trials, a number of subsequent reports have highlighted the development of various types of neuropathy in small numbers of patients treated with various statin drugs. Most are reports of an axonal sensorimotor polyneuropathy, but a definite causal association is not established. In Australia, the National Adverse Drug Reactions Advisory Committee received reports between 1993 and 2005 of 281 patients with peripheral neuropathy or symptoms consistent with a neuropathy that had been attributed to statins. Most of these were associated with simvastatin or atorvastatin and, less frequently, pravastatin and fluvastatin. Recovery occurred in about 50 percent of cases after stopping the drug, but symptoms persisted for months or even years in some cases. Population-based studies in the United Kingdom and Denmark found a greater risk of having peripheral neuropathy in patients taking statins than in controls. However, the confounding effects of glucose intolerance and hyperlipidemia could not be excluded in these studies, and in the Fremantle Diabetes Study of nearly 1,300 patients the risk of neuropathy was actually lower in diabetics treated with statins and fibrates.[15]

Hypnotic and Psychotropic Drugs

There have been occasional reports of neuropathy developing in patients taking phenelzine, methaqualone, glutethimide, imipramine, amitriptyline, lithium carbonate, and perazine.

Levodopa

There is increasing awareness of the development of peripheral neuropathy in patients with Parkinson disease treated with levodopa, with up to 30 percent of patients on oral levodopa being affected and 42 percent of patients on levodopa/carbidopa intestinal gel infusion therapy.[16] In patients on oral therapy the neuropathy is usually a slowly progressive small-fiber neuropathy, whereas in patients on gel infusion therapy it can be more acute or subacute.

Other Drugs

Various other drugs have occasionally been implicated in causing a neuropathy. A mild peripheral neuropathy can occur in patients on long-term treatment with phenytoin but is rarely symptomatic. Disulfiram, used in the treatment of alcoholism, may cause an axonal sensorimotor polyneuropathy, as well as an optic neuropathy.

There have been a number of reports of axonal polyneuropathy and trigeminal neuropathy developing in patients with hepatitis C treated with interferon-alpha; more recently, cases of Guillain–Barré syndrome have been reported with pegylated interferon-alpha, which is now more commonly used for the treatment of hepatitis C infection.

A number of older drugs including streptokinase, D-penicillamine, captopril, danazol, zimeldine, and gangliosides have been associated with the development of Guillain–Barré syndrome. A demyelinating neuropathy with features of chronic inflammatory demyelinating polyneuropathy has occurred in patients treated with tacrolimus and interferon-alpha. Peripheral neuropathy has also been reported in a number of patients with multiple sclerosis treated with interferon-beta.

Chronic intake of high doses of pyridoxine as a dietary supplement may cause a severe sensory polyneuropathy, and paresthesias may develop even in some patients taking conventional doses of this vitamin. Dichloroacetate may bring on or worsen peripheral neuropathy in patients with the syndrome of mitochondrial myopathy, lactic acidosis, and stroke-like episodes (MELAS).

NEUROMUSCULAR TRANSMISSION DISORDERS

Various drugs can interfere with neuromuscular transmission by causing a postsynaptic block or through a presynaptic effect on transmitter release, as occurs with botulinum toxin (Table 32-4). The most common clinical manifestation is the postoperative respiratory depression that occurs in patients being treated with aminoglycoside antibiotics or other drugs that can potentiate the effects of muscle relaxants used during anesthesia.

Many of the drugs listed in Table 32-4 can also unmask or aggravate a pre-existing myasthenic disorder by reducing the safety factor for neuromuscular transmission, and should therefore be avoided or used with caution in myasthenic patients. In particular, all antibiotics should be used with caution in myasthenic patients. Based on current recommendations, fluoroquinolones (ciprofloxacin and norfloxacin), macrolides (azithromycin and erythromycin), ketolides (especially telithromycin), aminoglycosides, and polymyxins are regarded as having the highest risk of aggravating myasthenia

TABLE 32-4 ■ Drugs that May Interfere With Neuromuscular Transmission

Antibiotics

Aminoglycosides
Polymyxins
Fluoroquinolones
Macrolides
Ketolides
Ampicillin
Imipenem
Clindamycin
Lincomycin

Anesthetic Agents

Muscle relaxants
Diazepam
Ketamine
Propanidid

Other Drugs

Botulinum toxin
Cholinesterase Inhibitors
Anticholinergics
Quinine
Thyroxine
Diuretics
Oxytocin
Carnitine
Deferoxamine
Ritonavir
Magnesium salts

and should all be avoided, whereas cephalosporins and penicillins, with the exception of ampicillin, are generally considered to be safe. Sulfonamides, clindamycin, lincomycin, imipenem, and voriconazole may also interfere with neuromuscular transmission and aggravate the symptoms of myasthenia.

Deterioration of myasthenia, and rarely even myasthenic crisis, may occur following therapeutic botulinum toxin injections, particularly when high cumulative doses are administered. Other drugs that should be used with caution in myasthenic patients include β-blockers, procainamide, quinine, quinidine, anticonvulsants, lithium, lidocaine and other local anesthetics administered intravenously, phenothiazines, anticholinergics, diuretics, and thyroxine. Statins have been implicated in the development of or aggravation of autoimmune myasthenia gravis in small case series and case reports, but a definite causal relationship has yet to be established. Although glucocorticoids are commonly used in the treatment of myasthenia, at high doses they may cause a significant exacerbation of symptoms when first commenced and such patients should therefore be kept under close observation when treatment is initiated.

Autoimmune myasthenia may develop in patients treated with α-interferon or on long-term treatment with D-penicillamine or thiopropine. These patients usually have acetylcholine receptor (AChR) antibodies in the serum, and rarely muscle-specific kinase (MUSK) antibodies. Since the introduction of cancer immunotherapy and the use of PD-1 immune checkpoint inhibitors there have also been increasing reports of the development of myasthenia, as well as other autoimmune disorders, in cancer patients treated with pembrolizumab, novolumab, and ipilimumb.[17]

MUSCLE DISORDERS

A variety of drugs may cause a myopathy or muscular symptoms through direct toxic effects on the skeletal muscles (Table 32-5).[18] In addition, a number of other drugs that are not intrinsically myotoxic may cause myopathy and weakness through an immune mechanism or by inducing severe hypokalemia or muscle ischemia, or cause rhabdomyolysis as a result of muscle compression during prolonged periods of unconsciousness after a drug overdosage ("crush syndrome").

Cholesterol-Lowering Agents

Myopathy is an important side effect of treatment with the 3-hydroxy-3-methylglutaryl—coenzyme A reductase (HMGCR) inhibitors (statins) and fibrate drugs that interfere with the biosynthesis of cholesterol. The risk of developing myopathy was shown to be increased 8-fold in patients on statins and 42-fold in patients on fibrates in a case-control study in the United Kingdom. A myopathy may also develop in patients treated with ezetimibe, which blocks cholesterol absorption, and in patients on high doses of nicotinic acid.

TABLE 32-5 ■ Drugs Associated With the Development of a Myopathy

Lipid-lowering Agents
- Statins
- Fibrates
- Ezetimibe
- Nicotinic acid

Antirheumatics
- Chloroquine
- Hydroxychloroquine
- Colchicine
- D-Penicillamine

Glucocorticoids
- Prednisone
- Methylprednisolone
- Dexamethasone
- Inhaled steroids

Immune Therapies
- Immune checkpoint inhibitors
- TNF-α inhibitors
- α-Interferon
- Tacrolimus
- Cyclosporine

Antineoplastic Agents
- Vincristine
- Bevacizumab
- Selumetinib

Cardiovascular Drugs
- Amiodarone
- Cardiac glycosides
- Perhexiline
- Hydralazine
- Scillaren

Hormonal Therapies
- Thyroxine
- Leuprolide
- Teriparatide
- Propylthiouracil

Other Drugs
- Antiretrovirals
- Clevudine
- Emetine
- Etretinate
- Proton-pump inhibitors
- Biotin
- ε-Aminocaproic acid
- Streptokinase
- Glycyrrhizic acid
- Germanium

Statins can cause a spectrum of myotoxic effects, ranging from asymptomatic hyperCKemia to a symptomatic necrotizing myopathy with myalgia and muscle weakness (Fig. 32-2), and the most extreme form, a syndrome of severe rhabdomyolysis and myoglobinuria that is potentially lethal. The risk of myopathy is greater with the lipophilic statins such as simvastatin, atorvastatin, and lovastatin, and is further increased by coadministration of a fibrate (e.g., gemfibrozol) or drugs that compete with or inhibit the CYP3A4 enzyme system. These include cyclosporine, macrolide antibiotics, calcium-channel blockers, SSRI antidepressants, azole antifungal agents, as well as grapefruit juice, which should be avoided or restricted during statin therapy. Acute rhabdomyolysis is the most severe form of statin myopathy and is rare, but in the past was associated particularly with cerivastatin, which was withdrawn from the market in 2001 after the occurrence of over 100 fatal cases of rhabdomyolysis. Other risk factors for statin myotoxicity include age, dose escalation, diabetes, hypothyroidism, renal failure, and hepatobiliary disease. Pharmacogenetic factors may also predispose to susceptibility. In the majority of cases of statin myopathy, there is progressive improvement in muscle symptoms and complete recovery usually occurs within 2 to 3 months following drug withdrawal.

In patients whose muscle symptoms fail to improve or continue to progress after withdrawal of the statin, further investigations including a muscle biopsy should be performed as statins may rarely induce an antibody-mediated form of necrotizing autoimmune myopathy (NAM), which is associated with the presence of circulating anti-HMGCR antibodies.[19] The muscle biopsy in this condition shows myofiber necrosis and regeneration, with upregulated MHC-I expression and deposition of the C5b9 membrane attack complex of complement, and a sparse or absent inflammatory infiltrate. The phenotypic spectrum of anti-HMGCR myopathy is now known to also include pediatric patients and young adults not previously exposed to statins, as well as a more chronic form of myopathy that may resemble limb-girdle muscular dystrophy. Treatment of anti-HMGCR NAM consists of withdrawing the responsible statin and initiating immunotherapy, the most frequently used agents being glucocorticoids, methotrexate, azathioprine, or mycophenolate, and in resistant cases rituximab and intravenous immunoglobulins. In most cases, more than one form of immunosuppression is required to achieve remission, and relapse is common after withdrawal or weaning of immunotherapy.

Statins may also unmask a previously unrecognized myopathy, such as mitochondrial or other metabolic myopathies, and may aggravate symptoms in patients with other myopathies.

Inflammatory Myopathies

A number of drugs may initiate an immune-mediated inflammatory myopathy. The best known are D-penicillamine and interferon-alpha, both of which may cause either polymyositis or dermatomyositis. More recently the main drugs implicated are the TNF-α inhibitors, particularly etanercept and adalimumab, and statins. In

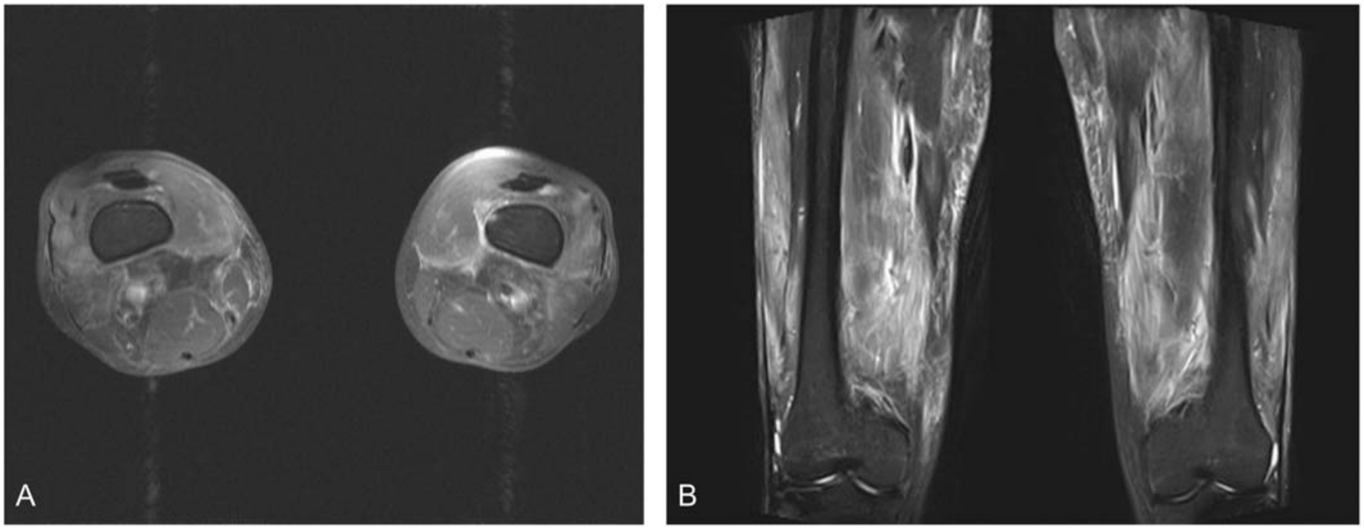

FIGURE 32-2 ■ Axial (*A*) and coronal (*B*) MRI of the proximal lower extremities showing extensive signal change in the quadriceps muscles in a 54-year-old man with a necrotizing myopathy that developed after he started atorvastatin.

the case of statins, in addition to NAM, dermatomyositis and polymyositis have been reported. There are reports of polymyositis, dermatomyositis, and especially NAM developing in patients treated with the PD-1 immune checkpoint inhibitors pembrolizumab, ipilimumab, and nivolumab.[17]

A condition referred to as macrophagic myofasciitis was first recognized in the 1990s in France, where over 130 cases were documented, and was also reported from other countries. It was characterized by diffuse myalgia, arthralgia, and fatigue, with a good response to corticosteroid therapy, and is now thought to have been caused by intramuscularly injected vaccines containing aluminum hydroxide. A syndrome of eosinophilic myositis and fasciitis associated with severe myalgia, edema, and induration of the skin was also reported in the early 1990s in patients taking a contaminated preparation of L-tryptophan as a hypnotic (the eosinophilia-myalgia syndrome).

An interstitial form of myositis characterized clinically by muscle pain, stiffness, and mild weakness has been reported rarely in patients treated with a number of drugs including procainamide, hydralazine, phenytoin, levodopa, cimetidine, leuprolide, or propylthiouracil.

Acute Rhabdomyolysis

Acute rhabdomyolysis is the most serious form of drug-induced myopathy and has been associated with statin treatment and a number of other drugs. It may also occur after self-administration of heroin, cocaine, amphetamines, ecstasy, or LSD, as well as with alcohol intoxication, drug-induced coma, seizures, dyskinesias, or the neuroleptic malignant syndrome (discussed earlier). Severe muscle pain, tenderness, and weakness typically develop over a period of 24 to 48 hours, often with marked limb swelling and in some cases the development of a secondary compartment syndrome. The serum CK is markedly elevated, and myoglobinuria is an early feature, sometimes leading to acute oliguric renal failure. Muscle biopsy usually shows widespread muscle fiber necrosis and often regeneration. The prognosis for recovery is generally good, but some more severely affected patients may die as a result of multiple organ failure. The management of patients with acute rhabdomyolysis is primarily supportive, with monitoring of renal function and fluid and electrolyte balance and early treatment of any metabolic derangements. Monitoring of compartment pressures is important in patients with muscle swelling as some patients require fasciotomy and muscle decompression.

Mitochondrial Myopathies

A myopathy with ragged-red fibers, paracrystalline mitochondrial inclusions, and depletion of muscle mtDNA has occurred in patients with acquired immune deficiency syndrome (AIDS) on long-term treatment with the antiretroviral agent zidovudine. It is characterized by myalgia, fatigue, proximal or generalized weakness, and raised serum CK level. Highly active antiretroviral (HAART) therapy, including the nucleoside analogues didanosine and stavudine, has also been reported to cause a mitochondrial myopathy with a clinical phenotype resembling chronic progressive external ophthalmoplegia.

A slowly progressive mitochondrial myopathy with marked serum CK elevation was originally reported in Korean patients with hepatitis B infection treated with the pyrimidine nucleoside analogue clevudine.

A mitochondrial myopathy has also been reported in patients taking germanium, which is a constituent of a number of dietary supplements and elixirs. Statin therapy may unmask a previously undiagnosed mitochondrial myopathy.

Potassium-Related Myopathies

Severe weakness with hypotonia, depressed tendon reflexes, and marked serum CK elevation may develop in patients with severe hypokalemia as a result of treatment with diuretics or fluoroprednisolone-containing nasal sprays, or as a result of purgative abuse or the consumption of large quantities of licorice or licorice extracts, which are ingredients of some traditional Chinese drugs and contain the potent mineralocorticoid analogue glycyrrhizic acid. Hypokalemia and myopathy may also complicate treatment with amphotericin B due to the development of renal tubular acidosis. Profound muscle weakness may occur in patients taking potassium-retaining diuretics who develop hyperkalemia.

Glucocorticoid Myopathy

A myopathy characterized by selective atrophy of type IIb myofibers is a frequent complication of prolonged treatment with glucocorticoids and is probably the most common drug-induced myopathy encountered in clinical practice. A symptomatic myopathy is more likely to develop in patients treated with the fluorinated glucocorticoids triamcinolone, betamethasone, and dexamethasone, but may also occur in patients taking prednisone or prednisolone (in doses exceeding 10 mg per day) for long periods. Those taking daily doses of 40 mg or more are at particular risk of developing a myopathy, whereas an alternate-day regimen is considered to be protective. The elderly and patients with cancer or other chronic diseases and immobility are particularly predisposed to develop a myopathy on glucocorticoids. A more acute form of glucocorticoid myopathy in which there is myofiber necrosis and elevated serum CK levels may also occur, usually in an intensive care setting in patients receiving high doses of intravenous glucocorticoids.

The muscles of the pelvic girdle and thighs are most severely affected in the chronic myopathy, whereas the weakness is more generalized in acute glucocorticoid myopathy. Muscles innervated by the cranial nerves are usually spared, but involvement of the laryngeal muscles leading to dysphonia can occur in patients using inhaled corticosteroids such as beclomethasone and fluticasone. Diaphragmatic weakness may develop in asthmatic patients taking corticosteroids, and weakness of the respiratory muscles has been reported in patients with chronic obstructive pulmonary disease and in cancer patients treated with corticosteroids. Serum CK levels are usually normal, and if elevated should suggest the possibility of an inflammatory or other type of myopathy.

Glucocorticoid myopathy is usually reversible if the drug is stopped or the dose reduced, or by switching to an alternate-day regimen or nonfluorinated glucocorticoid. Muscle atrophy and weakness can be prevented, at least in part, by a high-protein diet and regular program of physical exercise. Growth hormone and insulin-like growth factor-1 may also be protective.

Acute Quadriplegic Myopathy

Acute quadriplegic myopathy, also referred to as critical illness myopathy, occurs in critically ill patients such as severe asthmatics or organ-transplant recipients. It also occurs in patients with severe sepsis undergoing prolonged periods of mechanical ventilation and treatment with high doses of intravenous glucocorticoids and nondepolarizing neuromuscular blocking agents in the intensive care unit. There is profound generalized muscle weakness, hypotonia, and depressed tendon reflexes, and respiratory muscle weakness often leads to difficulties in weaning from the respirator. The serum CK level is usually moderately elevated, but may be normal. Muscle biopsy shows atrophy and necrosis of muscle fibers, with loss of myosin ATPase activity and a highly characteristic pattern of selective loss of myosin filaments in sarcomeres on electron microscopy. The condition has been referred to as an acquired myosinopathy. Electrophysiologic studies show reduced amplitude of compound muscle action potentials and reduced muscle excitability to direct electrical stimulation. Such studies are performed to exclude other conditions that may result in a similar clinical syndrome, such as critical illness neuropathy, Guillain–Barré syndrome, or a neuromuscular transmission disorder.

Gradual recovery usually occurs over a period of several months and is enhanced by an intensive program of physiotherapy.

Autophagic Myopathies

A number of amphiphilic cationic drugs cause autophagic degeneration and phospholipid accumulation in muscle and other tissues. These include chloroquine and hydroxychloroquine, which can cause a painless proximal myopathy or neuromyopathy after prolonged administration, and amiodarone, perhexiline, and colchicine, which can cause both a myopathy and a peripheral neuropathy. Immunohistochemistry for microtubule-associated protein light-chain 3 and p62 can facilitate tissue-based diagnosis of drug-induced autophagic vacuolar myopathies without the need for electron microscopy, making the diagnosis potentially more accurate and efficient.

Malignant Hyperthermia

Malignant hyperthermia is a condition in which susceptible individuals develop a potentially lethal state of severe generalized muscular rigidity, hyperpyrexia, tachycardia, metabolic acidosis, and myoglobinuria when exposed to certain volatile anesthetic agents such as halothane or other drugs such as succinylcholine during general anesthesia. Susceptibility is transmitted as an autosomal dominant trait and may be associated with either a clinically apparent or a subclinical myopathy. Mutations in the ryanodine receptor gene (*RYR1*) or the *CACNA1S* gene that encodes the α_1-subunit of the voltage-gated dihydropyridine receptor have been identified in only 50 to 70 percent of affected families, and genetic screening is as yet not sufficiently reliable to identify all at-risk individuals. The most reliable method is still the in vitro muscle contracture test to demonstrate abnormal sensitivity of muscle tissue when exposed to halothane and caffeine. A similar susceptibility to anesthetic reactions may also occur in some patients with Duchenne or Becker muscular dystrophy, myotonia congenita, myotonic dystrophy, core myopathies, and hypokalemic periodic paralysis.

The malignant hyperthermia crisis is thought to be due to an intrinsic abnormality of the excitation–contraction coupling mechanism in skeletal muscle, as a result of which exposure to anesthetic agents leads to the excessive release of calcium ions from the sarcoplasmic reticulum, causing sustained myofibrillar contraction. Management involves the urgent administration of dantrolene, body cooling, correction of fluid and electrolyte balance, and prompt treatment of complications.

Drug-Induced Myotonia

A number of drugs may induce myotonia in humans or experimentally in animals. These include the early-generation lipid-lowering agents clofibrate, triparanol, zuclomiphene, and 20,25-diazacholesterol. In addition, certain drugs may exacerbate myotonia in patients with a pre-existing genetic form of myotonia or unmask previously undetected myotonia. These include depolarizing muscle relaxants such as suxamethonium, which may markedly exacerbate myotonia during anesthesia, as well as β_2-adrenergic antagonists (e.g., propranolol and pindolol) and β_2-agonists (e.g., fenoterol and ritodrine). A number of diuretics, including acetazolamide, furosemide, mersalyl, and ethacrynic acid are known to induce myotonia in animals, and should be used with caution in patients with genetic forms of myotonia.

Myalgia, Cramps, and Twitches

Many different drugs including statins, fibrates, diuretics, β-adrenergic agonists, calcium-channel blockers, cytotoxic drugs, colchicine, lithium, cyclosporine, procainamide, and gold compounds may cause muscle pain and cramps that are reversible if the drug is withdrawn. In some cases, the serum CK activity may be transiently elevated. Similar symptoms may occur in patients with drug-induced myotonia, and may also be the early symptoms of a more severe necrotizing myopathy. Muscle pain and fasciculations are commonly associated with the use of suxamethonium during anesthesia. Muscle twitching (fasciculations and myokymia) has also been reported in patients treated with gold or D-penicillamine, and rarely rippling muscle disease with statins.

Other Rare Drug-Induced Myopathies

Muscle weakness is a common side effect of treatment with emetine in patients treated for amebiasis, and a severe myopathy has also been reported in individuals using ipecac syrup, which contains emetine, as an emetic agent. A proximal myopathy with myalgia, fatigability, and marked elevation of serum CK has been reported with use of large quantities of the cough-suppressant codeine linctus, one of the constituents of which is squill, which contains the cardiac glycosides scillaren A and B that inhibit the sodium–potassium pump. In the past, a severe necrotizing myopathy was a known complication of treatment with the antifibrinolytic agent ε-aminocaproic acid.

There are also rare reports of myopathy associated with the use of omeprazole and other proton-pump inhibitors, tetracyclines, griseofulvin, sulfasalazine, rifampicin, mercaptopropionyl glycine, vidarabine, ethchlorvynol, finasteride, etretinate, and isotretinoin. The protein kinase inhibitor selumetinib has been reported to cause a reversible focal myopathy of the neck extensor muscles. The recombinant human parathyroid hormone teriparatide, which is used to treat postmenopausal osteoporosis, can cause a reversible proximal lower-limb myopathy involving the gluteal muscles. A reversible myopathy with muscle lipid storage and weakness of the neck extensor muscles has also been associated with high-dose biotin administration.

Severe muscle fibrosis and contractures may occur as a result of repeated intramuscular injections in illicit drug abusers or rarely after prolonged courses of antibiotic injections.

ACKNOWLEDGMENT

Alcohol is the most commonly used recreational psychoactive substance worldwide. While moderate drinking may be beneficial to cardiovascular health, excessive use can result in alcohol use disorder, which is characterized by compulsive alcohol use despite harmful consequences and is often accompanied by serious complications resulting from alcohol toxicity and nutritional deprivation. In the nervous system, excessive alcohol consumption can damage virtually every level of the neuraxis (Fig. 33-1). Despite its protean nature, alcohol-associated neurologic disease often involves select anatomic structures or cell populations, suggesting that multiple, discrete pathophysiologic processes are involved.

ALCOHOL INTOXICATION AND WITHDRAWAL

Intoxication

In persons who drink alcohol infrequently, early signs of intoxication occur at blood alcohol concentrations less than 50 mg/dL (11 mmol/L) and include relaxation, loss of social inhibitions, increased talking, and impairment in some skilled tasks.[1] Ataxia, nystagmus, slurred speech, impaired judgment, and changes in mood and behavior generally occur at blood alcohol levels above 100 mg/dL (22 mmol/L) and are followed by central nervous system depression as blood levels increase. Amnesia for all or part of a drinking episode (“blackout”) may occur without loss of consciousness at blood levels above 140 mg/dL. Blood levels above 300 mg/dL (65 mmol/L) can produce coma, hyporeflexia, respiratory compromise, and hypotension. Although the behavioral effects of alcohol generally correlate with blood concentrations, tolerance can greatly modify the clinical response to a specific blood level. Acute tolerance develops even during a single bout of drinking and can cause the drinker to be unaffected at blood alcohol concentrations higher than those at which intoxication previously developed. In people who drink heavily, the degree of tolerance can be extensive, permitting sobriety at blood concentrations above 120 mg/dL and survival above 700 mg/dL.[1]

Alcohol Withdrawal Syndromes

In approximately 8 percent of people hospitalized for alcohol use disorder, characteristic signs of alcohol

withdrawal syndrome follow 1 to 3 days after abrupt cessation of heavy drinking.[2] Generalized tremor is a common early sign and resembles an accentuated physiologic tremor. It is often accompanied by insomnia, headache, and autonomic hyperactivity with increased arousal, tachycardia, diaphoresis, and flushing. These signs usually begin within 8 hours after cessation of drinking, peak at 72 hours, and resolve after 5 to 7 days.

Seizures may also occur shortly after chronic drinking is discontinued.[2] Alcohol withdrawal seizures are usually associated with a history of daily alcohol consumption, but briefer drinking sprees may also culminate in seizures following cessation. Generalized tonic-clonic seizures are most common; focal seizures suggest an etiology other than alcohol withdrawal, although alcohol can lower the seizure threshold in a patient otherwise predisposed to focal seizures. The majority of seizures occur 6 to 48 hours after cessation of drinking. Approximately 60 percent of patients have more than one seizure, but usually less than four, over a period of less than 12 hours. Status epilepticus may occur in up to 5 percent. More than half of withdrawal seizures are associated with underlying epilepsy, structural brain lesions, or concurrent use of other drugs.

In patients with repeated seizures in the setting of alcohol withdrawal, benzodiazepines (e.g., diazepam, chlordiazepoxide, and lorazepam) prevent seizure recurrence, but the evidence is not adequate to support the use of nonbenzodiazepine anticonvulsants. Status epilepticus that is suspected to be due to alcohol withdrawal is a medical emergency and should be treated with anticonvulsants in the same fashion as status epilepticus due to any other etiology, beginning with doses of benzodiazepines. It is important to recognize that alcoholics are at risk for a variety of other treatable conditions that may cause status epilepticus, including occult head trauma, meningitis, hypoglycemia, hyponatremia, and other drug ingestions.

Approximately 20 percent of patients become delirious 2 to 5 days after signs of alcohol withdrawal begin, and in 3 to 5 percent of patients hospitalized for alcohol withdrawal, the syndrome of delirium tremens develops with marked confusion, hallucinations, tremor, hyperpyrexia, and sympathetic hyperactivity. The risk of developing delirium tremens is higher in alcoholics with heavy daily alcohol intake, prior alcohol withdrawal seizures or delirium, decreased serum chloride and potassium concentrations, elevated serum levels of alanine aminotransferase and γ-glutamyltransferase, thrombocytopenia, and findings of tachycardia (≥100 bpm), ataxia, and polyneuropathy on admission.[2] The major threat to life is from associated illnesses or injuries, hyperthermia, dehydration, hypotension, arrythmias, and complications of seizures. Although initial studies reported mortality rates as high as 15 percent, rates with current methods of detection and treatment have declined to 1 percent or less.[2] A variety of sedatives, anticonvulsants, sympatholytics, and neuroleptics have been administered to patients with alcohol-withdrawal delirium, usually in uncontrolled trials. Several double-blind studies have suggested that benzodiazepines are effective in controlling the symptoms of alcohol withdrawal. Benzodiazepines and barbiturates are better than neuroleptics in reducing mortality from the delirium associated with alcohol withdrawal and should be used preferentially.

The dose of medication required to control alcohol-withdrawal symptoms can vary greatly among different patients and over time in the same patient. Three treatment approaches have been described.[2] The loading dose approach uses high doses of a long-acting benzodiazepine (e.g., 10 to 20 mg of diazepam every 1 to 2 hours) until the patient is sedated and then allows for tapering through endogenous clearance mechanisms. However, because high doses may cause respiratory depression, vital signs must be carefully monitored with each loading dose to avoid benzodiazepine toxicity, especially in patients with liver disease. In the second approach repeated fixed doses at regular intervals are administered; this strategy can be particularly useful when it is difficult to assess and monitor progression of withdrawal signs. A dose of 5 to 20 mg of diazepam can be given intravenously every 5 to 10 minutes until the patient is lightly somnolent, followed by 5 to 20 mg every few hours as needed to control delirium and agitation, with a ceiling dose of about 60 mg of diazepam per day. After the patient is stable for 2 to 3 days, the benzodiazepine can be slowly tapered over 7 to 10 days. In elderly patients or those with liver disease, repeated administration of shorter-acting benzodiazepines such as oxazepam or lorazepam may be safer. A third approach is symptom-guided by monitoring instruments such as the revised Clinical Institute Withdrawal Assessment for Alcohol (CIWA-Ar), which is a 10-item scale that can be administered at the bedside within 5 minutes. Using a CIWA-Ar score of at least 8 as a cutoff, treatment begins with diazepam (5 to 10 mg) followed by hourly assessment and repeated dosing until the score is less than 8. Thereafter, assessments can be made every 4 to 8 hours to determine the need for repeated dosing. All treatment methods have similar efficacy, but the loading-dose and the symptom-guided approaches may be faster and use less drug than the repeated fixed-dose method, resulting in less sedation and less risk of respiratory depression.

Patients refractory to benzodiazepines may respond to addition of a different class of sedative-hypnotic (e.g., barbiturates or propofol). Neuroleptics, such as haloperidol, are reserved for severe agitation as adjunctive therapy. Fluid and electrolyte abnormalities can be severe and require prompt therapy. Dehydration accompanying delirium tremens may require replacement of up to 4 to 10 liters of fluid during the first 24 hours. Hypomagnesemia is common, lowers seizure threshold, and should be treated with magnesium sulfate (e.g., 1 g intravenously every 6 hours during the first day in patients with adequate renal function). Potassium should be included in intravenous solutions because hypokalemia may be exacerbated by glucose administration, leading to cardiac arrhythmias.

DISORDERS OF COGNITION

More than 10 percent of patients with alcohol use disorder develop cognitive dysfunction.[3] The pathogenic mechanisms are often multiple and include neurotoxic effects of ethanol, nutritional deficiencies, and electrolyte disturbances. Several alcohol-related clinical syndromes with cognitive dysfunction as a prominent feature have been described.

Alcohol-Related Dementia

People with severe alcohol use disorder can suffer progressive memory impairment along with aphasia, agnosia, apraxia, or impaired executive function that persists beyond periods of intoxication or withdrawal and cannot be attributed to other causes. Heavy alcohol use can result in brain atrophy with neuronal loss in the frontal cortex, hypothalamus, and cerebellum; a reduction in the size of cell bodies and dendritic arbors in layer III pyramidal neurons of the superior frontal gyrus and motor cortices; and white matter loss, particularly in the hippocampus, corpus callosum, and cerebellum.[4] With several years of abstinence, cognitive function can improve.

Brain imaging studies have shown widespread volume loss affecting cortical gray and white matter and signal abnormalities in several subcortical structures, including the corpus callosum, pons, cerebellar hemispheres, and vermis.[5] These regions are less affected in patients with uncomplicated alcohol use disorder free of alcohol-associated electrolyte and nutritional disturbances. White matter abnormalities may be observed with greater sensitivity and detail using diffusion tensor imaging. These imaging and neuropsychiatric abnormalities are partly reversible during abstinence. Volume loss and recovery during abstinence may reflect changes in brain water, but longitudinal studies using MR spectroscopy have shown increases in *N*-acetyl aspartate and phospholipids in certain brain regions, suggesting actual recovery of neurons and white matter during abstinence.

Wernicke Encephalopathy

Wernicke encephalopathy is an acute disorder manifested by the classic triad of nystagmus and ophthalmoplegia, gait ataxia, and an acute confusional state.[6] However because not all patients exhibit the complete triad and because the diagnosis can be difficult to distinguish from drunkenness and other causes of confusion, it is missed in 75 to 80 percent of cases. To avoid underdiagnosis, one should consider Wernicke encephalopathy when two of the following four signs are present: dietary deficiency, oculomotor abnormalities, cerebellar dysfunction, and either an altered mental state or memory impairment. The differential diagnosis includes sedative drug intoxication and structural lesions of the posterior fossa. In the absence of overt ocular signs in patients with confusion or ataxia, the differential diagnosis includes ethanol intoxication and encephalopathy due to other causes such as hepatic insufficiency or infection. Magnetic resonance imaging (MRI) and sensitive measures of serum thiamine can improve diagnostic accuracy but should not delay treatment. The most characteristic MRI findings are of cytotoxic and vasogenic edema involving the thalamus, hypothalamus, and brainstem, appearing as symmetric signal intensities on T2-weighted images of medial thalamic nuclei, periventricular gray matter, midbrain tectum, and the mammillary bodies. Less common are symmetric alterations in the cerebellum, dentate nuclei, cranial nerve nuclei, caudate, splenium of the corpus callosum, and cerebral cortex.

Neuropathologic findings include neuronal loss, demyelination, glial and vascular proliferation, hemorrhage, and necrosis, particularly affecting the anterior and mediodorsal thalamus, mammillary bodies, basal forebrain, raphe nuclei, and cerebellar vermis. An underlying disorder that predisposes to malnutrition appears to be common to all cases. Alcohol use disorder is the most frequent predisposing factor. However, persistent vomiting due to a variety of causes such as starvation, malignancy or other chronic systemic diseases, and other mainly surgical causes of malabsorption has also been implicated,[6] as described in Chapter 13.

The link between malnutrition and Wernicke encephalopathy is a deficiency of vitamin B_1 (thiamine). In people with chronic alcohol use disorder, decreased dietary intake of thiamine may be compounded by alcohol-induced defects in intestinal absorption, metabolism, and hepatic storage of thiamine.[6] Thiamine pyrophosphate is a required cofactor for at least four enzymes involved in intermediary metabolism: pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, transketolase, and branched-chain α-ketoacid dehydrogenase. Metabolic impairment in glucose utilization, impaired amino acid transport and resultant excitotoxicity, impaired ion transport, acidosis from increased lactate production, and mitochondrial dysfunction with resultant oxidative stress and blood–brain barrier disruption have all been implicated in pathogenesis. Variant forms of transketolase and thiamine transport genes could provide a basis for the preferential vulnerability of certain patients to develop Wernicke encephalopathy.

Treatment of Wernicke encephalopathy is by repletion of thiamine. Patients should be hospitalized and receive 200 to 500 mg of thiamine intravenously three times daily for several days until there is no further improvement in signs and symptoms. It is important that thiamine replacement is started prior to or concurrent with administering glucose, to avoid worsening the encephalopathy. Improvement with therapy is considered evidence of correct diagnosis. Acute, reversible MRI abnormalities have also been described, and may be helpful in confirming the diagnosis in mild cases or those with atypical clinical features. Detection of a low blood thiamine level may also be useful; current guidelines recommend that total blood thiamine levels be sent at first diagnosis, immediately before beginning thiamine replacement.

The prognosis of Wernicke encephalopathy depends on the prompt institution of appropriate treatment. The overall mortality rate is about 17 percent.[6] After the institution of treatment, ocular and gaze palsies begin to improve within hours to days, and nystagmus, gait ataxia, and confusion within days to weeks. Long-term sequelae include residual nystagmus or gait ataxia in approximately 60 percent of patients and a chronic memory disorder (Korsakoff amnestic syndrome) in more than 80 percent.

Korsakoff Syndrome

Korsakoff syndrome is characterized by a disproportionate impairment of memory that typically arises in chronic alcoholics in the wake of one or more episodes of Wernicke encephalopathy. The main behavioral deficits are impairment of anterograde episodic memory, with semantic and retrograde memory affected to a lesser extent. The disability afflicting these patients is one of the most striking in clinical neurology. There is an inability to incorporate new memories (anterograde amnesia) and impaired retrieval of previously established, especially recent, memories (retrograde amnesia). Immediate recall is intact. Patients are typically disoriented to time and place, and hospitalized patients are characteristically unaware of their room numbers or hospital floor, how long they have been in the hospital, what they had for their last meal, or who visited them. At the same time, very distant memories may be preserved in detail; some patients appear to be stuck in time, insisting that the year is one from decades past. Patients with Korsakoff syndrome appear to be unaware of their deficit and commonly attempt to reassure the examiner that nothing is seriously wrong. Confabulation, the invention of material to fill in gaps in memory, is often but not invariably seen. Other aspects of cognitive function may exhibit subtle impairment, but alertness and language are intact. Emotional changes such as apathy or mild euphoria may also develop.

The distribution of histopathologic lesions is identical to that seen in Wernicke encephalopathy. Episodic memory processing requires a network of limbic structures, many of which are damaged in Korsakoff syndrome. Biochemical studies have provided evidence of oxidative stress, glutamate-mediated excitotoxicity, and inflammation in vulnerable brain regions as major mechanisms for brain damage due to thiamine deficiency.[7] Patients with Korsakoff syndrome may show evidence of other alcohol-related neurologic disorders. Nystagmus and gait ataxia related to past bouts of Wernicke disease are common, as are signs of a peripheral neuropathy. In many patients there is also evidence of frontal lobe dysfunction. The differential diagnosis of a chronic amnestic syndrome resembling Korsakoff syndrome includes pancerebral hypoxia or ischemia, bilateral posterior cerebral artery strokes, herpes simplex virus encephalitis, paraneoplastic limbic encephalitis, and brain tumors in the vicinity of the third ventricle. Although acute Wernicke encephalopathy should always be treated with thiamine, the effectiveness of thiamine in preventing the subsequent development of the chronic amnestic syndrome is uncertain. Similarly, thiamine has not been shown to be effective for the treatment of established Korsakoff syndrome, although patients with this disorder may improve spontaneously.

Pellagra

Endemic pellagra, which results from deficiency of niacin (vitamin B_3) or its amino acid precursor tryptophan, is an underappreciated cause of confusion and delirium in malnourished alcoholics.[8] Neuropathologic changes are most prominent in neurons of the pons and deep cerebellar nuclei, though neurons elsewhere are also involved. Affected neurons show chromatolysis, appearing swollen and rounded, with eccentric nuclei and loss of Nissl substance. Systemic manifestations of pellagra include diarrhea, glossitis, anemia, and erythematous cutaneous lesions that appear in sun-exposed areas. Although pellagra was named for the characteristic skin lesions, they are not always present. Early mental symptoms of irritability, depression, fatigue, insomnia, and inability to concentrate are nonspecific and suggest a psychiatric disorder. However, the later development of confusion, hallucinations, or paranoid ideation is characteristic of pellagra, and is usually accompanied by spastic weakness and extensor plantar responses. Tremor, rigidity, polyneuropathy, optic neuritis, and deafness may also be present. Pellagra responds readily to administration of niacin, although cerebral symptoms may not be completely reversible. Further details are given in Chapter 15.

Marchiafava–Bignami Disease

Marchiafava–Bignami disease is a rare disorder characterized by destruction of myelin mainly in the corpus callosum and anterior commissure.[9] Exceptionally, lesions extend laterally to involve the centrum semiovale, and in some instances the middle cerebellar peduncles are also demyelinated. Neurons in layer III of the cerebral cortex may be replaced by gliosis, possibly owing to disruption of involved callosal fibers. The disease is usually diagnosed at postmortem examination because the clinical signs are nonspecific, although MRI has made diagnosis more feasible during life. Most patients are alcoholics of long standing and many have associated malnutrition or liver disease, although the disease has appeared in a few nondrinkers. The etiology is not known.

Patients may present acutely with seizures and coma often accompanied by signs of upper motor neuron dysfunction, or alternatively they may follow a subacute course with gait disturbance, dysarthria, hyperreflexia, cognitive impairment, neuropsychiatric symptoms, and signs of interhemispheric disconnection. Cerebrospinal fluid (CSF) demonstrates a normal white blood cell count but may show elevated protein. Brain MRI features T2-hyperintense swelling of the corpus callosum, followed later in the course by callosal atrophy along with cortical and subcortical atrophy. T1-weighted images may show hypointense necrotic lesions of the corpus callosum. There may be gadolinium enhancement of lesions. Motor deficits, such as pyramidal tract signs and gait disturbances, tend to recover with abstinence from alcohol and improved nutrition, but many patients show residual cognitive impairment and a disconnection syndrome. About 10 percent of patients with concomitant alcohol use disorder show a good outcome. Early treatment with thiamine has been associated with a better outcome. People with multiple lesions on MRI are more likely to have a poor outcome. Patients who develop coma carry the greatest risk of serious disability or death, whereas those with little impairment in consciousness may recover with only mild disability.

Hepatocerebral Disorders

Severe alcoholism can cause hepatic cirrhosis with portocaval shunting and hepatic insufficiency, leading to serious secondary neurologic disorders. In its mildest, covert form, hepatic encephalopathy presents with a normal neurologic examination and deficits apparent only on psychometric testing. Overt hepatic encephalopathy presents as a confusional state with deficits in awareness, attention, and calculation ability or, in severe cases, somnolence, stupor, and coma. The pathogenesis and treatment of hepatic encephalopathy are discussed in Chapter 12.

Acquired (non-Wilsonian) hepatocerebral degeneration is a less common disorder that can accompany advanced liver disease and is characterized by parkinsonism, ataxia and, in some patients, dystonia, chorea, and orobuccolingual dyskinesia.[10] Cognitive dysfunction is common but is not always present. Occasional patients show signs of a myelopathy with corticospinal tract signs. Acquired hepatocerebral degeneration begins insidiously after many weeks or years of hepatic dysfunction and is usually progressive, with episodes of stability or spontaneous remissions and relapses. It is characterized by neuropathologic lesions that resemble those found in Wilson disease with diffuse, patchy necrosis and microcavitation at the junction of cerebral gray and white matter, and a loss of neurons and myelinated fibers in the basal ganglia and cerebellum. Protoplasmic type II (Alzheimer) astrocytes are increased in number, and Opalski cells may be present.

Acquired hepatocerebral degeneration is thought to result from central nervous system exposure to neurotoxic substances present in the portal circulation, such as ammonia, aromatic amino acids, and metals. A role for manganese in particular is supported by elevated serum and CSF manganese levels and by pallidal hyperintensities on T1-weighted MRI images of patients with severe liver disease, reminiscent of findings in occupational manganese toxicity. Dopaminergic drugs may reduce parkinsonian symptoms, although less effectively than in patients with Parkinson disease. Death usually occurs as a complication of advanced liver disease or intercurrent infection.

ALCOHOLIC CEREBELLAR DEGENERATION

In several alcoholic patients, a chronic cerebellar syndrome develops, sometimes as a long-term sequela of Wernicke encephalopathy. The neuropathologic features of alcoholic cerebellar degeneration include loss of cerebellar cortical neurons, especially Purkinje cells, with a particular predilection for the anterior and superior vermis; the anterior and superior cerebellar hemispheres are affected less often.[11] The distribution of this cerebellar pathologic process is strikingly similar to that seen in Wernicke encephalopathy, suggesting that the two disorders are linked pathophysiologically. Alcoholic cerebellar degeneration may also result from a direct toxic effect of alcohol on the cerebellum, or from a combination of thiamine deficiency and alcohol neurotoxicity.

The natural history of alcoholic cerebellar degeneration is variable. The syndrome usually occurs in the setting of chronic alcoholism of 10 years or more duration. The most frequent mode of onset is with ataxia that progresses steadily for weeks to months. A more gradually progressive disorder that evolves over years is also common. Less often, a mild and stable chronic deficit may suddenly worsen.

Although gait ataxia is the most prominent manifestation of both alcoholic cerebellar degeneration and Wernicke encephalopathy, the pattern of involvement in the two disorders may differ. Limb ataxia, which is absent in most patients with Wernicke encephalopathy, is usually detectable in alcoholic cerebellar degeneration. Examination of such patients typically demonstrates severe ataxia of the legs, with milder involvement of the arms. Dysarthria, which is usually mild, is also more frequent in alcoholic cerebellar degeneration than Wernicke encephalopathy. In contrast, nystagmus is present less often than in Wernicke encephalopathy. Patients with alcoholic cerebellar degeneration may also exhibit signs of a polyneuropathy (see later). Uncommon manifestations of alcoholic cerebellar degeneration include hypotonia, ocular dysmetria, and postural tremor.

Alcoholic cerebellar degeneration is a clinical diagnosis. Neuroimaging may show cerebellar cortical atrophy, but laboratory findings usually are helpful only for excluding other causes of ataxia. Other conditions that must be considered in the differential diagnosis of subacute or chronic cerebellar ataxia in middle life include multiple sclerosis, hypothyroidism, paraneoplastic cerebellar degeneration, idiopathic cerebellar or olivopontocerebellar degeneration, Creutzfeldt–Jakob disease, and posterior fossa tumors. Like alcoholic cerebellar degeneration, many of these disorders can produce ataxia that preferentially affects gait.

Ataxia due to alcoholic cerebellar degeneration often stabilizes or improves with cessation of drinking and improved nutritional status, although the relative importance of each of these two factors is uncertain. Patients should receive parenteral thiamine, although it is not yet known whether thiamine improves outcome, as it does in Wernicke encephalopathy.

CENTRAL PONTINE AND EXTRAPONTINE MYELINOLYSIS

Central pontine and extrapontine myelinolysis are forms of the osmotic dysregulation syndrome which is further discussed in Chapter 17. Patients typically present with seizures or confusion that improves but then is followed by rapidly evolving dysarthria, dysphagia, oculomotor dysfunction, and paraparesis or quadriparesis. A history of alcohol use disorder is common and found in 58 percent of affected patients.[12] Malnutrition accounts for 17 percent and nonalcoholic cirrhosis for 12 percent of cases. Less often, it develops with burns, renal failure, prolonged use of diuretics, psychogenic polydipsia, or pituitary or urologic surgery.

The characteristic pathologic lesion in central pontine myelinolysis is bilaterally symmetric, focal destruction of myelin in the ventral pons. Histologically, there is severe loss of myelin, and oligodendroglia are reduced in number. Neurons and axons are relatively spared, although axonal swelling and neuronal shrinkage may occur, particularly in the center of lesions. There is no inflammation, and blood vessels appear normal. In approximately 50 percent of cases, characteristic lesions are present outside the basis pontis, and in half of these cases with extrapontine lesions, no pontine lesions are present. Extrapontine myelinolysis has been observed in the cerebellum, thalamus (especially the lateral geniculate body), external and extreme capsules, basal ganglia, deep layers of cerebral cortex and adjacent white matter, and rarely in the fornix, anterior commissure, subthalamic nucleus, amygdala, optic tract, and spinal cord.

Co-existent illnesses often influence the clinical manifestations of central pontine myelinolysis, making it difficult to diagnose in some cases. Although some small lesions detected postmortem can be asymptomatic, certain clinical features are typical. Central pontine myelinolysis often evolves over several days to weeks in a severely ill patient, and mental confusion is a prominent feature in almost all cases. Demyelination of pontine corticobulbar fibers leads to early dysarthria or mutism. Spastic quadriparesis and pseudobulbar palsy are common, occurring in more than 90 percent of patients. When lesions extend into the midbrain, medulla, or pontine tegmentum, there may be pupillary and oculomotor signs, depressed consciousness or coma, and dysfunction of cranial nerves. Progressive demyelination of corticospinal and corticobulbar tracts in the basis pontis may produce a locked-in syndrome. Extrapontine lesions may cause ataxia, parkinsonism, choreoathetosis, and dystonia. Cognitive and behavioral symptoms include restlessness, emotional lability, apathy, agitation, insomnia, paranoia, delusions, rage, and disinhibition.

MRI scans may be normal during the first 2 weeks of illness, but eventually affected regions appear hyperintense on T2-weighted sequences and hypointense on corresponding T1-weighted sequences. Diffusion-weighted MRI may be more sensitive and show lesions within the first few days after onset of symptoms, prior to abnormalities developing on T2-weighted sequences.

Although the disorder has historically been considered to carry a poor prognosis, as many as 50 percent of patients show improvement after several weeks and some otherwise normal-appearing patients have the characteristic MRI abnormalities found incidentally. In general, outcome does not correlate with the severity of neurologic deficits during the acute phase of illness or with the degree of hyponatremia. Therefore, all patients with suspected central pontine myelinolysis should be supported aggressively, especially since substantial improvement may occur after several weeks to months.

Central pontine myelinolysis is mainly an iatrogenic disorder, and its appearance coincided with the widespread use of intravenous therapy for correction of fluid and electrolyte disorders. Hyponatremia frequently precedes central pontine myelinolysis, and aggressive correction of hyponatremia appears to be the precipitating factor in most cases. Over the past 20 years there has developed a consensus on the treatment of hyponatremia to minimize the risk of myelinolysis. Severe hyponatremia (≤ 120 mEq/L), if it develops rapidly, can cause life-threatening symptoms such as coma and seizures, and demands prompt treatment. If hyponatremia occurs slowly, however, symptoms are generally less severe and include malaise, nausea, headache, lethargy, and confusion. The general consensus is to increase the serum sodium level by no more than 12 mEq/L in 24 hours in patients with chronic hyponatremia.

ALCOHOL-RELATED NEUROPATHY

Neuropathy is the most frequently encountered chronic neurologic disorder related to alcohol abuse.[13] Both nutritional deficiency and a direct, toxic, dose-dependent effect of alcohol have been invoked as etiologies. Support for a toxic effect of ethanol comes from studies in rats demonstrating hyperalgesia following several weeks of ethanol ingestion. Axonal degeneration appears to be the principal pathogenic process. Segmental demyelination also occurs and may be secondary to the primary axonal disorder or a consequence of concomitant nutritional deficiency.

Alcoholic neuropathy usually presents after several years of alcohol abuse as a distal, symmetric, sensorimotor polyneuropathy that is gradual in onset and slowly progressive. Symptoms include weakness, pain, paresthesia, muscle cramps, numbness, gait ataxia, and burning dysesthesia. Neurologic examination may reveal any combination of reflex, sensory, and motor abnormalities, with predominant involvement of the legs. Absent or decreased muscle stretch reflexes and impaired vibration sense in the lower extremities are virtually universal findings. Defective appreciation of light touch and weakness are also seen in most patients. Pain and temperature sensation are affected less often, and symptomatic autonomic dysfunction and cranial nerve involvement are comparatively rare. In addition to the neurologic abnormalities, affected limbs may exhibit edema, hyperpigmentation or ulceration of the skin, and bony deformities.

Nerve conduction studies are useful for documenting the presence of neuropathy and for demonstrating the predominantly axonal pathologic process. Laboratory studies on blood and CSF can exclude other causes of polyneuropathy including diabetes, chronic inflammatory demyelinating polyneuropathy, uremia, dysproteinemia, and vasculitis.

Vitamin supplementation (especially thiamine) and abstinence from alcohol can often arrest the progression of alcoholic polyneuropathy and in some cases lead to clinical improvement. Neuropathic pain may respond to anticonvulsants or tricyclic antidepressants.

ALCOHOL-RELATED MYOPATHY

Excessive alcohol consumption has adverse effects on both skeletal and cardiac muscle. Both acute and chronic clinical presentations of alcohol-related myopathy are recognized.

Acute Necrotizing Myopathy

An acute, necrotizing myopathy may develop over the course of 1 to 2 days in the setting of heavy binge drinking and affects up to 2 percent of heavy drinkers. Symptoms include muscle pain and weakness, which, although classically symmetric and proximal in distribution, may be asymmetric or focal in nature. Neurologic examination shows tender, swollen muscles in the affected areas. Weakness is a prominent finding and may be associated with dysphagia. Signs of congestive heart failure are sometimes present.

Laboratory abnormalities include moderate to severe elevation of serum creatine kinase levels, and in some cases myoglobinuria. The electrocardiogram may reveal arrhythmias or conduction defects. Electromyography discloses myopathic changes in configuration and recruitment of motor unit potentials, as well as fibrillation potentials. The muscle biopsy shows necrosis of muscle fibers.

Acute alcoholic myopathy must be distinguished from other causes of acute weakness in alcoholic patients, such as hypokalemia and hypophosphatemia. In hypokalemia, weakness is not accompanied by muscle pain, and myoglobinuria does not occur. Hypophosphatemia closely reproduces the clinical features of acute alcoholic myopathy and may also contribute to its pathogenesis. Consequently, serum potassium and phosphorus concentrations should always be measured in acutely weak alcoholic patients.

Complications of acute alcoholic myopathy, such as cardiac disturbances and renal compromise due to myoglobinuria, should be treated urgently. Electrolyte abnormalities should be monitored carefully and corrected if necessary. Muscle pain and tenderness may improve with analgesics. With abstinence, recovery within weeks to months is the rule, but some patients exhibit residual weakness and long-standing cardiac conduction abnormalities.

Chronic Myopathy

The much more common form of alcohol-related myopathy is a chronic condition which develops insidiously over weeks to months, and is seen in 40 to 60 percent of patients, typically those with a history of more than 10 years of heavy alcohol use.[14] In animal and cell-culture studies, alcohol reversibly inhibits initiation of translation and protein synthesis in skeletal muscle.

In addition, disruption of carbohydrate and energy metabolism, oxidative stress, and apoptosis appear to contribute to myopathy. Chronic alcoholic myopathy is characterized by proximal weakness involving pelvic and shoulder girdles, with relative preservation of muscle stretch reflexes. In contrast to acute necrotizing alcoholic myopathy, muscle pain is uncommon or mild. Patients often show signs of other ethanol-induced end-organ damage such as cirrhosis or cardiomyopathy. Serum creatine kinase levels are elevated three- to sixfold in 40 percent of patients. When the clinical diagnosis is uncertain, chronic alcoholic myopathy can be distinguished from polyneuropathy by electrodiagnostic studies or by muscle biopsy, which shows atrophy mainly of type II muscle fibers along with myocyte necrosis without inflammation. The chronic form of myopathy is related to lifetime alcohol dose and may improve with abstinence or decreased drinking.

ALCOHOL AND STROKE

Epidemiologic studies suggest that alcohol consumption influences the risk of stroke.[15] For intracerebral and subarachnoid hemorrhage, the risk increases linearly with increasing daily alcohol intake. Possible explanations for this association include alcohol-induced disorders of coagulation or fibrinolysis, thrombocytopenia or impaired platelet function, and acute or chronic hypertension. In contrast, the relationship between daily alcohol intake and ischemic stroke is J-shaped. Thus, moderate drinking—two or fewer drinks per day—appears to reduce ischemic stroke risk compared with that observed in nondrinkers, whereas less temperate drinking patterns predispose to ischemic stroke. The protective effect of small amounts of alcohol has been attributed to elevated levels of prostacyclin, decreased platelet activation, enhanced fibrinolysis, increased levels of high-density lipoprotein cholesterol, and activation of signaling mechanisms involved in ischemic preconditioning. Mechanisms that could be responsible for an increased risk of ischemic stroke in heavy drinkers include alcohol-related cardiomyopathy or arrhythmias, alcohol-induced hypertension, the increased incidence of cigarette smoking in heavy drinkers, rebound thrombocytosis occurring with alcohol withdrawal, and hypercoagulable states.

INFECTIOUS COMPLICATIONS OF INJECTION DRUG USE
CONCLUDING COMMENTS

Recreational drug use can lead to neurologic problems stemming from both acute intoxication and chronic use, and physicians must be aware of these complications when faced with any patient presenting with neurologic symptoms. The landscape of drug use has shifted from primarily illicit substances manufactured with the sole purpose of recreational drug use, to the realization that many drugs of abuse are prescription medications. No longer do abusers need to obtain drugs exclusively on the street; physician offices, pharmacies, and medicine cabinets now have become common sources of these substances. Practitioners need to be aware of the potential for abuse by patients when prescribing these substances and also of the potential for these drugs to fall into the hands of other users, including family members and acquaintances of patients. This shift to abuse of prescription drugs has also changed the demographics of those at risk of drug abuse; young and old alike, spanning the full array of socioeconomic backgrounds, are at risk of abuse in the setting of relatively easy accessibility of these substances.

Standard urinary drug screens are inexpensive and utilized in most emergency departments when concern exists for acute intoxication. These screens also are employed in drug treatment programs and employee screens in order to monitor compliance with abstinence. They test for commonly used recreational drugs or their metabolites including alcohol, amphetamines, barbiturates, benzodiazepines, cannabis, and cocaine. Although this list captures many drugs of abuse, many agents discussed here are not included in typical urinary screens and either cannot be tested for easily or are only detected using serum screens that tend to be expensive and time-consuming. These serum screens remain the gold standard for testing, especially outside of the emergency setting. Other options for testing employed much less commonly include saliva and hair analysis, the latter having the advantage of detecting some drugs of abuse weeks to even months after ingestion.

COCAINE

Cocaine is a widely used, highly addictive stimulant that increases monoamine neurotransmitters through inhibition of reuptake. It is taken in a variety of different ways including by snorting, smoking (often as “crack” cocaine), and intravenous injection. Acute intoxication effects and risk depend on the method of ingestion and dose but, in general, as with other stimulants, a variety of neuropsychiatric effects—including psychosis and paranoia—can occur in addition to the expected euphoria and increased energy.

Adverse neurologic effects may include tremor and a number of other movement disorders including acute dystonia, tics, and dyskinesias, the latter of which can be long-lasting in some patients. As with other stimulant drugs, seizures can occur with acute intoxication and are difficult to predict by dose or route of drug administration; generalized tonic-clonic seizures are most common, but cocaine lowers the seizure threshold and can lead to focal-onset seizures in patients with an underlying brain lesion. Thus, any focality to seizures occurring in the setting of cocaine use should lead to urgent neuroimaging to exclude an underlying structural cause.

The most recognizable of the acute neurologic complications associated with cocaine are cerebrovascular in nature.[1] Dramatic rises in blood pressure shortly after use can lead to intracerebral hemorrhage as a result of exceeding the upper limits of the cerebral autoregulatory curve. In addition, patients with intracranial aneurysms may be at risk of rupture with the hypertension that accompanies intoxication. Ischemic stroke can also occur shortly after use due to the promotion of thrombosis via platelet activation and other downstream mechanisms; this hypercoagulability was first described in myocardial infarction but applies similarly to ischemic stroke.

In contrast to the acute effects, chronic cocaine use can lead to ischemic stroke and cerebral transient ischemic attacks (TIAs) through a variety of mechanisms, many of which remain incompletely understood. Some cocaine abusers appear to develop a noninflammatory vasculopathy similar to accelerated atherosclerosis in both large and small vessels of the intracranial circulation, predisposing them to stroke at a young age. It has been suggested that part of the rise in stroke incidence in younger populations is accounted for by the increased use of recreational stimulants such as cocaine.[2] Other purported mechanisms of cocaine-induced stroke have included vasospasm of small arteries and an increased incidence of cervical artery dissection—these appear to be less common than atherosclerotic-like changes but should be considered in cocaine-related stroke and TIAs.

In addition to direct effects on the cerebral circulation, a variety of ischemic cocaine-related complications stem from the varied effects of the drug on the heart. Cocaine-induced arrhythmias, both atrial and ventricular, can predispose to cardioembolic events with either acute or chronic use of the drug. The cardiomyopathy that accompanies cocaine-related myocarditis can also lead to cardioembolic disease when the ejection fraction is moderately-to-severely depressed. Myocardial infarction in the setting of acute use is one of the more common causes of concern when a cocaine user presents to the emergency department with chest pain. Stroke can occur when wall motion abnormalities of the heart or an apical aneurysm set the stage for stasis and intracardiac clot formation that can subsequently embolize to the cerebral circulation. Acute aortic dissection, which is well described in cocaine users due to effects on the aortic endothelium and to acute hypertension, can lead to cerebrovascular events when the dissection involves the origins of the great vessels, leading to either hypoperfusion or a proximal embolic source.

Acute and chronic white matter changes have also been described with cocaine use. Chronic changes likely reflect in part the effects of sustained hypertensive episodes and may present with cognitive decline featuring prominent executive dysfunction. A more fulminant acute leukoencephalopathy may in some cases be due to adulterants found in cocaine, including the antiparasitic medication levamisole.

METHAMPHETAMINES

The numerous methamphetamine-containing compounds that are available to recreational users all work through a common mechanism of increased norepinephrine, epinephrine, and serotonin transmission at the synapse while also activating dopamine receptors. The stimulant effects of acute intoxication are therefore similar in many respects to those occurring with cocaine, with euphoria and increased energy predominating along with the risk of occasional paradoxical reactions including agitation and paranoia. As the effects of the drug wear off, dysphoria and increased sleep commonly occur, mimicking some of the effects of sedatives.

Other neurologic effects of acute intoxication involve intracerebral hemorrhage due presumably in part to severe hypertension, even in patients without a history of chronic use; subcortical locations of hemorrhage are most common. As with other stimulants, tremor and tonic-clonic seizures can occur with acute intoxication. Any focal features of the seizure or in the postictal period should trigger a neuroimaging search for an underlying lesion.

A number of neuropsychatric complications are well described in chronic users of methamphetamines. Psychosis, attention-deficit hyperactivity disorder, and

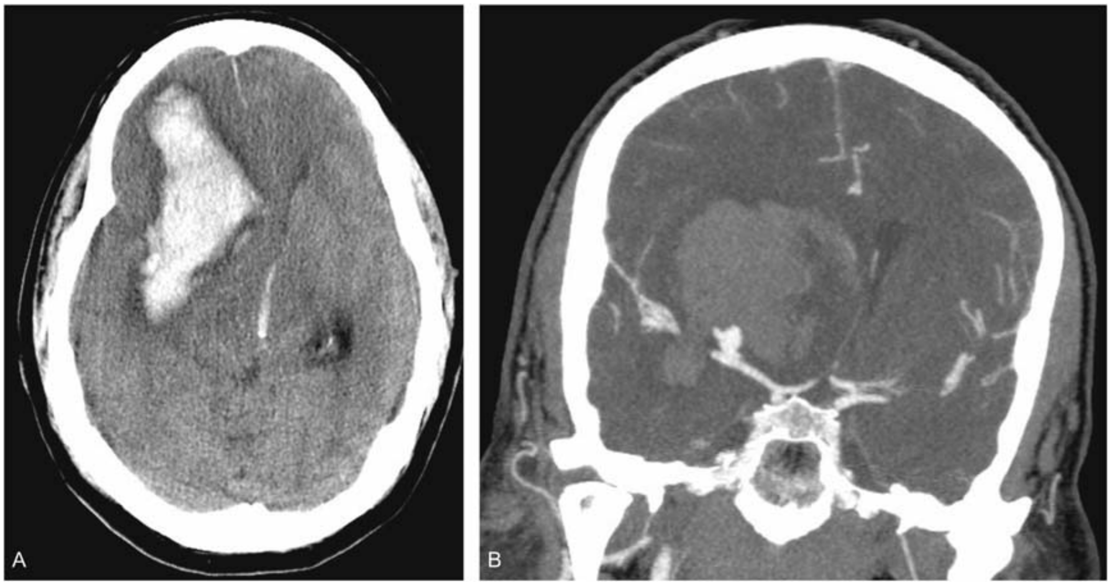

FIGURE 34-1 ■ Noncontrast CT (*A*) and CT angiogram (*B*) of the brain in a 41-year-old man with a history of chronic methamphetamine abuse who presented with confusion and left hemiparesis. A large right-hemispheric intracerebral hemorrhage is demonstrated, resulting from a bilobed 8 × 8 × 6-mm aneurysm in the region of the right middle cerebral artery bifurcation.

chronic memory and executive function deficits may occur, with resultant-poor psychosocial and behavioral outcomes. Individuals who chronically abuse methamphetamines typically require psychologic assistance in addition to substance abuse counseling. The chronic neurotoxicity that leads to these complications is thought to involve both dopaminergic and serotonergic fronto-striatal-thalamocortical networks. Compulsive performance of repetitive, mechanical tasks such as assembling or disassembling an object, termed "punding," is likely the result of this dopaminergic overactivity and is well described in chronic users of methamphetamines (termed "tweaking" by some users).[3] Although studies have been mixed, users of methamphetamines may have an increased risk of developing parkinsonism later in life due to involvement of striatal dopamine pathways; additional longitudinal investigations are addressing this possibility.

Cerebrovascular complications of chronic methamphetamine use include the development of an often dramatic cerebral vasculopathy with fusiform enlargement of the large vessels of the brain with a tendency toward aneurysm formation (Fig. 34-1). These aneurysms can be large enough to contain clot, which serves as an embolic source for ischemic stroke. Other patients with vasculopathy in the setting of methamphetamine use demonstrate narrowing of some distal branches of the cerebral vessels, leading to ischemia.[4] It is likely that this vasculopathy is a result, at least in part, of direct toxicity of the drug or adulterants rather than simply the consequence of hypertension. Some have suggested an inflammatory process (e.g., cerebral vasculitis) within the vessel wall, although studies supporting this have been mixed, and typical findings in the cerebrospinal fluid and on histologic and gross pathologic examination are noninflammatory.

In addition to an increased risk of ischemic stroke, methamphetamine abusers have an increased risk of subarachnoid hemorrhage relating to their tendency to aneurysm formation. In patients with methamphetamine-related subarachnoid hemorrhage, the complications of vasospasm and delayed cerebral ischemia are particularly common and severe, even when adjusted for severity of bleed. These effects are apparently more long-lasting than in most patients with aneurysmal subarachnoid hemorrhage and require vigilance for 3 to 4 weeks following initial bleed. As a result, subarachnoid hemorrhage has a worse prognosis when related to methamphetamine use than otherwise, when adjusted for Hunt and Hess grade. Similar to cocaine, methamphetamines can also importantly lead to a cardiomyopathy, myocardial ischemia, or aortic dissection, all of which predispose patients to stroke.

BATH SALTS AND FLAKKA

An increase of the use of so-called bath salts has been recently observed, particularly in the United

States. These compounds, which contain various synthetic cathinones and have no relationship with actual substances used in bathing, are usually swallowed or snorted with effects similar to other stimulants.[5] The mechanism of action involves interactions with plasma membrane transporters for dopamine, norepinephrine, and serotonin; the duration of action is typically 3 to 4 hours. Low doses often produce euphoria and increased alertness, but neurologic side effects include tremors and seizures as well as hallucinations, agitation, and dysphoria among some users. An agitated delirium can result that is often accompanied by tachycardia and hyperthermia; this constellation of findings should alert healthcare workers to possible ingestion of these substances, which are not detected by typical drug screens. These compounds were until recently widely available legally in over-the-counter form. A related synthetic compound, "flakka", was previously legally available and has led to outbreaks beginning in 2014 of a striking hyperactive delirium and rhabdomyolysis; combining this so-called zombie drug with other sedatives and amphetamines is common, especially among young persons.

MDMA (ECSTASY)

The synthetic compound 3,4-methylenedioxymethamphetamine (MDMA, ecstasy, "Molly") is a serotonergic amphetamine that became popular at dance parties ("raves") and is often taken in combination with other psychotropic drugs. As with other stimulants, the desired effects among users are euphoria and a sense of well-being. Ecstasy is also known for leading to disinhibition and sexual arousal. In some patients, agitation and anxiety can paradoxically occur at the time of intoxication or once the acute effects of the drug have worn off.

The association between severe hyponatremia and MDMA ingestion is important to recognize and can lead to serious neurologic complications. Users of the drug develop both a primary polydipsia and a drug-induced increase in antidiuretic hormone secretion, limiting the ability of the kidneys to secrete water and leading to, at times, a precipitous decline in the serum sodium level. The polydipsia may be in part due to an attempt among users to avoid hyperthermia in crowded dance arenas. The resultant hyponatremia may lead to seizures as well as potentially fatal cerebral edema; therefore, serum sodium measurement is important in any patient presenting with altered mental status or seizures following MDMA use. Careful correction is important to avoid osmotic demyelination, as discussed in Chapter 17, although in the setting of life-threatening neurologic complications, more rapid correction may be necessary. As is the case with most stimulants, seizures can also occur with MDMA ingestion independent of the serum sodium level.

Use of MDMA can also lead to a serotonin syndrome characterized by altered mental status, fever, and other neurologic abnormalities such as clonus, myoclonus, and tremor. There is likely a spectrum of this disorder ranging from mild confusion to life-threatening circulatory collapse when autonomic instability occurs. The risk of serotonin syndrome increases when MDMA is combined with other serotonergic drugs such as selective serotonin reuptake inhibitors. Treatment options include supportive care in a cool environment for milder cases to treatment with cyproheptadine in more severe instances.

Individuals with a history of heavy use of MDMA appear to demonstrate cognitive problems in memory and attentional domains that may be long-lasting.[6] Some studies, however, have suggested that these cognitive deficits may relate, at least in part, to underlying comorbidities, including the behavioral and psychologic disturbances that led originally to use of recreational drugs. These chronic cognitive effects seem to be mainly observed in those with a history of heavy use rather than in those with more infrequent use of the drug.

GAMMA HYDROXYBUTYRATE

Gamma hydroxybutyrate (GHB) leads to both euphoria and stimulant effects with purported sexual enhancement and disinhibition. The drug is the precursor to γ-aminobutyric acid (GABA), one of the most common inhibitory neurotransmitters in the central nervous system. Previously marketed for body-building, it is now used recreationally, often simultaneously with other "club drugs" including MDMA. The drug is ingested orally, usually in liquid form. GHB has a narrow window of safety and therefore overdosing and emergency department visits are common.[7] Interestingly, the drug has found a therapeutic purpose and is marketed for treatment of narcolepsy with cataplexy or excessive daytime sleepiness.

The most commonly cited neurologic effect of GHB intoxication is coma, which may occur rapidly after ingestion and necessitate intubation and admission to the hospital in order to protect the airway and avoid fatal ventilatory failure. Since GHB is not detected in most routine urine toxicology screens, neurologists are often consulted for an otherwise unexplained coma in a young person. An impressively sudden reversal of coma is sometimes observed, which is strongly suggestive of GHB intoxication. Other neurologic complications of acute use include ataxia and nystagmus. Its effects on consciousness may preclude safe driving.

When GHB wears off, an agitated delirium with self-injurious behavior may be observed, and some patients will alternate quickly between agitated and sedated states. Patients with GHB intoxication are at risk of seizures, and myoclonus is typically seen especially when patients are in the agitated phase. Patients using GHB are usually quite amnestic to events, even when they are conscious, leading to its use in sexual assault.

SEDATIVE-HYPNOTICS

The sedative-hypnotic class of drugs is mainly used for medical purposes including induction of sleep and relief of anxiety. However, these compounds have developed into common drugs of abuse with a potential for dependence as prescription drug abuse has increased. Historically, barbiturates were replaced by the benzodiazepine class of drugs in part due to an increased safety profile in overdose; however, both classes of drug have a similar potential for abuse. The sedative and anxiolytic properties of all of these medications resemble those of alcohol since both act in part at the level of the GABA system in the brain; alcohol withdrawal syndromes are treated with long-acting forms of these drugs.

The sedation that accompanies acute intoxication represents an important neurologic manifestation of these compounds that is typically easy to recognize. Reversal of acute intoxication with benzodiazepines by flumazenil, a benzodiazepine receptor antagonist, for purely diagnostic purposes is generally discouraged, and its use is limited to life-threatening situations, given its tendency to produce seizures and rapidly induce withdrawal.

The most important neurologic effects of sedative medications involve withdrawal, which can lead to tachycardia, agitation, tremor, and hallucinations that may develop into frank psychosis. Seizures are an important concern, and abrupt withdrawal of these medications can lead to ictal events even in those without an underlying epileptic disorder. Treatment for these seizures usually involves administration of benzodiazepines, often in intravenous form, followed by a slow taper which may need to last for days or weeks depending on the duration and dose of use prior to withdrawal. As a general rule, traditional antiepileptic medications that are not of the benzodiazepine or barbiturate class are ineffective.

Recently, a number of benzodiazepine-related substances including zolpidem, zaleplon, and eszopiclone have emerged with a safety profile that is so favorable that they are available in many countries without a prescription for use as a short-term sleeping aid. With this greater availability has emerged a potential for abuse as well as symptoms of withdrawal with prolonged exposure. Some patients may inadvertently use these medications at doses or frequencies that have potentially dangerous effects.[8] Zolpidem in particular has also been widely used by teenagers in the United States to produce a high rather than induction of sleep. Neurologic symptoms that have been described include depression, behavioral changes including irritability, unusual complex behaviors similar to sleepwalking, and severe amnesia for events, leading it to be used by sexual predators.

OPIATES

Abuse of opiates remains an extremely important public health concern. Emphasis has shifted from abuse of intravenous heroin and similar substances to recreational use of opiates prescribed for pain relief.[9] Physicians need to be particularly aware of this possibility when prescribing these medications—many of these drugs end up either for sale on the street or abused by persons other than the individual for whom the prescription was intended.

The neurologic effects of opiate intoxication are well known and include miosis and an altered mental status that can progress to coma with high doses, especially in those without previous exposure to this class of medications. Some specific opiates can lead to seizures, including fentanyl, meperidine (particularly in the setting of renal insufficiency), tramadol, and pentazocine. Individuals taking opiates reliably demonstrate diffuse myoclonus, which can be mistaken for seizures or a separate movement disorder, often leading to neurologic

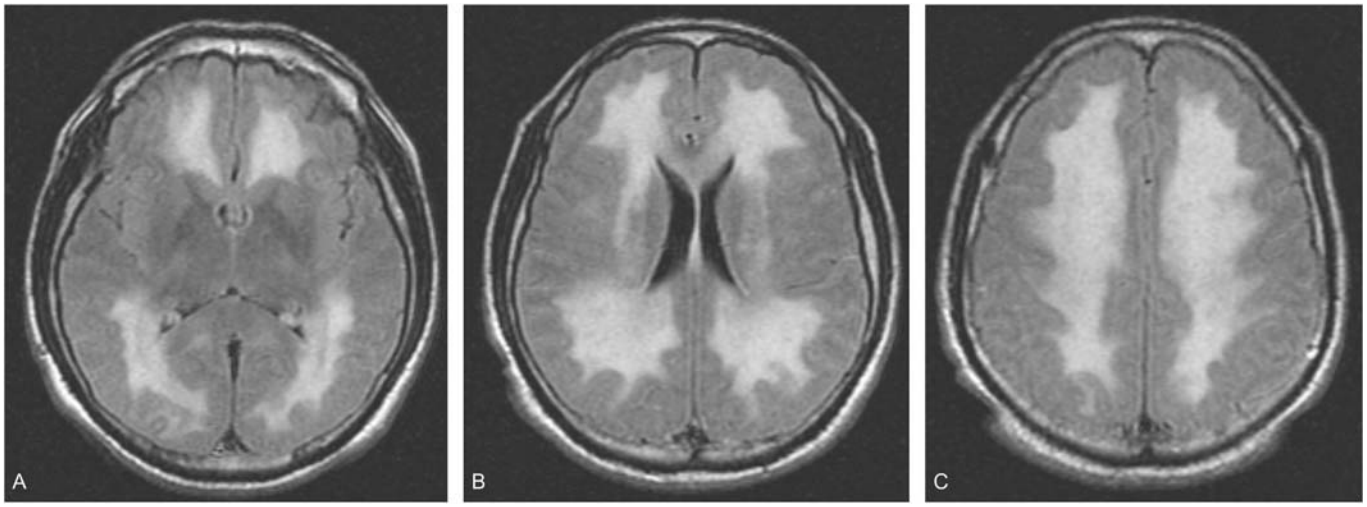

FIGURE 34-2 ■ Axial FLAIR MRI images of the brain from a 39-year-old man presenting with progressive altered mental status and parkinsonism 7 days after inhalation of vaporized heroin ("chasing the dragon"). Extensive white matter hyperintensities spare the subcortical U-fibers. No enhancement occurred on postcontrast images (not shown).

consultation; this condition is generally self-limited and of no consequence, reversing with discontinuation of the drug. Patients in whom opiate intoxication has led to profound respiratory depression are at risk of hypoxic-ischemic injury to the brain and may present with persistent coma even after withdrawal or reversal of opiates. Changes on neuroimaging may be nonexistent or subtle in cases of hypoxic-ischemic injury, and therefore the condition is a diagnosis of exclusion.

There are a number of neuromuscular complications of which opiate abusers are at risk. Myalgias can represent direct muscle involvement from opiate intoxication; frank rhabdomyolysis remains a rare but important complication that needs to be treated aggressively in order to prevent acute kidney injury. Repeated intramuscular injections of opiates may lead to a fibrotic myopathy due to a local direct toxic effect, and therefore users who inject opiates should be asked regarding site of injection.

Beginning in the mid-1990s, an epidemic of wound botulism was described, mainly in California, in users of so-called black tar heroin when the drug was administered via skin popping. This important public health concern can present with outbreaks of multiple cases of botulism in a single community when a batch of the substance becomes contaminated with *Clostridium botulinum*. Patients present with weakness and depressed muscle stretch reflexes, often along with bulbar signs that include difficulty swallowing, double vision, and slurred speech from facial weakness. The pupils may be dilated and poorly reactive to light, but this varies with the serotype of the offending organism and therefore should not be used to make or exclude the diagnosis. If botulism is recognized at an early stage, antitoxin administration is important to avoid ventilatory failure from neuromuscular weakness, which in many cases may be prolonged and necessitate tracheostomy.

Withdrawal from opiate medications reliably leads to dysphoria and akathisia. Muscle pain, nausea, vomiting, yawning, and rhinorrhea are a few of the non-neurologic symptoms of withdrawal that are well recognized. Treatment of life-threatening acute intoxication involves administration of opiate antagonists such as naloxone, which increasingly is widely available to the public in many communities to combat a rise in fatal overdoses. Complications from withdrawal symptoms should be anticipated when these antagonists are given, especially in patients who are chronic users or in whom use involves longer-acting opiate preparations.

When an opiate, often heroin, is inhaled by the user after vaporization on a piece of aluminum foil ("chasing the dragon"), a toxic leukoencephalopathy may result and is characterized on magnetic resonance imaging (MRI) by diffuse and symmetric T2 hyperintensities in the white matter (Fig. 34-2).[10] Symptoms range from mild abulia and parkinsonism to akinetic mutism or coma. Onset of the disorder may be delayed by days to weeks following opiate exposure, and clinical and neuroimaging features may progress before reaching a plateau after a few weeks. There is no effective treatment. Postmortem examination reveals a spongiform-like degeneration in the white matter that spares the U-fibers.

An important, mainly historical, opiate compound is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which in the early 1980s was found to cause a parkinsonian syndrome when the drug was inadvertently created in an attempt to create a synthetic form of meperidine. MPTP leads to neuronal death over a fairly short period of time in neurons in the substantia nigra pars compacta and has led to the development of an important animal model of Parkinson disease.

HALLUCINOGENS

The intent of use of hallucinogens is to alter neurologic perception and mood, often leading to vivid visual illusions which may be colorful and well formed. A distortion of sensory input and synesthesia occurs with the prototypic drug lysergic acid diethylamide (LSD). At times, LSD ingestion can be characterized paradoxically by agitation, panic, or dysphoria in what is termed a “bad trip” by users. Rare adverse effects that may be due to LSD or its adulterants include more permanent visual disturbances and vasospasm leading to cerebral ischemia. Due to its effects on the serotonin receptors in the brain, serotonin syndrome can result, especially when LSD is combined with other serotonergic drugs including prescription antidepressants.

Long-term effects of LSD use may include “flashbacks,” where a hallucination that accompanied intoxication is experienced again months to years later and is usually not distressing. Exposure to serotonergic drugs may be the trigger for such flashbacks in some patients. In contrast, hallucinogen persisting perception disorder is a long-term and potentially disabling recurrent condition in which hallucinations are experienced again; the disorder is unpleasant, disruptive, and difficult to treat.[11]

Other important drugs of abuse with properties similar to LSD include mescaline, which is found in the peyote cactus in the southwestern United States. Ingestion leads to tachycardia, agitation, and mydriasis along with hallucinations and altered perceptions. Mushroom intoxication recreationally involves those that contain psilocybin and are consumed often in dried form; headache often accompanies intoxication with these so-called magic mushrooms.

N-METHYL-D-ASPARTATE ANTAGONISTS

Phencyclidine (PCP, “angel dust”) was first developed as a surgical anesthetic, but some patients developed a long-lasting psychotic syndrome following its administration. The drug subsequently emerged as a recreational drug of abuse due to its dissociative effects. One important site of action for PCP is antagonism of *N*-methyl-D-aspartate (NMDA) glutamate receptors, which are widely distributed in the brain, especially in the medial temporal lobes and throughout the limbic system.

Manifestations of PCP intoxication in the emergency setting include tachycardia, hypertension, violent outbursts, and nystagmus, which classically can be vertical in direction. Higher doses of PCP may induce an acute psychosis with hallucinations and agitation, whereas a striking akinetic mutism with unresponsiveness and preserved eye opening may accompany overdose. PCP’s stimulant effects can lead to hyperreflexia as well as dystonia and occasionally seizures. The agitation that results may itself cause rhabdomyolysis, which has otherwise been attributed to a direct toxic effect of the drug. Long-term use of PCP can lead to a condition resembling chronic schizophrenia, and the drug has been used to create animal models of schizophrenia for research purposes.

The anesthetic ketamine has also emerged as a recreational drug of abuse, sometimes in those prescribed the medication for chronic pain. The main mechanism of action involves NMDA antagonism similar to PCP. One of the advantages of its use in anesthetic settings is its relatively favorable safety profile in high doses and, similarly, respiratory depression is an extremely rare occurrence in abusers. Intoxication is characterized by acute CNS depressant effects of slurred speech and impaired consciousness and can lead to injury. Long-term effects of use may not only partially mimic schizophrenia as is the case with PCP, but may also lead to a more subtle permanent cognitive disorder with deficits of memory and mood. A nasal form of the drug recently has been approved in some countries for the treatment of refractory depression; whether this will lead to increased abuse as the drug becomes more readily available remains to be seen.

DEXTROMETHORPHAN

Dextromethorphan has been used for decades as a cough suppressant but has emerged more recently as a recreational drug of abuse, especially among teenagers due to its stimulant and dissociative properties.[12] At high doses, dextromethorphan can present with PCP-like effects on NMDA receptors. Patients

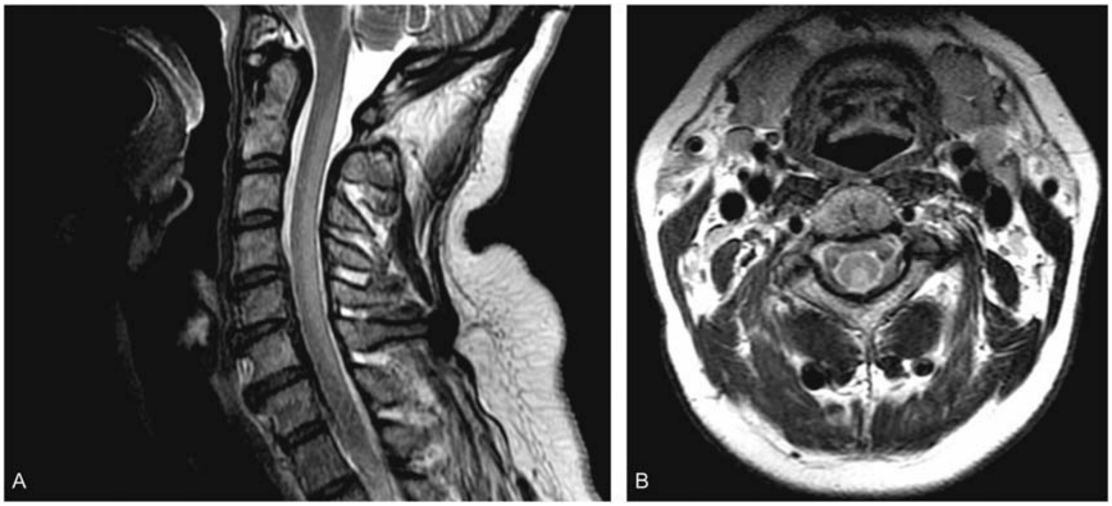

FIGURE 34-3 ■ Sagittal (*A*) and axial (*B*) T2-weighted MR images of the cervical spine in a 51-year-old woman presenting with gait difficulties and ataxia following a 6-month history of recreational nitrous oxide abuse. Hyperintensity is demonstrated in the posterior portion of the cord, corresponding to the location of the dorsal column pathways.

may present with hallucinations, agitation, and ataxia; although in its extreme form coma can result. Elevated blood pressure and heart rate are common along with stimulant and perceptual effects similar to psilocybin. Serotonin syndrome can result from overdose, especially when combined with other serotonergic agents. Widespread abuse of the drug has led to regulatory controls in many states of over-the-counter sale of dextromethorphan-containing compounds.

NITROUS OXIDE

Nitrous oxide is often used recreationally by inhaling the gas from a balloon ("whippet") or other canisters such as those that deliver whipped cream, where the gas is used as a propellant. Although commonly used by young people recreationally, abuse among health-care providers with access to nitrous oxide, such as among those in the dental field, is also well documented.[13] The neurologic manifestations result from effects on vitamin B_{12} pathways. Under normal conditions, nitrous oxide converts vitamin B_{12} to an inactive form that inhibits a key enzyme used in DNA and RNA synthesis, methionine synthase. Patients present with similar symptoms and signs to those occurring with vitamin B_{12} deficiency, although the serum B_{12} level may be normal. Some patients who are exposed to nitrous oxide anesthesia may develop a similar syndrome if they have pre-existing vitamin B_{12} deficiency from, for example, pernicious anemia.

Central nervous system manifestations include psychosis and cognitive decline, but far more common is a myeloneuropathy with prominent posterior column signs. MR imaging may demonstrate increased T2 signal in the posterior columns, often with a predilection for the cervical spinal cord (Fig. 34-3). Patients present with a sensory ataxia, decreased vibratory and proprioceptive thresholds, and a spastic gait with or without weakness of the limbs. Some of these abnormalities can be reversed with vitamin B_{12} supplementation and abstinence from nitrous oxide use, but chronic users may not seek medical attention until the condition is irreversible.

MARIJUANA AND RELATED COMPOUNDS

Tetrahydrocannabinol (THC) is the principal active component of marijuana, which is typically smoked recreationally but can also be consumed orally, where its effects are more delayed. Marijuana use typically leads to euphoria as well as a decrease in anxiety and perceptual changes that can involve slowing of time and vivid colors. There may be relatively mild psychedelic effects in comparison with the hallucinogen class of drugs. Intoxicated patients demonstrate decreased coordination and gait along with psychomotor slowing that can impair safe driving. Some reports have rarely associated marijuana use with stroke, presumably on the basis of vasoconstriction as the likely mechanism. Some chronic heavy users may develop a withdrawal syndrome of irritability, fatigue, anxiety, and difficulty sleeping.

Chronic users of the drug may exhibit an amotivational syndrome characterized by apathy and lack of ambition and drive. It is unclear from the literature whether heavy users of marijuana can develop more permanent cognitive sequelae including deficits of executive function, memory, and attention.[14] Marijuana users appear to be at increased risk of developing psychotic disorders or affective symptoms, but these studies may be confounded by any underlying psychiatric disorder (or tendency) leading to marijuana or other drug use. The increased availability of this substance due to changes in state and federal laws in some jurisdictions will lead to increased focus on both beneficial and adverse events in the coming decade.

The terms “Spice” or “K2” are brand names used to describe a variety of herbal medicines that are widely available and mimic the effects of marijuana.[15] These synthetic compounds may be labeled as “incense” or “herbal smoking products” and have only recently been banned from over-the-counter sale in the United States. Although these drugs resemble cannabinoids, they are often not detectable in the usual screens for THC in the urine; emergency medical personal should be aware of these drugs in patients presenting with symptoms and signs of marijuana intoxication with negative drug screens.

INFECTIOUS COMPLICATIONS OF INJECTION DRUG USE

Many of the recreational drugs discussed here are administered intravenously, and the risk of infectious complications is substantial. This risk is due not only to sharing of needles with associated bacterial and viral contaminants, but also to a lack of sterile technique that can introduce skin flora and other nearby bacteria into the blood stream.

Endocarditis remains an important cause of stroke and cerebral abscess among those with intravenous drug abuse. *Staphylococcus* and *Streptococcus* species are particularly common culprits. Embolic ischemic strokes from endocarditis have a propensity for hemorrhagic transformation, and septic emboli should be considered in patients presenting with multiple hemorrhagic strokes. Subarachnoid hemorrhage may result from ruptured mycotic aneurysms. Those that are ruptured should be secured, usually via surgical clipping; unruptured mycotic aneurysms that are stable are usually treated with antibiotics alone, despite the lack of good data supporting this practice. Intracerebral abscess is a dreaded complication that usually begins as a less walled-off cerebritis, occasionally in the setting of endocarditis; early surgical management is typically recommended along with administration of broad-spectrum intravenously administered antibiotics with good penetration across the blood−brain barrier.

Bacteremia can also lead to seeding of the spinal column and thus to discitis, osteomyelitis, and epidural abscess, important considerations when patients with a history of intravenous drug use present with new back pain, with or without fever. MR imaging is the modality of choice for the spinal cord, and surgery with intravenous administration of antibiotics is the preferred treatment when clinical signs of spinal cord compression are present.

Sharing of needles can also lead to infections such as with human immunodeficiency virus, human T-lymphotropic virus types 1 and 2, and hepatitis virus. Their neurologic presentations are discussed in Chapters 42 and 43. Clinicians need to be aware of these infections and their neurologic complications in patients with a history of intravenous drug use.

CONCLUDING COMMENTS

Neurologic complications of drug abuse continue to be common, and knowledge of these substances and their effects, both during intoxication and with chronic use, is essential for evaluation of patients presenting with neurologic disorders. Because new substances and methods of ingestion are continually emerging, physicians should remain familiar with current recognition and management decisions in this rapidly changing field.

  - *Delayed Syndrome: Polyneuropathy*
  - *Prolonged Low-Level Exposure*
- Organochlorine and Pyrethroid Insecticides
- Pesticides, Herbicides, and Parkinsonism

CONCLUDING COMMENTS

Occupationally related disorders are commonly due to injury or to working conditions that involve physical strain, such as hand-arm vibration or performing the same movement repetitively. These disorders are not the focus of the present chapter, which is concerned instead with the consequences of exposure to neurotoxins in the workplace. Many of the chemical agents present in the workplace environment may produce behavioral, cognitive, motor, sensory, or autonomic disturbances resulting from disorders of the central or peripheral nervous system (CNS or PNS). Exposure to such neurotoxic substances may affect workers using them or involved in their manufacture as well as those exposed in industrial, agricultural, horticultural, or military settings. The occurrence of such occupationally related neurotoxic disorders has been known for centuries, but their prevalence is unknown.

In order to demonstrate that a particular chemical is neurotoxic or that a certain syndrome is due to neurotoxin exposure, it must be shown that the suspected neurotoxin causes neurologic dysfunction of a consistent nature in exposed humans. The disorder occurring in one subject must be consistent in character with that occurring in others exposed to the same chemical agent. The neurologic manifestations must be related temporally to exposure to the presumed toxin, and their subsequent course should accord with the biologic properties of that toxin. In other words, the clinical disorder must be biologically plausible. The nature of the toxin and the intensity of exposure will determine how soon after exposure any symptoms develop. The neurologic dysfunction may vary in severity between individuals but—depending on their level of exposure—all exposed workers should have some signs of neurotoxicity. Involvement of a single worker suggests that the disorder is not due to a toxin, that toxin exposure did not occur at work, or that exposure resulted from some individual work habit, such as failure to use a protective mask. Diagnosis of an occupationally related neurotoxic disorder may be difficult when symptoms are common and nonspecific and may occur for a variety of reasons. Moreover, once a neurotoxic disorder is suspected, identical symptoms may develop in suggestible subjects with little or no exposure to the presumed toxin.

Ideally, to establish the toxic basis of a neurologic disorder, it should be possible to identify reproducible pathologic or pathophysiologic changes in the nervous system in humans or experimentally in animals, and these should account for the clinical features of the disorder. In practice, it is often not feasible to reproduce a suspected neurotoxic syndrome in animals. Variation in species susceptibility may be responsible, and certain impairments (e.g., cognitive or affective disturbances) are anyway difficult to reproduce in animals. Furthermore, human exposure is often to combinations of several chemicals, which individually may be harmless but in combination lead to neurologic dysfunction. This is because the effects of the different chemicals may be additive or one may potentiate the neurotoxic effects of another, as is illustrated by the effect of adding the nontoxic methyl ethyl ketone to a lowered concentration of the known neurotoxin *n*-hexane, a practice that led in the past to an outbreak of toxic neuropathy.

The temporal profile of the clinical disorder may be informative. Depending on the toxic agent, there is often little or no latent period between the time of exposure and onset of symptoms, but certain toxic neuropathies (arsenic, thallium, organophosphates) occur after a delay on the order of 2 to 3 weeks. Although cessation of exposure may lead to clinical stabilization or improvement, deterioration may continue for some days to weeks after termination of exposure to certain neurotoxins, a phenomenon termed “coasting.”

Improvement of symptoms during periods away from work, such as at weekends or during vacations, may raise the possibility of a work-related exposure to a neurotoxin, but other factors may be responsible, such as anxiety or disputes with co-workers. These various points are summarized in Table 35-1.

TABLE 35-1 ■ Features Suggestive of an Occupational Neurotoxic Disorder

History of exposure to a potential neurotoxin

Pattern of neurologic dysfunction accords with previously reported cases

Exposed co-workers also affected

A temporal relation exists between toxin exposure and onset of symptoms, and between cessation of exposure and arrest of progression (sometimes after coasting)

If the pathologic and pathophysiologic bases of the disorder have been identified, they should be reproducible and account for the clinical disturbance; an animal model of the disorder may exist

Other causes of the disorder have been excluded

Attention must be directed at distinguishing between a neurotoxic and pseudoneurotoxic disorder. The latter may relate to a psychogenic illness or to the coincidental onset or worsening of an unrelated or preexisting disorder. Pseudoneurotoxic disorders may be accompanied or followed by the multiple chemical sensitivity syndrome, and by affective symptoms, lassitude, malaise, and social withdrawal. The underlying pathophysiology is unclear and there is no specific treatment, but any mood disturbance requires treatment.

MANIFESTATIONS OF OCCUPATIONAL NEUROTOXIC DISORDERS

There are usually no specific clinical manifestations of a neurotoxic disorder. The symptoms and signs are frequently indistinguishable from those of other neurologic disorders. General examination may, however, reveal additional features suggestive of a toxic cause, such as the presence of hyperkeratosis and desquamation of the skin of the palms and soles and of Mees lines in the nails of patients with arsenic exposure.

Acute Encephalopathy

An acute encephalopathy is a common but nonspecific manifestation that may consist solely of headache and malaise that settle shortly after exposure is discontinued. With more severe involvement, symptoms may come to include confusion, irritability, poor concentration, impaired judgment, drowsiness, vertigo, tinnitus, sensory complaints, ataxia, weakness or fatigue, and nausea and vomiting. Neurologic examination is usually normal. Neuropsychologic examination may be abnormal but, because recovery is rapid and complete (usually within 24 hours), is rarely performed. With continued exposure, level of consciousness becomes depressed, sometimes leading to coma; seizures may also occur. Recovery is then likely to be more protracted and may be incomplete. The cause of this acute syndrome usually is easy to determine because of the history of exposure, because many workers are affected, and because a variety of other manifestations are common, such as conjunctival, mucosal, and cutaneous irritation, and respiratory difficulties.

Chronic Encephalopathy

The occurrence of a chronic encephalopathy relating to long-term low-level neurotoxin exposure is widely reported but of uncertain validity. Its symptoms include headache, "dizziness," poor concentration, memory impairment, irritability, affective disorders, various sleep disturbances, loss of libido, numbness and paresthesias, and "weakness." Such symptoms are nonspecific in nature, usually mild in degree, but may lead to surprising disability. Examination is typically normal, but ataxia and nystagmus are sometimes found; the results of laboratory and electrophysiologic studies are generally unhelpful or of questionable significance or relevance. Neurobehavioral studies may be abnormal, but often the findings are inconsistent, difficult to interpret in the absence of premorbid baseline studies, and of uncertain relevance. At present, then, whether such an entity truly exists—and its pathophysiologic basis—remains unclear.

Peripheral Neuropathy

Peripheral neuropathy is a better understood consequence of toxin exposure in the workplace. It may occur as a delayed effect of single high-dose exposure or after short-term repeated exposure to certain organophosphates, arsenic, or thallium. Chronic exposure to these and other neurotoxins, such as acrylamide and many organic solvents, also leads to neuropathy, causing that portion of the axon farthest from the cell body to degenerate, a phenomenon described as a *distal axonal neuropathy* or *axonopathy*, or a *dying-back neuropathy*. Its clinical features are similar to those of neuropathies of other etiologies. Symptoms and signs begin distally in the legs and then progress proximally depending on the severity of exposure. Sensory axons pass both peripherally to the limbs and centrally into the spinal cord; both degenerate toward the cell body. Some of the central sensory fibers ascend in the posterior columns to the cuneate and gracile nuclei in the medulla and, because of their length, are often among the first to degenerate. As regeneration does not occur in the CNS, recovery after axonal degeneration will be incomplete despite effective regeneration of the peripheral nerves.

The presence of abnormalities on general examination may help to suggest a toxic cause of the neuropathy. For example, sweating and bullous dermatitis of the hands is found in acrylamide toxicity, and scalp alopecia occurs with thallium poisoning.

In subjects who are chronically exposed to other neurotoxins in the workplace but who have no clinical deficit, minor electrodiagnostic abnormalities are sometimes found. Although these will not necessarily progress to clinical neuropathy, such subjects need careful monitoring to limit exposure and minimize any risk of progression.

SCREENING AT-RISK WORKERS

Screening workers for signs of toxicity may help to identify individuals with incipient or subclinical neurologic dysfunction or exposure to low levels of a neurotoxin, and thereby limit further exposure. Screening of fellow workers may also be diagnostically helpful when a subject with a suspected, occupationally related, neurotoxic disorder is encountered, because similarly exposed workers are likely to have at least some symptoms and signs of intoxication, although to a varying degree that probably relates to differences in age, gender, ethnicity, genetic background, health status, and other factors. In general, however, screening techniques are insensitive and poorly tolerated by patients. They are also expensive and time-consuming.

Clinical Evaluation

An occupational history is an important part of the medical record, especially when patients with obscure neurologic disorders are encountered. Job titles may need clarification for the nature of an occupation to be appreciated. If exposure to toxins is suspected, a detailed list of chemicals used in the workplace—and at previous places of employment, if symptoms are longstanding—should be obtained. Details of the work environment are also important, such as whether it is well ventilated, the nature of any protective measures (such as a requirement to wear special clothing and gloves, and the use of other devices including masks and goggles), and the provisions made for washing after exposure and for storage of food. The most common routes of occupational exposure are inhalation and through the skin.

It may be necessary to question co-workers to determine whether they have similar symptoms to those of a subject with a suspected neurotoxic disorder, and even to examine those working in a similar environment. When asymptomatic but exposed co-workers are screened, questioning may be focused, based on the clinical features in recognized cases; self-administered, standardized symptom questionnaires may be especially helpful.

Neurotoxin exposure may also relate to environmental factors (such as a subject's residence or its location close to, for example, an industrial plant) and to social and personal factors (such as hobbies, other recreational activities, or dietary peculiarities) rather than to the workplace. The history must therefore exclude these possibilities.

Routine neurologic examination is of limited utility for screening purposes, its principal role being to exclude other conditions that might underlie the patient's symptoms. Generalized rather than focal neurologic abnormalities are the expected finding in many neurotoxic disorders. In some instances, however, focal findings—such as parkinsonism from manganese exposure—may be conspicuous. Techniques have been developed for quantifying aspects of the neurologic—especially the sensory—examination for screening purposes and for following changes over time. These include quantitative tests of muscle strength, coordination, body sway, balance, vibration and discriminative tactile sensibility, cold and warm thermal thresholds, and heat pain thresholds.

Electrodiagnostic Testing and Neuroimaging

Electroencephalography (EEG) and evoked potential studies can be used to assess CNS function. The EEG is commonly slowed diffusely—but occasionally more focally—in patients with acute toxic or metabolic encephalopathies, but may be normal in chronic encephalopathies. It is therefore of little use in screening patients for neurotoxic injury. Changes are nonspecific and do not distinguish between toxic and other encephalopathies or between different toxic disorders. Evoked potentials provide some measure of the functional integrity of certain afferent CNS pathways, but normal responses may show marked amplitude variation between subjects and on the two sides of the same subject. Because most neurotoxins produce axonal degeneration, which causes changes in amplitude rather than latency of responses, evoked potentials are of limited utility in evaluating patients with suspected neurotoxicity.

Electromyography (EMG) and nerve conduction studies evaluate the function of the PNS, neuromuscular junctions, and muscle. The findings help to identify subclinical disease, follow disease progression, and characterize the pathophysiologic basis of symptoms. Nerve conduction studies are useful in studying both axonal and demyelinating neuropathies. Needle EMG can indicate the cause of weakness and localize pathologic processes to different regions of the motor units (spinal cord, nerve root, plexus, peripheral nerve, neuromuscular junction, or muscle). When evaluating exposed workers, comparison with appropriate control subjects is important. For example, sedentary office workers should not be used as controls for manual workers, who frequently develop minor abnormalities of nerve conduction as a result of occupationally related, repeated minor trauma or subclinical entrapment neuropathies.

Neuroimaging of the CNS, when normal, does not exclude a neurotoxic disorder. In some instances, however, the findings may show characteristic abnormalities, such as in manganese poisoning, discussed later.

Neuropsychologic Evaluation

Advances in neuropsychologic test procedures have improved their utility as a screening device. Such test procedures may reveal subtle cognitive dysfunction but the findings are not diagnostic of toxic encephalopathy. Moreover, testing is time-consuming even when self-administered questionnaires and computerized test procedures are used, and thus costly and impractical for screening large numbers of subjects. Careful matching for age, gender, ethnicity, and social, cultural, and educational background is necessary when making comparisons between groups.

Other Laboratory Testing

Workers with possible occupationally related neurotoxic disorders commonly come to medical attention when exposure has already ceased and laboratory testing is of limited utility. With the exception of screening for heavy metal excretion in the urine or their presence in other tissues, laboratory studies are generally unhelpful in screening for neurotoxic disorders.

SELECTED NEUROTOXIC DISORDERS

Only a limited number of neurotoxins and the disorders that they produce can be discussed in the space available here, and readers seeking more specialized information should consult standard textbooks or compendia on neurotoxicology.

Organic Solvents

Organic solvents, either individually or in combinations, are widely used in the workplace, for example, as cleaners, degreasers, and thinners, and in manufacturing other chemicals. Most are highly volatile liquids. Accordingly, exposure occurs primarily by inhalation, so the risk of toxicity is greatest in poorly ventilated areas. Some absorption also takes place through the skin, especially of those solvents that are both lipid and water soluble and are somewhat less volatile.

Ridgway and co-workers assessed the published evidence that industrial organic solvents as a generic group can induce long-term neurologic damage detectable by brain imaging, neurophysiologic testing, or postmortem studies of exposed workers.[1] Some of the studies provided evidence for marginal atrophic abnormalities in the brain or deficits in nerve conduction velocity in solvent-exposed workers. However, methodologic limitations, absence of a consistently strong association between exposure and effect, lack of a dose–response relationship, the nonspecific nature of the reported changes, and the lack of coherence between the human and experimental animal data were problematic. Overall they were unable to draw reliable conclusions with respect to the presence or absence of nervous system damage related to the common properties of organic solvents.

CENTRAL EFFECTS

Most organic solvents have high lipid solubility, so that they rapidly enter the brain and act as nonspecific depressants of the CNS. Acute exposure can cause the syndrome of acute encephalopathy described earlier. The exposed individual must be removed from exposure; recovery after mild exposure occurs rapidly (minutes to hours), usually without sequelae, although headache may continue for longer. When exposure has led to coma, however, recovery may be incomplete, perhaps because of hypoxic brain damage.

Several epidemiologic studies have suggested that neuropsychologic dysfunction has an increased prevalence in spray painters, who are chronically exposed to solvents used as thinners. Both level and duration of exposure may be important in its development. However, it is unclear whether the entity of painters' encephalopathy truly exists, because it is based on studies, mainly from the 1970s, which are so methodologically flawed that they are invalid. These studies were primarily epidemiologic in nature. Objections to them include concerns about the manner in which neuropsychologic tests were conducted and that other factors (such as alcohol, medications, or the residual effect of acute solvent exposure) may have caused the encephalopathic features ascribed to chronic exposure. Details concerning work conditions and extent of solvent exposure were often not provided or based on subjective recall. Some studies failed to allow for the influence of various confounding factors on neuropsychologic test results. In others, inappropriate controls may have confounded any comparisons that were made. This is well exemplified by the study of Gade and co-workers, in which 20 solvent-exposed workers, mostly painters, were re-examined 2 years after the diagnosis of chronic toxic encephalopathy was made.[2] Neuropsychologic test results were unchanged, but the earlier impression of significant cognitive decline was not confirmed when comparison was now made to a nonexposed control group and allowance was made for age, educational background, and level of intelligence.

Nevertheless, the concept of painters' encephalopathy has come to be accepted by many authorities and diagnostic criteria have been proposed by several working groups and organizations despite the doubts that exist concerning its existence as a specific entity. It appears to be nonprogressive, with no deterioration of functioning—or, in some cases, improvement—occurring after diagnosis, presumably because of cessation of exposure. It is characterized by fatigue, irritability, mood changes, difficulty in concentration, forgetfulness, and impairment in various modalities on neuropsychologic testing. If such a syndrome of chronic painters' encephalopathy exists, it may have been caused by toluene, as most subjects were exposed to solvent mixtures, often of unknown composition, and toluene is a common constituent of such mixtures.

Chronic abuse of toluene in large doses taken for recreational purposes may cause dementia, ataxia, dysarthria, nystagmus, tremor, and spasticity. Magnetic resonance imaging (MRI) shows diffuse cerebral and cerebellar atrophy and widespread periventricular white matter lesions. Brainstem auditory evoked potentials (BAEPs) may be abnormal, even in the absence of clinical or neuroimaging abnormalities, suggesting that the BAEP may be useful for screening at-risk workers. A similar syndrome has not been seen with occupational exposure, perhaps because of the prolonged exposure to very large doses during abuse, but contamination of the solvents with other toxins or the concomitant use of other chemicals and drugs may also be relevant. In any event, the diagnosis of chronic solvent exposure is being made less often, perhaps because exposure to solvent mixtures has declined in developed countries, although many workers remain chronically exposed to such mixtures.[3]

A more persuasive example of toxic encephalopathy with chronic exposure to organic solvents is the chronic encephalopathy that follows long-term exposure to carbon disulfide, used to manufacture cellophane and rayon.

PERIPHERAL NEUROPATHY

Discussion here focuses on *n*-hexane and methyl *n*-butyl ketone (MnBK) because the use of these hexacarbons has led to several outbreaks of neuropathy. Their metabolite, 2,5-hexanedione, is primarily responsible for the distal axonopathy that occurs with repeated and prolonged exposure to *n*-hexane. Methyl ethyl ketone, a common constituent of organic solvent mixtures, potentiates the neurotoxic properties of *n*-hexane and MnBK.

Onset is typically insidious and progression occurs slowly. Numbness begins distally in the feet, spreading proximally with continuing exposure, and then comes to involve the hands. Motor disturbances are less conspicuous but, in severe cases, mild footdrop and weakness of the intrinsic hand muscles develop. With recreational exposure, which is typically heavier than occupational exposure, more rapid progression occurs and symptoms may be more extensive and severe. Examination shows significant cutaneous sensory deficits, and loss or attenuation of muscle stretch reflexes, especially distally. Gradual improvement (by axonal regeneration) eventually follows cessation of exposure, but coasting may occur for a period of several weeks.

Electrodiagnostic screening is useful in the detection of subclinical hexacarbon neuropathy. In a major outbreak of MnBK neuropathy in Ohio, 43 percent of cases had characteristic electrophysiologic abnormalities in the absence of symptoms and signs of neuropathy.[4] Needle electromyography usually showed signs of active denervation in distal leg muscles, and motor conduction velocity was slowed. Pathologically, the neuropathy is characterized by defective axonal transport, axonal degeneration, and secondary demyelination. Such changes may be seen on sural nerve biopsy and are also present at autopsy in the distal (i.e., most rostral) portion of the sensory axons in the posterior columns of the spinal cord.

A distal axonopathy can also result from exposure to trichloroethylene, which has been used as a degreaser. It is confined to the cranial nerves, initially the trigeminal nerve, with early onset of facial numbness, analgesia, or dysesthesias and later weakness of the masticatory muscles. The lower cranial nerves are involved in some patients; optic neuropathy (with an enlarged blind spot, paracentral scotoma, or constricted fields) has also been described. Recovery occurs with time after discontinuation of exposure, but patchy facial sensory loss may persist indefinitely.

Heavy Metals

Heavy metals accumulate, especially in bone, during lengthy periods of low-level exposure, as in the workplace, and it may take years to eliminate them from the body. Heavy metals are neurotoxic but also have other effects, particularly on the hematopoietic and gastrointestinal systems. The present discussion focuses on lead and arsenic, as exposure to these is most likely to occur, on mercury because of the large outbreaks that have occurred in the past (to environmental rather than occupational exposure), and on manganese because of suggestions that it may be a cause of classic Parkinson disease.

LEAD

Industrial exposure is mainly to inorganic lead and occurs by inhalation of fine particulate matter; lead may also be absorbed after ingestion, as occurs in children. Occupational exposure occurs in the construction industry as well as in various other industrial settings (such as lead production or smelting; scrap metal handling; battery manufacturing; lead and other metal foundries; lead soldering; metal radiator repair; firing ranges; and ceramics or plastics manufacturing). Lead is taken up into bone and then slowly released into the blood over many years and excreted primarily through the urine, with smaller amounts in feces, hair, nails, and sweat.

There is increasing concern about the health effects of lead at blood levels once thought to be harmless. For example, a causal relationship of low-level lead exposure to hypertension has been found, with implications for stroke prevention, as has an association with declining cognitive function and with the development of amyotrophic lateral sclerosis. Preliminary studies suggest also that cumulative exposure to lead increases the risk of Parkinson disease. Recent studies have led to a reappraisal of the levels of lead exposure that may be safely tolerated in the workplace.[5] It is important that workers are in well-ventilated premises; wear appropriate personal protective equipment such as goggles, boots, special clothing, and proper respiratory protection; shower after work; and undergo routine determination of blood lead level.

Lead Encephalopathy

Acute occupational exposure to lead results mainly in systemic effects involving the hematopoietic, gastrointestinal, and renal systems, rather than the nervous system. An acute lead encephalopathy, resulting from increasing cerebral edema, tends to occur in children rather than exposed workers and is therefore not considered further here. A chronic encephalopathy may follow long-term exposure to low levels of lead, and progressive cerebral atrophy can occur long after further exposure is prevented.[6] Symptoms may include apathy, fatigue, insomnia, reduced libido, headache, irritability, memory loss, and difficulty in concentration; testing reveals neuropsychologic and neurophysiologic abnormalities.

Lead Neuropathy

Chronic exposure (i.e., for several years) to lead causes neuropathy. In one study, the average duration of exposure in subjects with lead neuropathy was almost 22 years. Nerve conduction slowing may occur earlier, increasing with duration of exposure and blood lead levels, but whether these neurophysiologic changes progress to overt neuropathy is unclear.

Lead neuropathy, when it develops subacutely, is unusual in that it is predominantly motor, often asymmetric, and affects the arms more than the legs, and the wrist and finger extensors more than other muscles. Wrist drop is characteristic. This form of neuropathy typically develops after a relatively short period of intense exposure.[7] A more typical toxic neuropathy, with distal sensory impairment and weakness, may also occur, however, especially after prolonged exposure.[7] Individuals with lead neuropathy generally have a microcytic, hypochromic anemia; basophilic stippling of red blood cells is not always present and is not specific for lead poisoning. In patients with continuing exposure to lead, neuropathy is unlikely if the urinary δ-aminolevulinic acid (δALA) is normal. Lead interferes with hemoglobin synthesis by inhibiting the enzyme δALA dehydrase, and the enzyme substrate begins to appear in the urine when the blood lead level reaches 40 to 50 μg/dL, which is less than the level at which neuropathy usually results. An increased blood lead level or increased 24-hour urinary excretion should also be present in patients with suspected lead neuropathy, provided that exposure to lead is ongoing. When the blood lead level is mildly elevated ($>$ 25 μg/dL), it may be helpful to measure free erythrocyte protoporphyrin or zinc protoporphyrin, which reflect the inhibitory effect of lead on enzymes involved in hemoglobin synthesis and thus the lead exposure over the preceding 3 months. Past excessive exposure to lead can be measured through its accumulation in teeth or bones, but this is seldom practical.

The pathophysiologic basis of lead neuropathy in humans is unknown. There are species differences in the effects of lead on the nervous system. The early development of slowed conduction velocity suggests that the primary pathologic process is demyelination, but in established neuropathy the predominant abnormality is axonal degeneration.[7]

Management involves removal of the individual from the toxic environment to prevent further exposure. Workers exposed to lead occupationally should undergo regular determination of the blood lead level, and exposure terminated in those with an increased level before neuropathy develops. The blood lead level reflects the amount of lead in the blood and soft tissues but does not indicate either previous or current exposure, or total body burden. National and state guidelines indicate surveillance requirements (including blood level monitoring requirements) for at-risk workers, such as those of the California Department of Public Health Occupational Lead Poisoning Prevention Program. Based on a literature review and their own experience in evaluating lead-exposed adults, Kosnett and colleagues recommended in 2007 that subjects should be removed from occupational lead exposure if a single blood lead level exceeds 30 μg/dL or two successive blood lead levels measured over a 4-week interval exceed 19 μg/dL.[5] Removal of individuals from lead exposure should be considered to avoid long-term risk to health if exposure control measures over an extended period do not decrease blood lead concentrations to less than 10 μg/dL or if selected medical conditions exist that would increase the risk of continued exposure. They recommended that medical surveillance for all lead-exposed workers should include quarterly blood lead measurements for individuals with blood lead concentrations between 10 and 19 μg/dL and semiannual blood lead measurements when sustained blood lead concentrations are less than 10 μg/dL. The aim should be to maintain the blood lead levels of exposed workers below 20 μg/dL, and preferably below 10 μg/dL.

It is unclear whether chelation therapy, which accelerates removal of lead from the blood and soft tissues (but less so from bone), benefits the clinical neuropathy. Clinical trials are lacking. Guidelines are controversial and liable to change. One therapeutic approach has been with EDTA; another oral agent, 2,3-dimercaptosuccinic acid (DMSA; succimer), seems equally effective and can be used alone or after EDTA. Regardless of the treatment chosen, it should be continued until a steady-state level of lead excretion has been achieved. In patients with large lead stores in bone, chelation may be followed by movement of lead from bone back into the blood and soft tissues, leading to a rebound increase in blood lead level after an initial drop. Chelation therapy is not appropriate for workers with continuing lead exposure as prophylaxis against rising blood lead levels.

ARSENIC

Arsenic intoxication may occur occupationally but more commonly by ingestion of contaminated food or water. It may relate to attempted homicide. Occupational exposures may occur in the manufacture of paints, fungicides, wood preservatives, and semiconductors; in certain mining and smelting operations; from combustion of arsenic-containing coal or incineration of certain preserved wood products; and in pesticide spraying. A hemorrhagic encephalopathy and various systemic effects (including QTc prolongation on the electrocardiogram and subsequent ventricular tachycardias) occur with acute intoxication; the role of arsenic in the development of a chronic encephalopathy is controversial. Arsenic leads to a peripheral neuropathy that is a predominantly sensory, distal axonopathy and occurs after exposure to high levels of arsenic, usually by ingestion with suicidal or homicidal intent, or after long-duration low-level exposure. Chronic exposure is associated also with an increased risk of skin and various other cancers. Acute intoxication leads to prominent gastrointestinal symptoms followed, after 1 to 3 weeks, by the onset of neuropathy. Numbness, burning, and paresthesias begin in the feet and spread to the legs, hands, and arms. Pain is sometimes prominent. Sensory ataxia occurs in severe cases. Weakness is usually mild and overshadowed by the sensory disturbances, but marked weakness and respiratory insufficiency may occur with severe intoxication. Autonomic instability is usually a minor feature. Examination confirms that there is symmetrical, distally conspicuous sensory loss and weakness.

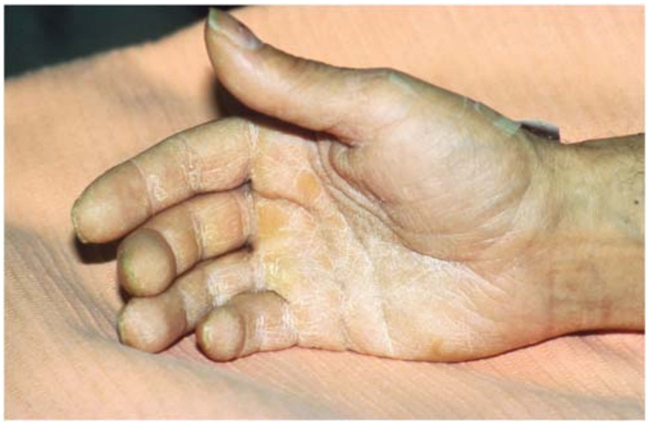

FIGURE 35-1 ▪ Hyperkeratosis and desquamation of the skin of the palms of the hands from arsenic toxicity. (Courtesy of J. Richard Baringer, MD, University of Utah.)

Other toxic effects of arsenic accompany the neuropathy and include hyperkeratosis and desquamation of the skin, particularly in the palms (Fig. 35-1) and soles; redness and swelling of the hands and feet; patchy areas of skin discoloration with chronic intoxication; and, particularly with acute poisoning, transverse gray lines in the nails (Mees lines; Fig. 35-2). Kidney failure may occur. Anemia is common, and red blood cells may show basophilic stippling.

An acutely evolving neuropathy may be misdiagnosed as Guillain–Barré syndrome, especially if the

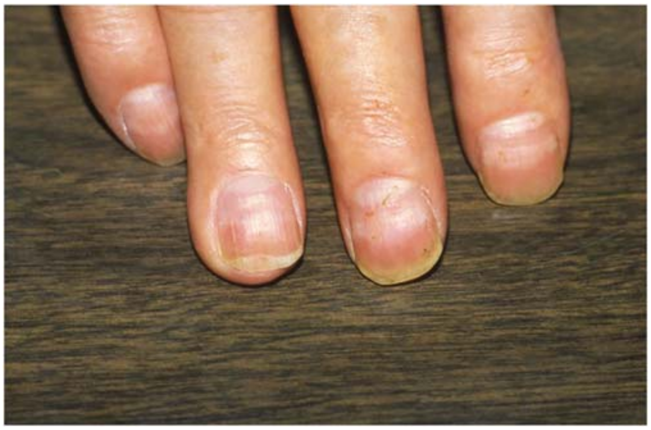

FIGURE 35-2 ▪ Transverse gray lines in the nails (Mees lines) related to arsenic toxicity. (Courtesy of J. Richard Baringer, MD, University of Utah.)

initial gastrointestinal symptoms are mistaken for a prodromal illness and the cerebrospinal fluid shows an albuminocytologic dissociation, as sometimes occurs in early arsenic neuropathy. The electrodiagnostic findings may also resemble those of Guillain–Barré syndrome because the underlying axonal degeneration is accompanied by proximal demyelination. The diagnosis requires the demonstration of arsenic in blood, urine, or tissues. Measurement of blood levels is usually diagnostically unhelpful because arsenic is cleared very rapidly, but urinary excretion is increased for weeks. The most reliable means of monitoring exposure in at-risk occupations is by determining the 24-hour urinary arsenic level, which should be determined after subjects have abstained from eating fish, seaweed, or shellfish for 48 to 72 hours. Arsenic is cleared from blood into tissues; for example, it comes to be bound to keratin of growing hair or nails and may be found in slow-growing hair, such as pubic or axillary hair, for months or even years after exposure. This is important when exposure is not suspected until long after the event. The results of such analyses when performed in commercial laboratories, however, may be inaccurate.

Treatment consists of removing the subject from further exposure. Removal of clothing and cleaning the skin and hair to prevent further contamination are particularly important in those exposed to pesticides. Chelation therapy hastens the excretion of arsenic, but there is no evidence that it increases the rate of recovery from neuropathy, which takes months to years. Patients with mild neuropathy may recover completely, but those with a severe neuropathy are likely to have a residual deficit.

MERCURY

Both organic and inorganic mercury may cause toxicity. Ingestion of methyl mercury in contaminated food such as fish leads to optic neuropathy, hearing loss, cerebellar deficits, and cognitive or behavioral changes. There are also prominent sensory abnormalities that are probably central in origin. Exposure to organic mercury should be stopped and a 24-hour urine sent for measurement of mercury concentration. There is no effective treatment and neurologic damage is likely to be permanent.

Inorganic mercury is mainly absorbed by inhalation during smelting, which is the major means of occupational exposure. Occupational exposure also occurs in chloralkali plants, during mining operations, during the manufacture of medical appliances, glassware, and jewelry, and in dental offices during the preparation of fillings. Ingestion of mercury-containing medications is also sometimes responsible for toxicity. Inorganic mercury may produce a variety of general medical disorders including gastrointestinal symptoms and nephrotic syndrome.

Neurotoxicity is common in the workplace with exposure to mercury vapor levels exceeding 50 μg Hg/m^3. It can manifest as a toxic encephalopathy. The past use of mercury in felt hat production led to many symptoms of high-level mercury neurotoxicity, and thus to the popular phrase “mad as a hatter.” Signs include irritability, anxiety, agitation, social withdrawal, and insomnia; continuing exposure leads to development of a fine tremor of the hands (“hatter’s shakes”) and then of the facial muscles and tongue. In mild cases, encephalopathy and tremor improve gradually over several years once exposure is discontinued. Peripheral neuropathy resembling an inflammatory polyneuropathy has also been attributed to exposure to both forms of mercury, but with only limited supportive evidence. The neuropathy may still be detected many years after the end of exposure, depending on its severity. The diagnosis is confirmed by measuring the blood mercury and 24-hour urinary mercury levels. Exposure should be discontinued, supportive care ensured, and for acute poisoning (typically by ingestion) chelation therapy can be considered, depending on severity.

MANGANESE

Inhalation of dust or vapor during the mining or smelting of manganese may lead to intoxication. Occupational exposure also occurs in manganese alloy producers, cell-battery factory workers, and farmers using manganese-containing fungicides. As much of the dietary intake of manganese is cleared by the liver, liver failure or even asymptomatic hepatitis may precipitate manganese neurotoxicity in exposed workers. The earliest manifestation is a toxic psychosis, with behavioral and cognitive abnormalities; headache, dysarthria, tremor, and incoordination may develop later. Extrapyramidal changes, with dystonia (such as involuntary plantar flexion of the feet) or parkinsonism (abnormalities of gait and balance, bradykinesia, rigidity, rest and action tremor, hypomimia) may eventually develop. A characteristic “cock-gait” is described. After exposure is terminated, early behavioral changes may stabilize and reverse, but extrapyramidal deficits may continue to progress for several years before reaching a plateau.[8]

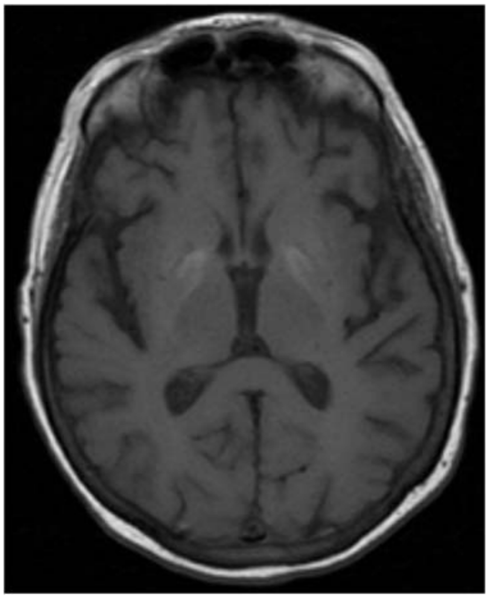

FIGURE 35-3 ■ Bilateral globus pallidus hyperintensity in T1-weighted axial MRI suggestive of manganese accumulation. (Courtesy of William P. Dillon, MD, University of California, San Francisco.)

MRI, positron emission tomography (PET), and single-photon emission computed tomography (SPECT) have been used to study manganese-induced parkinsonism. T1-weighted MRI (Fig. 35-3) shows increased signal intensity in the globus pallidus and midbrain bilaterally in exposed workers who are either asymptomatic or have signs of manganese intoxication. [^{18}F]dopa PET and SPECT are normal, indicating the integrity of the nigrostriatal dopaminergic system. Thus, the damage in manganese toxicity is presumably downstream of the nigrostriatal system, and this would account for the poor response to levodopa in such patients.

Manganese-induced parkinsonism is distinguished from classic Parkinson disease by the history of manganese exposure, usually symmetric clinical features, neuroimaging findings (abnormal T1-weighted MRI and normal fluorodopa PET and SPECT scans), and poor response to levodopa.[9] There are also pathologic differences at autopsy.[9] Exposure to manganese in low dose, as in welders, has been incriminated as a risk factor for the early onset of Parkinson disease, but no relationship between welding and Parkinson disease could be identified in other studies.

Organophosphate and Carbamate Pesticides

Organophosphates and carbamates are used as pesticides or herbicides, and some organophosphates have also been used for terrorism or as warfare agents. Inhibition of acetylcholinesterase (AChE) accounts for their early acute toxicity, and inhibition of neuropathy target esterase (NTE) relates to the delayed neuropathy that occurs after exposure to some of them. Although inhibition of NTE is necessary for the development of peripheral neurotoxicity, not all organophosphates that inhibit NTE cause neuropathy; other factors are also involved. Different organophosphates have differing potencies against these enzymes, although almost all have some anticholinesterase effects. Most organophosphates and carbamates are readily absorbed transdermally during and after spraying, as well as by inhalation and ingestion.

EARLY (TYPE I) SYNDROME

The earliest manifestations represent inhibition of AChE at CNS cholinergic and postganglionic parasympathetic receptors (Table 35-2). The CNS effects are characterized by behavioral changes, mainly agitation, and may progress to convulsions, obtundation, and even coma, which sometimes has a delayed onset. Life-threatening peripheral muscarinic effects include bradycardia and hypotension, or even complete cardiovascular collapse. Bronchospasm, increased secretions, and pulmonary edema can occur. Less threatening peripheral muscarinic effects include meiosis, diarrhea, urinary urgency or incontinence, and increased salivation, lacrimation, and sweating. Muscle fasciculations and weakness reflect nicotinic (neuromuscular junction) effects. In severe intoxication, death occurs from respiratory failure or cardiac arrhythmias.

The speed and extent of inhibition of AChE govern the onset and severity of the clinical disorder. Muscarinic features typically appear first and are most obvious except in severe toxicity, when nicotinic features may be especially conspicuous. The cholinergic effects of organophosphate poisoning usually begin within hours of exposure. AChE inhibition by carbamates is reversible, and symptoms and signs of carbamate toxicity are generally less severe and of shorter duration than with organophosphate poisoning.

Diagnosis is clinical and is suggested by signs of cholinergic overactivity. Electrodiagnostic studies initially reveal repetitive firing of the compound muscle action potential after a single stimulus to the motor nerve, and later a decremental muscle response to repetitive nerve stimulation. Measurement of AChE activity in plasma or red blood cells to confirm suspected intoxication or to monitor exposed subjects is of dubious value.

TABLE 35-2 ■ Effects of Organophosphate Poisoning

Muscarinic Effects

Respiratory
- *Smooth muscle (contraction):* bronchoconstriction; dyspnea
- *Glandular secretions (increased):* rhinorrhea; bronchorrhea; pulmonary edema
- *Multifactorial:* cough; dyspnea

Cardiac
- *Conducting system:* bradycardia; arrhythmias; heart block

Gastrointestinal
- *Smooth muscle (contraction):* nausea; vomiting; abdominal cramps; diarrhea
- *Secretions (increased):* nausea; vomiting; diarrhea
- *Sphincter (relaxation):* fecal incontinence

Urinary bladder
- *Smooth muscle (contraction):* frequency; urgency
- *Sphincter (relaxation):* urgency; incontinence

Eye
- *Contraction of iris and ciliary muscle:* meiosis; blurred vision

Other
- *Secretions (increased):* sweating; salivation; lacrimation

Nicotinic Effects

Skeletal muscle
- *Excitation:* fasciculations; cramps; followed by weakness, paralysis; areflexia

CNS Effects

Excitation: agitation; anxiety; headache; ataxia; confusion; delirium; behavioral abnormalities; convulsions

Depression: obtundation; coma; respiratory depression

Prompt treatment is essential. Continuing exposure should be stopped, for example, by removing contaminated clothing when dermal exposure is likely. Respiratory and circulatory functions must be maintained. Atropine blocks the binding of acetylcholine (ACh) to muscarinic receptors; a test dose of 0.5 mg intravenously causes tachycardia and mydriasis in normal subjects but has little effect in organophosphate-intoxicated subjects. After this, 1 mg is administered intravenously and repeated every 10 to 20 minutes until clinical evidence of atropinization is achieved, and bronchorrhea and rhinorrhea are controlled. It is then maintained for 24 to 48 hours. In severe cases, continuous intravenous infusion of atropine is required. Patients should be managed in the intensive care unit because atropine can precipitate cardiac arrhythmias, especially in the setting of hypoxemia. Atropine has no effect on nicotinic neuromuscular receptors and thus fails to help any weakness or respiratory impairment, and similarly does not influence the CNS effects (agitation and convulsions).

Reactivators of phosphorylated AChE, such as pralidoxime, are also utilized in organophosphate poisoning, but are of uncertain benefit. Effectiveness is independent of receptor type. The complex that forms between the organophosphate and cholinesterase is initially reversible, but subsequently configurational changes occur, and pralidoxime is then ineffective. Treatment is started early with pralidoxime (1 g) intravenously; in the absence of improvement, the dose is repeated after 30 minutes or continuous infusion is commenced at 0.5 g/h. Treatment with oxime is not necessary for carbamate poisoning, because spontaneous reactivation of AChE occurs rapidly. A benzodiazepine is given to allay anxiety and for anticonvulsant effect and supportive therapy with other anticonvulsants may also be needed.

Prognosis depends on the severity of poisoning and on how it is managed. Neurobehavioral sequelae unrelated to structural brain damage have been noted after recovery from acute poisoning. It is unclear whether long-term low-level exposures to anticholinesterases have neurologic or behavioral consequences.

INTERMEDIATE (TYPE II) SYNDROME

This occurs a few days after exposure in up to 50 percent of cases of severe organophosphate poisoning. Its pathogenesis is unknown, but it may relate to a persistent excess of ACh at the neuromuscular junction.[10] It does not respond to atropine or pralidoxime. Presentation is with acute respiratory failure, weakness of neck flexors and proximal limb muscles, and cranial neuropathies. An acute, reversible extrapyramidal disorder has also been attributed to organophosphate poisoning following massive exposure. Treatment is supportive. Recovery may take several weeks.

The intermediate syndrome rarely—if ever—occurs after carbamate insecticide poisoning.

DELAYED SYNDROME: POLYNEUROPATHY

Certain organophosphates cause a distal, predominantly motor, subacute axonal neuropathy that manifests about 1 to 3 weeks after exposure. With those insecticides currently in use, the neuropathy follows an episode of severe cholinergic toxicity.[10] It is unclear whether neuropathy also follows severe carbamate intoxication.[10] The neuropathy relates to inhibition of NTE, followed by "aging" of the phosphoryl−NTE complex, but how this leads to development of the neuropathy is unknown.

The usual initial symptoms are of cramping muscle pain in the calves, followed by distal paresthesias in the feet. Lower-extremity weakness and areflexia then occur, beginning distally and spreading proximally. The upper limbs are involved in severe cases, but the cranial nerves are not affected. Progression occurs over 2 or 3 weeks, followed by gradual improvement. CNS involvement is common after severe exposure but is obscured initially by the peripheral neuropathy; spasticity and ataxia become apparent as the neuropathy improves. Organophosphate toxicity should be considered in any subacute, progressive distal axonopathy even in the absence of a history of exposure. The electrodiagnostic findings are abnormal but nonspecific. There is no specific treatment.

Carbamates are generally held not to be associated with delayed polyneuropathy.[10] A few incompletely reported cases of delayed polyneuropathy in this context have been published, but it is uncertain whether these related to carbamate toxicity.

PROLONGED LOW-LEVEL EXPOSURE

There is no convincing evidence that prolonged low-level exposure to organophosphates causes delayed or any other type of neuropathy.[10] The evidence is also conflicting whether low-level occupational exposure to organophosphates affects neurobehavioral function. A meta-analysis of 14 studies assimilated data from more than 1,600 participants and found a significant association between low-level exposure to organophosphates and impaired cognitive functions such as psychomotor speed, executive function, visuospatial ability, and working and visual memory.[11]

Organochlorine and Pyrethroid Insecticides

Dichlorodiphenyltrichloroethane (DDT) and various organochlorines, such as aldrin, dieldrin, and lindane, were previously used widely as insecticides. Because of their slow degradation, they persist for long periods in animals and the environment. Their use is now banned. Decline in neurobehavioral functioning and increase of neuropsychologic and psychiatric symptoms have been reported in retired DDT workers. Cognitive performance deteriorated with increasing duration of exposure to DDT. Although such data suggest that exposure to DDT may be associated with permanent decline in neurobehavioral functioning, the limited number of studies and uncertainties about exposure levels prevent a firm conclusion from being drawn. Because organochlorine pesticides are potent tremor-producing agents, exposure to DDT, dieldrin, and certain other chlorinated hydrocarbons has been examined as a possible etiologic factor for the development of essential tremor, but no association was found. Similarly, studies in animals have failed to show any effect of DDT or dieldrin on the nigrostriatal system, making unlikely a relationship between exposure to these insecticides and development of Parkinson disease.

Chlordecone, another persistent chlorinated hydrocarbon, was involved in a major industrial exposure and environmental contamination in the 1970s from a manufacturing plant in Hopewell, Virginia. Some workers developed a neurologic illness from dust inhalation, characterized by postural and intention tremor (primarily of the hands but sometimes affecting the head or entire body), opsoclonus, clumsiness, slurred speech, and mild gait ataxia. Mood changes, irritability, and memory loss also occurred. Idiopathic intracranial hypertension occurred in a few cases. Recovery occurred slowly over several years and was sometimes incomplete.[12] Use of chlordecone is now banned.

Pyrethrins are now preferred over organophosphates or organochlorines as pesticides because of their biodegradability. They occur in the seed cases of the perennial plant *Pyrethrum*, and have been synthesized to produce the pyrethroid insecticides. DDT, the pyrethrins, and the synthetic pyrethroids (which account for about 20% of the world insecticide market) act on the voltage-gated sodium channel proteins of insect neuronal membranes. Transmission of nerve impulses is disrupted by binding of the insecticides, leading to paralysis and eventual death.

Occupational exposure to pyrethroids occurs primarily through the skin but sometimes by inhalation in professional sprayers for agricultural purposes or to control vectorborne diseases. Reports of human poisoning are relatively few. Pyrethroid toxicity in humans causes paresthesias affecting the face and hands. This has been attributed to an effect on voltage-dependent sodium channels, resulting in prolonged inward sodium currents leading to repetitive firing and subsequently to membrane depolarization. There is no correlation between the occurrence of paresthesias and urinary excretion of pyrethroids or their metabolites. Paresthesias generally disappear within 24 hours and there is no specific treatment. Other common symptoms are "dizziness," headache, and fatigue; palpitations, chest tightness, and blurred vision are less frequent. Coma and convulsions occur in rare instances and may then be life-threatening.

A slowly progressive motor neuron disease simulating amyotrophic lateral sclerosis has been reported after heavy and prolonged exposure to various pyrethroids and to organochlorines, but further studies of such possible associations are required before any conclusions can be reached about their significance.

Pesticides, Herbicides, and Parkinsonism

The pathogenesis of Parkinson disease probably involves both genetic and environmental factors. Case-control studies in humans have related parkinsonism to farming, rural living, and well-water consumption. Pesticide exposure is one risk factor for developing the disease, but it is difficult to expand on this effect. Exposures typically occur many years before the development of clinical parkinsonism, probably involve several pesticides that may have had additive effects, and often are of unknown duration and severity. Genetic factors may affect the response to environmental factors. Furthermore, toxin-mediated effects may remain clinically silent until normal age-related dopaminergic cell loss reaches a certain critical level, accounting for the delay between exposure and clinical disease.

Parkinsonism has developed in humans who took methylphenyl tetrahydropyridine (MPTP) for recreational purposes. MPTP is converted in the body to methylphenyl pyridinium (MPP), which causes selective degeneration of the dopaminergic nigrostriatal system involved in the genesis of the motor deficits of parkinsonism. MPP structurally resembles paraquat, a herbicide. New models of selective nigrostriatal damage, such as neurotoxicity induced by the pesticides rotenone and paraquat, indicate that these environmental agents may indeed contribute to the neurodegenerative process in parkinsonism. Mitochondrial complex I activity is reduced in Parkinson disease; MPP inhibits mitochondrial complex I, as does rotenone. Epidemiologic studies have found an association of Parkinson disease with pesticide exposure, depending on duration of exposure. Petrovitch and colleagues undertook a prospective cohort study with 30-year follow-up of Hawaiian plantation workers, and found a relative risk of Parkinson disease of 1.0, 1.7, and 1.9 for those who had worked on the plantation for 1 to 10, 11 to 20, and more than 20 years, respectively, compared to those who had never done plantation work.[13] Participants were exposed to pesticides but also to many other substances, and the findings from this study cannot determine which exposures influenced the development of parkinsonism. In Taiwan, a history of rural living, farming, use of herbicides/pesticides, and use of paraquat were associated with an increased risk of parkinsonism in a dose–response manner. After adjustment for multiple risk factors, the relationship between Parkinson disease and previous use of herbicides/pesticides and paraquat remained significant, the risk being greater among subjects who had used paraquat plus other herbicides/pesticides rather than in those who had not used paraquat.[14] The risk of developing Parkinson disease was increased more than six times in those exposed for more than 20 years to paraquat.[14]

At the present time, then, it seems that exposure to certain pesticides or herbicides increases the risk of developing Parkinson disease, including pyrethroids, organochlorines, and organophosphates, and 2,4-dichlorophenoxyacetic acid (2,4-D), a constituent of Agent Orange. The precise mechanisms and pesticides or herbicides involved are not known and probably vary depending on genetic and other factors. By assessing lifetime use of pesticides selected by mechanism in a case-control study, however, Parkinson disease has been associated with use of pesticides that inhibit mitochondrial complex I, including rotenone, and with use of pesticides causing oxidative stress, including paraquat.[15]

CONCLUDING COMMENTS

Most physicians have only limited experience of occupationally related neurotoxic disorders, even though the majority of patients with such disorders come under the care of neurologists, primary care physicians, or internists, at least at some point during the course of their disorder. It is therefore important that physicians become and remain sensitive to the possibility that their patients may have diseases induced by toxic exposures occurring at work. Unfortunately, there remains a shortage of physicians with expertise in occupational medicine who can act as clinical or educational resources, and this shortage has proved difficult to remedy. The emphasis has moved to the prevention of occupationally related disorders. In the United States, federal and state legislation regulates and enforces comprehensive safety and health programs in the workplace and also provides for various informational and educational services to improve occupational safety. Nevertheless, physicians must be aware of the basic principles of occupational medicine and understand how to screen for possible neurotoxic disorders, as well as the limitations of the screening process. They must also know the implications of making such diagnoses, understand their responsibilities within the framework of any local or national workers' compensation system, and be aware of any requirements to alert health or regulatory agencies to suspected occupationally related neurotoxic disorders.

THERMOREGULATORY SYSTEM

Mammals maintain their core body temperature within a narrow range despite exposure to a broad range of environmental temperatures. This thermoregulation is achieved by activating a set of thermoeffector systems that generate or dissipate heat, as necessary.[1–4] Basal metabolic activity produces heat, and within a narrow range of ambient temperatures called the thermoneutral zone the core temperature can be maintained by adjusting the metabolic rate. Outside this range, heat generation is achieved primarily by shivering. Newborn infants do not shiver, and shivering is probably not fully effective until several years of age; before then, nonshivering thermogenesis occurs in brown adipose tissue. The mitochondria of brown adipose tissue contain an uncoupling protein that, when induced, diverts the energy generated by oxidative phosphorylation into heat production rather than adenosine triphosphate synthesis, so that heat becomes the primary product of metabolism rather than a byproduct as in other tissues. Piloerection (goosebumps), cutaneous vasoconstriction, and behavioral adaptations (such as postural changes or dressing for the cold) are additional mechanisms of nonshivering thermogenesis.

Heat dissipation is achieved by evaporation (sweating) and by nonevaporative heat loss (conduction, convection, and radiation). Evaporative heat loss is the most important of these mechanisms in most clinical situations. Nonevaporative heat loss can occur only when the ambient temperature is lower than the skin temperature, and the amount of heat it dissipates is a function of vasomotor activity; increased skin blood flow promotes heat dissipation, and reduced skin blood flow minimizes it.

The activity in each of these thermoeffector systems is a function of thermal input from spatially distributed thermoreceptors providing information about body temperature, both in the core (the brain and viscera of the thorax and abdomen) and in the shell (peripheral tissues, primarily skin). Most of the research regarding peripheral sensation of non-noxious thermal stimuli has focused on skin thermosensors. In humans, fibers activated by cold are rapidly adapting A-delta fibers, and fibers activated by warm temperatures are primarily C-fibers.[1–3,5] Their temperature sensitivity is probably mediated by transient receptor potential channels, a family of cation channels expressed in cell membranes. Nine members of this family are sensitive to temperature, with relatively narrow—but overlapping—ranges

Aminoff's Neurology and General Medicine, Sixth Edition.

of temperature sensitivity. In addition to skin thermosensors, the afferent limb of the thermoregulatory system includes visceral thermosensors, vascular thermosensors, and neurons within the hypothalamic regulatory areas that are sensitive to the temperature in the hypothalamus itself. Thermosensitive neurons are also present in the brainstem and spinal cord and, possibly, in the abdominal viscera.

The preoptic anterior hypothalamus is the principal site at which the afferent thermal input is integrated and the thermoeffector systems are activated. The specific function determining effector activity in response to a given thermal input is different for each thermoeffector system. The combined activity of all the thermoeffector systems results in a body temperature at which heat gain matches heat loss, referred to as the balance point, or equilibrium point.[1–3] Thermoregulatory disorders occur when thermal afferent pathways or thermoeffector systems malfunction or environmental conditions overwhelm their capacity.[6] Fever is caused by altering the functions relating thermoeffector activity to thermal afferent input, resulting in a shift of the thermoregulatory balance point.

CAUSES OF ABNORMAL THERMOREGULATION

Most thermoregulatory disorders are caused by environmental conditions that overwhelm the body's thermoeffector systems, but some are caused by neurologic disorders that disrupt thermoregulatory function. The main neurologic causes of abnormal thermoregulation are diseases of the hypothalamus or its autonomic outflow. In addition, a few neurologic disorders result in excessive heat production that overwhelms the thermoregulatory system. Tables 36-1 and 36-2 summarize the main causes of hyperthermia and hypothermia.[6–8]

Neurologic Causes of Abnormal Thermoregulation

HYPOTHALAMIC LESIONS

Hypothalamic lesions may produce either hyperthermia or hypothermia, although hypothermia is more common. Hyperthermia has been described with tumors, stroke, encephalitis, trauma, and surgery. Hypothermia has been reported with tumors, stroke, subarachnoid hemorrhage, sarcoidosis, multiple sclerosis, neuromyelitis optica, limbic encephalitis, Parkinson disease, and idiopathic gliosis. Hypothermia is common in Wernicke encephalopathy and may be the presenting feature. In contrast, although fever occurs in about 12 percent of patients with Wernicke encephalopathy, a superimposed infection is almost always responsible. Prominent abnormalities of sweating (anhidrosis or hypohidrosis) have been described in primary autonomic failure,

TABLE 36-1 ■ Causes of Hyperthermia

Malfunction of Thermoregulatory System

- Hypothalamic disorders
  - Tumor
  - Stroke
  - Encephalitis
  - Head trauma
  - Surgery
- Other lesions
  - Hydrocephalus
  - Posterior fossa surgery

Interruption of Effector Pathways

- Spinal cord lesions
- Autonomic neuropathies

Overwhelming Heat Production or Exposure

- Neurologic conditions
  - Status epilepticus
  - Delirium tremens
  - Tetanus
  - Malignant hyperthermia
  - Neuroleptic malignant syndrome
  - Serotonin syndrome
- Non-neurologic conditions
  - Heat stress disorders (exertional or nonexertional)
    - Heat shock

- Skin disorders (exfoliative dermatitis, psoriasis, ichthyosis, erythroderma)

multiple system atrophy, and as an isolated condition, and hyperthermia may develop when these patients are exposed to hot climates without air conditioning.[8]

LESIONS OF EFFECTOR PATHWAYS

Interruption of the autonomic outflow from the hypothalamus may produce either hyperthermia or hypothermia by impairing the effector mechanisms necessary for heat dissipation or production, respectively. Lesions of the spinal cord above the thoracic level may interrupt descending input to the thoracic intermediolateral cell column, producing both vasomotor abnormalities and disorders of sweating, or to anterior horn cells, impairing or eliminating shivering below the level of the lesion.

Any neuromuscular disease that is severe enough to cause profound weakness can impede shivering. Polyneuropathies that involve autonomic fibers can produce abnormalities of vasomotor activity and sweating, and either hypothermia or hyperthermia may result.[7,8] For example, hypothermia is common in patients with diabetes, probably because of impaired vasomotor reflexes. In contrast, some patients with diabetes manifest a syndrome of heat intolerance that is attributed to anhidrosis. Because the autonomic nerve involvement in diabetes is usually predominantly distal, these patients sometimes exhibit profuse sweating over the head and upper trunk ("compensatory hyperhidrosis").

MISCELLANEOUS LESIONS

Disorders that produce widespread damage to the central nervous system (CNS) can impair thermoregulation, but the precise mechanism is often difficult to establish. Degenerative diseases can be associated with hypothermia, possibly because of impaired behavioral adaptations to cold. Hyperthermia has been reported in patients with acute hydrocephalus, posterior fossa surgery, ischemic strokes, and intracranial hemorrhage, but as a general rule, hyperthermia should not be attributed to "neurogenic factors" even when a patient has CNS disease unless there is clear involvement of the hypothalamus or its effector pathways and other causes of fever have been excluded.[9]

Agenesis or dysplasia of the corpus callosum may be associated with episodic hyperhidrosis and hypothermia (Shapiro syndrome).[6,10] There may also be associated structural abnormalities in the septal region, cingulate gyrus, and posterior hypothalamus. The periods of sweating may last from minutes to hours, and the hypothermia may last from 30 minutes up to several weeks. Episodes may be separated by intervals of months to years. There is often ataxia and impaired cognition during the hypothermic episodes. A similar syndrome has occasionally been seen without any associated abnormality of the corpus callosum, and neurotransmitter abnormalities have been identified in some cases. Episodic hypothermia without hyperhidrosis has also been described. Recurrent hypothermia has also been attributed to "diencephalic epilepsy," but electrographic seizures have not been demonstrated consistently.

Cases of periodic hyperthermia associated with agenesis of the corpus callosum ("reverse Shapiro syndrome") have been reported. Episodic hyperthermia (or hypothermia) associated with other manifestations of autonomic dysfunction has also been described after head trauma and many other neurologic disorders.

THERMOREGULATORY SYSTEM OVERLOAD

Several neurologic diseases produce thermoregulatory disorders by creating conditions that overwhelm the capacity of the thermoregulatory system. Just as paralysis may eliminate effective shivering and result in hypothermia, muscle hyperactivity may result in hyperthermia. Elevated body temperatures are common after generalized seizures, tetanus, and delirium tremens, for example. Three important examples of hyperthermia associated with increased muscle activity are malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome.

Malignant hyperthermia is characterized by vigorous muscle contractions and an abrupt increase in temperature on exposure to certain drugs, most commonly inhalational anesthetics and succinylcholine.[11] It can occur at any time during anesthesia administration or shortly thereafter. The hyperthermia is probably a direct result of the heat produced by sustained muscle activity resulting from defective regulation of intracellular free calcium. Malignant hyperthermia is inherited as an autosomal dominant trait with variable penetrance, and a predominance of expression in young males. More than 50 percent of patients have mutations in the gene for the ryanodine receptor, the primary channel for release of calcium stored in the sarcoplasmic reticulum; other cases are due to mutations in the gene encoding the main subunit of the dihydropyridine receptor, a voltage sensor that interacts closely with the ryanodine receptor, or in the gene coding for Stac3 protein, which is thought to be important for effective co-location of dihydropyridine receptors and ryanodine receptors. Mutations in the gene for the ryanodine receptor have also been implicated in several congenital myopathies including central core disease, centronuclear myopathy, multiminicore disease, congenital fiber-type disproportion, and nemaline rod myopathy; some, but not all, patients with these conditions are also at risk of malignant hyperthermia. Although patients with other myopathies, muscular dystrophies, and myotonia may have adverse effects from anesthesia (e.g., contractures after administration of succinylcholine, increased susceptibility to respiratory depression after receiving barbiturates or opiates, disease-related cardiac complications, or rhabdomyolysis), they do not appear to have an increased risk of malignant hyperthermia.

Both *neuroleptic malignant syndrome* and *serotonin syndrome* are characterized by hyperthermia, diaphoresis, rigidity, mental status changes, tachypnea, tachycardia, and hypertension or labile blood pressure.[12] Patients with neuroleptic malignant syndrome typically have hyporeflexia, normal pupillary responses, and normal or decreased bowel sounds, whereas serotonin syndrome is associated with hyperreflexia, dilated pupils, and hyperactive bowel sounds. Patients with neuroleptic malignant syndrome often have laboratory abnormalities that are not present in serotonin syndrome, including peripheral leukocytosis, elevated serum creatine kinase, increased liver enzymes, and low serum iron, magnesium, and calcium levels. The pathophysiology of these two syndromes is poorly understood. The elevated body temperatures are at least partly due to increased muscle activity, but increased sympathetic activity and increased levels of acute-phase reactants probably contribute to the hyperthermia of neuroleptic malignant syndrome, and nonshivering thermogenesis in brown adipose tissue and cutaneous vasoconstriction may contribute to the hyperthermia of serotonin syndrome. Neuroleptic malignant syndrome is typically triggered by exposure to neuroleptic agents, including atypical antipsychotic agents, but it has also been described in patients being treated for presumed Parkinson disease after sudden withdrawal of dopaminergic agents or changes in their medication regimen (sometimes referred to as parkinsonism hyperpyrexia). When associated with neuroleptics, the condition typically arises within 2 weeks of starting therapy or increasing the dose, but at times it may begin within hours or after a delay of months. Serotonin syndrome can occur with any serotonergic drugs—notably tricyclic antidepressants, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, and meperidine—especially when used in combination.

Environmental Causes of Abnormal Thermoregulation

Most cases of abnormal thermoregulation occur in individuals without a primary neurologic disease and are caused by external temperature conditions (or, less commonly, internal metabolic derangements) that overwhelm the thermoregulatory system.

HYPERTHERMIA

Conditions in which the thermoregulatory system is overwhelmed by extremely high external temperatures are called *heat stress disorders*. The most severe form is heat stroke, defined as a core body temperature exceeding 40°C (or 41°C according to older sources) associated with CNS dysfunction such as delirium, seizures, or coma.[6,13,14] Heat stroke is characterized by hot, dry skin, but this is not used as a diagnostic criterion. Heat exhaustion is a milder form, characterized by progressive lethargy, headache, vomiting, tachycardia, and hypotension, with less severe neurologic impairment than occurs in heat stroke. These two conditions form a continuum: if untreated, heat exhaustion may progress to heat stroke.

Classic heat stroke results from prolonged exposure to high environmental temperatures while the individual undertakes normal activities; exertional heat stroke occurs in situations of physical exertion, typically in healthy young individuals, often athletes or military personnel. Inadequate cardiovascular conditioning, poor acclimatization, dehydration, heavy clothing, low work efficiency, and reduced ratio of skin area to body mass all are risk factors. Congenital or acquired abnormalities of sweat gland function may contribute. Classic heat stroke is typically seen in the elderly, especially in those with chronic diseases (e.g., alcoholism, malnutrition, diabetes, cardiovascular dysfunction, obesity), but prepubertal children are also at risk. Some medications predispose to the condition, including anticholinergics, β-blockers, diuretics, antihistamines, antidepressants, and amphetamines. People in lower socioeconomic groups are at particular risk, especially those living in urban areas, because they may be exposed to a greater thermal load and live in apartments with inadequate ventilation.

The most common cause of hyperthermia is simple dehydration because it results in vasoconstriction and decreased sweating, interfering with heat dissipation. Heat dissipation may also be impaired in advanced scleroderma or in miliaria, or by extensive use of occlusive dressings. Both thyrotoxicosis (mainly during thyroid storm) and pheochromocytoma may cause hyperthermia on the basis of hypermetabolism. Drug exposure can also produce hyperthermia in several ways, including increased metabolic rate, hyperactivity, and impaired heat dissipation (Table 36-3).

HYPOTHERMIA

As with hyperthermia, hypothermia is usually due to conditions that overwhelm the thermoregulatory system, rather than a consequence of primary malfunction in the system.[6,14,15] Accidental hypothermia is defined as an unintentional decline in the core temperature below 35°C. It is most common in neonates, the elderly, and those who are unconscious or immobile, especially from drug exposure. Alcohol, in particular, is a vasodilator, a CNS depressant, an anesthetic, and a risk factor for trauma and environmental exposure, all of which increase the risk of hypothermia. Other drugs predispose to hypothermia through a variety of mechanisms including depression of the hypothalamic center, inhibition of shivering by neuromuscular blockade, and vasodilation (Table 36-4).

Patients with severe burns, exfoliative dermatitis, or other dermatologic conditions may develop hypothermia because of increased evaporative and nonevaporative heat loss and the inability to regulate these processes through vasoconstriction. Hypothermia may also occur in the setting of several endocrine disorders that impair metabolism including hypothyroidism, hypoadrenalism, and hypopituitarism. Hypoglycemia, diabetic ketoacidosis, and hyperosmolar coma are also associated with hypothermia, but it is not clear whether this is because of a hypometabolic state or a direct effect on the hypothalamus.

EFFECTS OF TEMPERATURE ON THE NERVOUS SYSTEM

Neuronal function is significantly affected by even moderate changes in temperature.[16] Basic electrical parameters (such as membrane capacitance, axoplasmic resistance, maximal sodium and potassium conductances, and ion channel rate constants) vary systematically with temperature. Consequently, temperature affects the action potential amplitude, duration, maximal rate of rise, net ionic movements, and conduction velocity, and therefore changes the likelihood of signal propagation or conduction block. Clinical electrophysiologic tests reflect these effects; for example, the maximal motor conduction velocity of the ulnar nerve falls by 2.4 m/sec for every 1°C decline in temperature. As the temperature declines, compound action potential

amplitudes increase, the duration of motor unit action potentials increases, mean amplitude declines, and polyphasic potentials become more frequent. Hypothermia also prolongs the latencies of visual, somatosensory, and brainstem auditory evoked potentials.[15]

Although these alterations in function can have clinical consequences, actual nervous system injury does not occur until extreme temperatures are reached. Direct thermal injury to the brain and spinal cord results in the production of a variety of cytokines and altered expression of heat-shock proteins, leading to excitotoxicity, endothelial cell injury, breakdown of the blood–brain barrier, and diffuse microvascular thrombosis, ultimately causing cell death, edema, and hemorrhage.[6,16,17]

Cerebral metabolic rate and oxygen metabolism increase with rising temperatures between 38° and 42°C, but decline as temperatures rise further. Hypothermia leads to slowing of the rate of chemical reactions, decrease in the metabolic requirement for oxygen, and reduction of cerebral blood flow by 4.4 to 6.0 percent for every 1°C decline in temperature.[15] This reduction in metabolic rate is protective, but neural damage still occurs. It is difficult to know to what extent the neuronal damage is a direct effect of low temperatures rather than a consequence of secondary injury from the systemic effects of hypothermia (including cardiovascular collapse).

MANIFESTATIONS AND MANAGEMENT OF ABNORMAL THERMOREGULATION

Hyperthermia

Neurologic Manifestations

The earliest neurologic manifestations of hyperthermia include thirst, weakness, and fatigue. Skeletal muscle cramps may occur in the exertional heat stress disorders and are probably related to hyponatremia and increased intracellular calcium release. Patients with heat exhaustion are frequently agitated and may develop delirium and incoordination. Tetany or paresthesias sometimes will occur secondary to hyperventilation.

Heat stroke may present with the sudden onset of stupor or coma, or patients may pass through a prodromal period that can include progressive headache, drowsiness, confusion, agitation, and delirium.[6,14,17] Seizures occur in 60 to 70 percent of patients. Pupils are usually small and often pinpoint, and vestibulo-ocular ("cold caloric") responses are intact except terminally. Diffuse hypertonia is common, but flaccidity has also been described. Hemiplegia, cerebellar deficits, and papilledema may also occur. Cerebrospinal fluid (CSF) from patients with heat stroke is usually normal but may show an increased protein concentration, xanthochromia, or mild lymphocytic pleocytosis. Slowing of the electroencephalogram (EEG) occurs at temperatures above 42°C.

Most patients who recover from heat stroke have no permanent neurologic sequelae, but some may have persistent ataxia and dysarthria; a few cases of hemiparesis, myelopathy, or quadriparesis have been reported. There are also reports of persistent polyneuropathy after patients have been treated with experimental whole-body hyperthermia for cancer, and localized neuropathies following hyperthermic isolated limb perfusion. Survivors of severe heat stroke may also develop premature cataracts, attributed to dehydration.

SYSTEMIC MANIFESTATIONS

Heat stroke is associated with diffuse systemic derangements.[6,13] The mildest are dependent edema and syncope. Respiratory alkalosis is almost always present, and tetany may occur. Hypoxia, metabolic acidosis, hypokalemia, hyperkalemia, hypernatremia, hypophosphatemia, hypomagnesemia, and hypoglycemia have each been described. Peripheral leukocytosis in the range of 20,000 to 30,000 cells/mm^3 is common.

Cardiovascular manifestations include low cardiac output and low diastolic pressure. Subendocardial hemorrhages may occur. Minor electrocardiographic changes are sometimes found and include transient conduction abnormalities and inverted or flattened T waves. Apart from the respiratory alkalosis, pulmonary manifestations may include pulmonary edema and acute lung injury in the presence of disseminated intravascular coagulation.

Rhabdomyolysis is almost universal in exertional heat stroke but is uncommon in classic heat stroke. Elevated serum creatine kinase levels occur in both conditions, often followed by elevated levels of lactate dehydrogenase. Acute renal failure occurs in about 25 percent of patients with exertional heat stroke but is uncommon in classic heat stroke. Diarrhea and vomiting are common; melena and hematemesis may occur in severe cases. Elevated serum amylase and liver enzymes are common; liver injury is usually asymptomatic, but acute liver failure occurs in 5 percent of patients with exertional heat stroke. Clinically significant coagulopathies are common and, in severe heat stroke, disseminated intravascular coagulation is almost always present.

PATIENT MANAGEMENT

There are three components to the management of the hyperthermic patient: treatment of the underlying cause (when possible), cooling, and treatment or prevention of common complications.[6,13,14]

Most of the hypothalamic causes of hyperthermia are not amenable to acute treatment, although corticosteroid administration is appropriate when there is vasogenic edema. Compressive spinal cord lesions associated with hyperthermia (e.g., epidural hematoma or abscess) may require immediate treatment, but no acute treatment is possible for most other lesions. Hyperthermia caused by excessive muscle activity (including status epilepticus) is treated by reducing or eliminating the muscle activity.

Patients with malignant hyperthermia are treated by stopping the responsible anesthesia, placing activated charcoal filters, instituting hyperoxygenation, and intravenously administering dantrolene, a skeletal muscle relaxant that uncouples excitation and contraction by preventing the release of calcium from the sarcoplasmic reticulum.[11] Although dantrolene has been used successfully to treat neuroleptic malignant syndrome, bromocriptine and amantadine have also been tried in some cases, probably because of the apparent role of dopaminergic systems in neuroleptic malignant syndrome. Electroconvulsive therapy may be useful in severe, refractory cases. Cyproheptadine is the most commonly recommended medication for serotonin syndrome, but it has not been studied rigorously.[12]

Non-neurologic causes of hyperthermia may also be amenable to specific treatment. Thyrotoxic storm or crisis is treated with β-adrenergic antagonists, glucocorticoids (because of increased requirement and reduced adrenal reserve), and administration of an antithyroid agent. Patients with pheochromocytoma are treated with α-adrenergic antagonists. Dehydrated patients are rehydrated as necessary. For hyperthermic patients in whom a precipitating drug can be identified, treatment is directed at minimizing the drug's toxicity. Patients with alcohol withdrawal and delirium tremens require large doses of benzodiazepines. For the hyperthermia of heat stress disorders, treatment of the underlying cause simply consists of removing the patient from the hot environment and cooling the patient.

Cooling may be achieved by either evaporative or direct external methods.[6,13] Centrally acting antipyretic medications affect the thermoregulatory balance point, so they are appropriate for use in fever, where the balance point is abnormally high, but not in heat stroke or heat exhaustion. Evaporative cooling methods involve wetting the skin with tepid water and directing bedside fans at the patient. Direct external cooling involves immersion of the patient in ice water, use of a hypothermic mattress, or packing the patient in ice. These direct external cooling techniques produce vasoconstriction, which impedes removal of heat from the core; therefore, in order to counteract this response, these cooling methods are applied (either simultaneously or in alternation) with vigorous skin massage, tepid (40°C) water spray, or exposure to hot moving air (45°C). Cooling is more rapid and more effective with direct external methods than with evaporative methods, but evaporative techniques are often adequate and permit easier patient management and monitoring. In rare instances where neither method is sufficient, more aggressive options include peritoneal lavage with iced saline, gastric lavage or enemas with ice water, and hemodialysis or cardiopulmonary bypass with external cooling of blood.

Regardless of the cooling method used, shivering often occurs as the body temperature falls and hampers cooling. In the case of cold water immersion, the rate of heat transfer is high enough that the heat produced by shivering is generally not a concern. If necessary, shivering can be treated with phenothiazines, benzodiazepines, meperidine, or nondepolarizing muscle relaxants; serotonin uptake inhibitors, α_2 agonists, and *N*-methyl-D-aspartate antagonists have also been proposed. As the patient's core temperature reaches 38° or 39°C, cooling should be stopped to avoid overshoot hypothermia.

The most important complication of hyperthermia is hypotension, which should be treated with fluid administration. Vasopressors may be used if necessary, but those that produce vasoconstriction should be avoided. Patients should receive 100 percent oxygen until adequate oxygenation is documented. Serum electrolyte and glucose concentrations should be assessed frequently and treated as necessary. To promote urine output, patients are often given an initial dose of mannitol or furosemide and subsequent doses of diuretics as necessary. If seizures occur they should be treated with benzodiazepines. Disseminated intravascular coagulation should also be treated if it occurs. Appropriate treatment of heat stroke results in a 90 to 95 percent survival rate. Poor prognosis is associated with a peak temperature higher than 41°C, prolonged symptoms before initiation of treatment, acute renal failure, elevated serum liver enzymes, red blood cell apoptosis on early peripheral blood smears, and persistence of coma after restoration of normothermia.

Hypothermia

NEUROLOGIC MANIFESTATIONS

The neurologic manifestations of hypothermia progress in a relatively predictable manner.[6,14,15] Thought processes may be normal with rectal temperatures as low as 34°C, but below this temperature most patients exhibit psychomotor slowing, speech perseveration, lethargy, or confusion. A few patients have been described as alert with rectal temperatures as low as 31°C, but this is uncommon. Dysarthria develops at temperatures below 33.5°C, and below 28°C most patients only grunt in response to questions, although some patients remain verbally responsive at temperatures as low as 23.5°C. Most patients still make purposeful responses to noxious stimuli even with temperatures approaching 20°C.

Pupillary reaction to light becomes progressively more sluggish as temperatures decline below about 32°C, but pupillary size and eye movements do not correlate reliably with temperature. Deep tendon reflexes are typically normal or even increased at temperatures as low as 29.5°C, but they become progressively diminished at lower temperatures. Extensor plantar responses are rare at any level of hypothermia. Increased muscle tone is frequent even in mild hypothermia, and it is universal at temperatures below 29.5°C. Myotonia is a common finding. Focal dystonias and dyskinesias are rare, but patients may exhibit a characteristic posture consisting of flexion in all four limbs.

No specific CSF abnormalities have been described in hypothermia. The EEG frequency spectrum changes, with increased beta and theta activity and reduced alpha activity. At temperatures below 28°C, there is progressive slowing. As the temperature declines further, a burst-suppression pattern appears, with the EEG becoming isoelectric below 10° to 20°C. Brainstem auditory evoked potentials show increasing latencies of waves I, III, and V as temperature decreases. Visual evoked potential latencies also increase progressively as temperature declines. The changes that occur in electromyographic and nerve conduction studies were discussed earlier.

Patients who recover from hypothermia usually have no long-term neurologic problems.

SYSTEMIC MANIFESTATIONS

During the shivering phase (typically between 35° and 30°C), there is an initial rise in metabolic rate and oxygen consumption, with corresponding increases in respiratory rate, heart rate, and blood pressure, but at temperatures below about 30°C shivering ceases and there is a rapid decline in metabolic rate and oxygen consumption—respiration slows and becomes shallow, the heart rate decreases, and cardiac output declines.[6,15] Clinically significant hypotension typically does not occur until temperatures of 25°C and below are reached. The principal cardiac concern with hypothermia is arrhythmia. Arrhythmia is preceded by the characteristic J-point elevation (or

"Osborn wave") that appears in the electrocardiogram at about 33°C and becomes increasingly prominent as the temperature declines. Atrial fibrillation is common below 33°C, but all types of atrial and ventricular arrhythmias can occur.

Mild hypothermia induces diuresis because peripheral vasoconstriction redistributes blood to internal organs including the kidneys, and also because of inhibition of antidiuretic hormone release and decreased renal tubular function. As hypothermia progresses and cardiac output diminishes, renal blood flow and glomerular filtration rate decline, ultimately resulting in acute renal failure. Hemoconcentration increases the hematocrit by 2 percent for every 1°C drop in core temperature. With falling temperatures, the platelet count progressively declines due to bone marrow suppression and splenic or hepatic sequestration. Platelet function is also impaired. Cold suppresses the enzymatic function of activated clotting factors, leading to coagulopathies that may not be detected on standard laboratory tests which are performed at 37°C. Hypercoagulability can also develop due to thromboplastin release from cold tissue, catecholamine and steroid release, and circulatory collapse. Granulocytopenia may occur with temperatures below 28°C.

Hypothermia has no consistent effect on potassium, calcium, magnesium, or other electrolytes, but moderate hypoglycemia is common. Endocrine functions generally remain normal. Ileus is frequent, and ischemic pancreatitis can also occur; serum amylase levels appear to correlate with the severity of hypothermia. Depressed airway reflexes result in a high incidence of pneumonia.

PATIENT MANAGEMENT

The management of hypothermia is analogous to the management of hyperthermia. The three principal components are treatment of the underlying cause (when possible), rewarming, and treatment or prevention of common complications.[6,14,15]

Treatment of hypothalamic and spinal cord pathology causing hypothermia is similar to that discussed for hyperthermia. In addition, thiamine should be given routinely to hypothermic patients unless Wernicke encephalopathy has been excluded. Spells of episodic hyperhidrosis and hypothermia have responded to cyproheptadine, clonidine, β-blockers, anticonvulsants, dopamine agonists, or peripheral muscarinic blockade with oxybutynin or glycopyrrolate.

Any metabolic derangement predisposing to hypothermia should be corrected. For example, exogenous thyroxine is usually required to treat myxedema coma. Patients should be evaluated for trauma and drug or toxin ingestion. For patients with dermatologic conditions and those without any predisposition to hypothermia other than environmental exposure, treatment of the underlying cause consists of drying the patient and removal from the cold environment.

There are three rewarming methods: passive external rewarming, active external rewarming, and active core rewarming.[6,14,15] Passive external rewarming is the slowest and least invasive of these techniques: patients are placed in a warm environment and covered with blankets or aluminized body covers, and intravenous fluids are warmed to a temperature of 36° to 39°C. This technique is usually adequate for patients with a core temperature of 32°C or above as long as the external hypothermic stresses are removed; patients who must avoid the cardiovascular stress of shivering may require active rewarming unless the shivering can be suppressed with benzodiazepines or meperidine or eliminated through neuromuscular blockade (in patients who are already sedated and receiving mechanical ventilation).

Active external rewarming consists of heating the skin with heating pads, heated blankets, hot water bottles, or a forced air heating system; radiant heat from a light source; or immersion in warm water. Concerns include the risk of burn injuries to the vasoconstricted skin and the possibility of "core temperature after-drop" because warming the skin prior to the core may result in peripheral vasodilatation and enhance return of cold, acidic blood to the core.

Active core rewarming techniques include the administration of heated oxygen by face mask or endotracheal tube, warmed intravenous fluids, warm gastric or bladder irrigation, warm lavage (peritoneal, thoracic, mediastinal, or colonic), and cardiopulmonary bypass or extracorporeal membrane oxygenation. The optimal rewarming rate is unknown, and the relative efficacy of these methods has not been established. Extracorporeal rewarming is preferred in patients with circulatory arrest.

All hypothermic patients with a severely depressed level of consciousness should be intubated to prevent aspiration. Patients should receive 100 percent oxygen until adequate oxygenation has been documented. Blood gas interpretation is complicated in the setting of hypothermia, and the optimal strategy for managing acid–base status remains controversial.

Hypotension in hypothermic patients is generally due to dehydration resulting from increased urine output, and fluid resuscitation is usually adequate. The role of inotropic agents is debated, because they have reduced efficacy at temperatures below 30°C and may be arrhythmogenic. Similarly at temperatures below 30°C, cardiac arrhythmias are resistant to many pharmacologic agents, pacing efforts, and defibrillation. Fortunately, many atrial arrhythmias and transient ventricular arrhythmias convert spontaneously during rewarming. For persistent ventricular arrhythmias, no antiarrhythmic agent has been shown to be safe and effective.

Treatment of hypothermia can lead to changes in serum electrolyte levels, requiring frequent monitoring. Hyperkalemia or hypophosphatemia may be particularly severe. Patients should be assessed for coagulopathy, including disseminated intravascular coagulation. A nasogastric tube should be inserted and serum amylase level checked because of the risk of ileus and pancreatitis.

The prognosis in hypothermia is influenced more by the patient's age and underlying disease than by the magnitude of the temperature decline. Some patients have been successfully resuscitated after 2 hours of apparent arrest, and others have survived temperatures below 20°C. This has prompted some to advocate warming all patients to normal temperatures before concluding that resuscitation is futile ("patients are not dead unless they are warm and dead").

THERAPEUTIC HYPOTHERMIA

A 12- to 24-hour period of therapeutic hypothermia to a target of 32° to 34°C is recommended for unconscious adults who have achieved return of spontaneous circulation after out-of-hospital cardiac arrest when the initial rhythm was ventricular fibrillation or pulseless ventricular tachycardia, based on studies showing reduced mortality and improved neurologic outcome.[18] Further investigation is required to determine the optimal duration of treatment, target temperature, and cooling method, as well as the efficacy of hypothermia when cardiac arrest occurs in the hospital or after other rhythms. Therapeutic hypothermia has not been demonstrated to improve outcomes after head trauma or other neurologic injury, or during neurosurgical procedures. Clinicians assessing prognosis in patients who are comatose following cardiac arrest need to recognize that predictive clinical findings and laboratory tests may be less reliable following therapeutic hypothermia.[19] Even the criteria for brain death in this setting may need to be revisited.

Concussion

CATHRA HALABI

DEFINITIONS AND EPIDEMIOLOGY
PATHOPHYSIOLOGY AND BIOMARKERS
CLINICAL APPROACH
  Active Recovery
  Concussion Subtypes
SUBSEQUENT DEVELOPMENT OF NEURODEGENERATIVE DISEASE
CONCLUDING COMMENTS

Traumatic brain injury (TBI) is a leading cause of morbidity and mortality worldwide.[1] The vast majority of injuries are classified as “mild” using current diagnostic criteria, and concussion is considered the mildest form of TBI. Concussion and mild TBI (mTBI) are terms that are often used interchangeably, with some controversy.[2] Many position statements and clinical practice guidelines from professional organizations use the term “concussion/mTBI,” and while all concussions are classified under the umbrella of mTBI, all mTBIs are not concussions. When there are intracranial abnormalities on brain imaging, a classification of “complicated mTBI” should be applied rather than concussion and may be associated with worse outcomes.

The term “postconcussion syndrome” has historically been used to describe a persistent constellation of symptoms following concussion/mTBI. However, these long-lasting symptoms may also reflect alternative diagnoses including premorbid medical conditions. The term “persistent postconcussive symptoms” may be preferred, in part to minimize misattribution of symptoms to ongoing or active brain injury,[3] and to minimize maladaptive perspectives toward recovery for both patients and their clinicians. “Subconcussive head trauma” refers to impact without clinical signs or symptoms meeting the threshold for concussion/mTBI diagnosis, though exposure to repeat subconcussive head trauma has been associated with neurodegenerative disease, including chronic traumatic encephalopathy (CTE).

Despite classification as the mildest form of TBI, concussion/mTBI may cause a wide range of debilitating symptoms with related functional impairment spanning the acute and chronic postinjury periods. Early recognition, reassurance, and systematic treatment strategies may improve outcomes and help guide safe return-to-activity parameters. There are numerous position statements and practice guidelines from professional organizations that address the recognition, diagnosis, and management of concussion/mTBI, and these are updated frequently.[4–6] This chapter focuses on the clinical approach to concussion/mTBI in adults and highlights this complex condition as a treatable entity.

DEFINITIONS AND EPIDEMIOLOGY

Concussion/mTBI is a purely clinical diagnosis. Characteristics include a history of altered neurologic function due to an external force transmitted to and through the brain, often leading to transient changes in the level of alertness or orientation. Concussion/mTBI may occur in a diverse range of circumstances. Common examples include blunt nonpenetrating head trauma from community events such as falls or assault, acceleration and deceleration forces from whiplash in traffic collisions, body checking in contact or collision sports, or blast injury among military personnel. Based on clinical features ascertained at

Aminoff’s Neurology and General Medicine, Sixth Edition.

time of injury (sometimes specified as within 30 minutes from index event), a diagnosis of concussion/mTBI can be distinguished from moderate and severe TBI in several ways using the current system of injury stratification. There is usually a transiently altered level of alertness or orientation, no or only brief (0 to 30 minutes) loss of consciousness, peri- or post-traumatic amnesia lasting less than 24 hours, the onset of neurologic or other symptom immediately or within 1 to 2 days, and a Glasgow Coma Scale (GCS) score of 13 to 15. In 2015, the Department of Defense (DoD) published a memorandum indicating that the GCS should not be used in diagnoses of TBI.

Concussion/mTBI is a global health problem. In the United States alone, there may be at least 2.5 million TBI-related emergency department encounters annually, and this is likely an underestimate due to unrecognized concussive injury, patient or clinician misappropriation of symptoms to alternative diagnoses, or under-reporting.[1] The majority (80 to 90% or more) of all head injuries are classified as concussion/mTBI. Traffic and other community accidents may occur indiscriminately, but there are several groups at particular risk for sustaining head injury, including athletes, older adults (from falls), military personnel, and individuals with a prior history of TBI. Different mechanisms of injury may instigate distinct pathophysiologic sequelae, such as with blast exposure. There may also be unique patient or population level attributes that affect acute and subacute periods (e.g., physical resilience in athletes, cognitive vulnerability in older adults). Nonetheless, current injury classifications and subsequent management strategies are applied broadly to identify and treat concussion/mTBI since there is a paucity of evidence at this time to promote significantly differing management strategies solely based on the mechanism of injury.[6] Patient-level characteristics should always be taken into consideration as with any complex medical condition.

Commonly utilized postinjury epochs include the immediate period (week 1), the acute period (weeks 1 to 6), the postacute or subacute period (weeks 7 to 12), and the chronic period thereafter. Many individuals recover briskly after concussion/mTBI within hours to days (typically 1 to 2 weeks), though symptoms may dissipate over several weeks in others. A frequently used benchmark for complete symptom resolution is 3 months, although some individuals remain symptomatic for weeks or even months afterward.

The majority of individuals with a history of concussion/mTBI can still expect a full recovery even if symptoms persist after 3 months. However, at least 10 to 25 percent of those with a history of concussion/mTBI may have a protracted symptom burden extending well beyond the traditionally quoted time periods noted above.[7] In this setting it may become challenging to disentangle unmasked or exacerbated premorbid conditions such as mood, headache, or sleep disorders from those persisting after injury. An additional complicating factor is that many of these same comorbid conditions may place an individual at risk for a protracted recovery course perhaps due to as-yet undefined pathophysiologic or psychosocial vulnerabilities. Moreover, neuroendocrine dysfunction is an under-recognized consequence of concussion/mTBI and, like impaired sleep, can accentuate symptom burden.

PATHOPHYSIOLOGY AND BIOMARKERS

Concussion/mTBI and more severe TBIs are linked by a common pathophysiology on a continuum of increasing complexity which is modified by (1) mechanism of injury; (2) the type, direction, and intensity of forces; and (3) a diversity of accompanying traumatic wounds including penetrating injuries, skull base fractures, intracranial lesions, and related conditions such as seizure or cerebral edema.[8] Subsequent secondary or tertiary systemic and neurologic abnormalities further propagate neurologic injury.

By historical definition, commonly used clinical neuroimaging methods such as computed tomography (CT) and magnetic resonance imaging (MRI) should not reveal brain structural abnormalities in concussion, and there should be no evidence of diffuse axonal injury, the so-called pathognomonic lesion of more severe injuries linked with potentially worse outcomes. Characterization of the underlying patterns and distribution of microstructural, biochemical, physiologic, and functional connectivity changes after concussion/mTBI is an active area of investigation using advanced noninvasive structural and functional neuroimaging techniques including diffusion tensor imaging, functional MRI, magnetoencephalography, and positron emission tomography.

Following concussion/mTBI, different central nervous system cell types release numerous substances, some of which are ultimately detectable in the systemic circulation. Many of these substances have been investigated for their utility as biomarkers, including glial fibrillary acidic protein (GFAP), ubiquitin carboxyl-terminal esterase L1 (UCH-L1), S100 calcium-binding protein B (S100-B), neuron-specific enolase (NSE), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) peptide, and tau. Tests measuring peripheral GFAP and UCH-L1 in particular have received FDA clearance to support acute diagnostic evaluations of adults with mTBI in the emergency setting, particularly to select individuals who should undergo brain imaging. However, a clinically indicated head CT even after such selection may not reveal acute abnormalities in patients presenting within concussion/mTBI. A proportion of these patients will demonstrate abnormalities on short-interval follow-up brain MRI that were undetectable on CT, excluding a diagnosis of concussion in favor of at least mild or complicated mild TBI. Recently, distinctly elevated plasma GFAP concentration measured within 24 hours of injury was shown to identify individuals likely to have abnormal MRI findings and, by proxy, ongoing follow-up needs, even when the initial head CT was negative.[9] GFAP levels were still elevated to a degree in MRI-negative mTBI cases compared with a control group. It is not yet known whether tracking plasma GFAP or other protein levels during recovery further stratifies clinical course. Combining measures from varying modalities may offer additional prognostic information. For care beyond the emergency department, most recent position statements and clinical practice guidelines do not yet recommend routine use of the above tests during recovery to guide management.

The heterogeneous clinical manifestations of concussion/mTBI reflect complex pathophysiologic mechanisms within and distal to the epicenters of brain injury, likely modulated by numerous patient-level features such as age at time of injury, type of injury, genetics, robustness and persistence of any innate inflammatory or other physiologic responses, and comorbid conditions. An ideal biomarker or set of biomarkers should be widely available, practical, inexpensive, and predictive of acute brain injury, recovery, and resolution. Recovery and return-to-activity guidance remain clinical determinations, necessitating systematic yet tailored treatment approaches until such markers are available. Symptom burden in the days following concussion/mTBI may be the currently most consistent predictor of slowed recovery.[10]

CLINICAL APPROACH

An organized diagnostic framework will allow accurate and swift determination that (1) a brain injury has occurred, even when the preceding event is atypical, particularly for those who do not present to the emergency department or urgent care clinic; (2) the symptoms experienced by an individual are actually a result of the injury; (3) there are no competing or complicating diagnoses (e.g., seizure, neurovascular lesions such as dissection, neurosurgical emergencies such as hematoma expansion); and (4) that investigation of reversible and treatable sequelae are undertaken. The latter often requires a thorough history and examination with judicious, targeted use of diagnostic tests such as neuroimaging, neuropsychologic testing, serum neuroendocrine screening, and specialty consultations. The manifestations of concussion/mTBI are highly variable and a patient may present to a number of different clinical venues or specialists before undergoing a comprehensive diagnosis. It is essential to emphasize to patients and to clinicians across multiple specialties that the consequences of concussion/mTBI are treatable.

Due to the tremendous variability in manifestations of concussion/mTBI, a patient may present to clinical care in late acute, subacute, or chronic phases with a debilitating milieu of symptoms. A systematic and domain-based evaluation creates a structured path forward for the patient, the primary or referring provider, and multidisciplinary care collaborators. The focus of care is multifaceted but includes safe, yet relatively prompt, return to usual activities. It is reasonable to select the most bothersome impairments, or the greatest barriers to usual activities, and target diagnostics and treatment strategies accordingly. Initial steps include allowing the patient to debrief regarding the injury while ascertaining date and mechanism of injury and severity classification. Important physical and neurobehavioral domains to query are noted in Table 37-1.

A detailed history paired with general and neurologic examinations will then allow for packaging of symptoms into distinct post-traumatic diagnoses, even if there is overlap of symptoms among domains. Diagnostic and treatment plans can then remain targeted and organized.

No single clinical examination maneuver, outcome measure, or set of outcome measures is uniformly applicable to all concussion/mTBI patients. However, position statements and clinical practice guidelines are updated regularly, highlight broadly used (and in some cases validated) instruments relevant to specific patient populations, and describe emerging techniques that can aid in diagnosis and treatment.[4–6] As

TABLE 37-1 ■ Manifestations of Concussion/Mild Traumatic Brain Injury

Post-traumatic Headache
Migraine phenomenology (e.g., photo-/phonophobia)
Tension-type headache
Occipital neuralgia
Other Pain
Pain in distribution of point of impact
Neck pain
"Dizziness"
Light-headedness
Vertigo
Imbalance
Orthostatic symptoms
Vision Changes
Vision loss (structural injury to optic nerve, retina)
Blurry vision (impaired accommodation)
Diplopia
Oscillopsia
Photophobia
Hearing Changes
Tinnitus
Phonophobia
Hearing loss
Neuroendocrine Dysfunction
Libido changes
Menstrual cycle irregularity
Erectile dysfunction
Mood impairment
Cognitive impairment
Cognitive Impairment
Short-term memory impairment
Inattention and other executive dysfunction
Slow processing
"Cognitive fog"
Mood Impairment
Exacerbated or de novo anxiety or depression
Irritability
Emotional dysregulation
PTSD
Affect changes
Fatigue
General fatigue
Excessive need for sleep
Exacerbated sleep disorders
Sleep Disturbance
Insomnia
Increased sleep duration
Frequent awakenings
Daytime somnolence
Symptoms suggestive of sleep apnea
Anosmia
Related weight changes
"History of Priors"
Timing and mechanisms of prior head injury
Headache history
Premorbid mood disorder(s)
Learning disability
Substance use
Family history of mood, cognitive, or learning disorders

Patients should be questioned about each individual domain. Common and/or often under-recognized sequelae are listed and suggested as prompts.

but one example, vestibular and vision system impairment is common after concussion/mTBI and the two systems have a high degree of overlap; the Vestibular/Ocular Motor Screening (VOMS) Assessment measures vestibular and oculomotor impairments by assessing eye movement smooth pursuits, saccades, near point convergence, vestibulo-ocular reflex (VOR), and visual motion sensitivity.[11] Impairments have been shown to identify individuals with sports-related concussion/mTBI. Taken in context with the clinical presentation and whole examination, the results from VOMS can inform subsequent consultation strategies (e.g., neuro-ophthalmology, neuro-otology, vestibular rehabilitation, vision therapy) while providing trackable metrics. In general, examination maneuvers and related diagnostic studies or consultations parallel the domains queried in Table 37-1.

When possible, measures documenting impairment or symptom severity should be tracked over time in order to gauge recovery trajectory or efficacy of treatment plans. Such measures should focus on observed or elicited clinical metrics and self-reported symptom

TABLE 37-2 ■ Suggested Approach to Diagnosis and Management

Post-traumatic Headache
Determine primary headache disorder semiology most consistent with presenting symptoms
Use established treatment strategies for the above disorder(s) including procedural interventions
Refer to consulting specialist if usual treatment strategies fail
Other Pain
Obtain physical therapy consultation (e.g., for cervical pain)
Consider comprehensive pain management/consultation
"Dizziness"
Determine etiology (e.g., central vs. peripheral vs. autonomic)
Arrange for formal balance evaluation
Refer to relevant consulting specialist
Arrange for vestibular rehabilitation
Vision Changes
Formal neuro-ophthalmologic evaluation
Formal balance testing
Consider vision therapy
Consider vestibular rehabilitation
Hearing Changes
Formal hearing test
Refer to relevant consulting specialist
Coping strategies (such as for tinnitus)
Consider migraine treatment, if appropriate, for phonophobia
Neuroendocrine Dysfunction
Serum neuroendocrine screen if indicated or if history of prior head injury, followed by referral to relevant specialist if abnormal
Cognitive Impairment
Address confounders (e.g., pain, mood, sleep)
Formal neuropsychologic evaluation and/or refer to specialist if persistent
Exclude reversible/treatable etiologies if persistent
Refer for neuroimaging if persistent
Refer for cognitive rehabilitation
Mood Impairment
Address confounders
Consider pharmacologic management
Refer to psychologist and/or psychiatrist (consider early referral in some cases)
Exclude reversible/treatable etiologies if persistent
Fatigue
Address confounders
Exclude reversible/treatable etiologies if persistent
Sleep Disturbance
Sleep hygiene counseling
Address confounders
Exclude reversible/treatable etiologies
Refer to relevant consulting specialist
Anosmia
Monitor weight
General Strategies
Abstinence from alcohol while symptomatic
Abstinence from activities that could lead to subsequent head injury during recovery
Consider testing only in chronic period, or 6–12 months after injury
Counseling regarding possible symptom triggers with cognitive, physical, or even emotional loads
Reassurance and education

Testing should be guided by the history and examination. Note overlapping confounders and strategies across many categories.

inventories. Unexplained focal neurologic signs or symptoms consistent with alternative diagnoses should prompt neuroimaging to exclude a structural cause. New signs or symptoms emerging after the first 1 to 2 weeks should also lower the threshold for neuroimaging or other indicated diagnostic studies. Targeted cognitive screening may be appropriate early after injury, depending on the patient population, to ensure impairments are within typical domains and not indicative of another condition. However, referral for full neuropsychologic evaluation for common complaints may not be warranted until confounders such as pain and sleep impairment are addressed. The VA/DoD Clinical Practice Guideline for Management of Concussion/mTBI recommends against comprehensive testing within the first 30 days of injury for service members with concussion/mTBI, particularly until competing diagnoses and confounders have been addressed.

Table 37-2 lists examples of potential diagnostic and therapeutic strategies for each domain listed in Table 37-1. For each category, ruling out red flags with urgent or emergent diagnostics is implied.

An additional "general strategies" category is also listed and is typically broadly applicable to most patients.

Many professional organizations recommend that clinicians educate patients via verbal and written material when possible regarding diagnosis, recovery, and clinic or emergency room return precautions. This material is typically available online through these organizations. In addition to these position statements, practice guidelines, and online patient-facing material, there are additional resources for the clinician which highlight practical management strategies for concussion/mTBI supported by evidence and longitudinal experience.[12]

Active Recovery

Active recovery approaches necessitate collaboration between the patient, family, and care team. The approach includes rapid identification and characterization of brain injury followed by targeted diagnostic and therapeutic programs that also involve patient education. In general, 1 to 2 days of rest is appropriate, including cognitive and physical rest with avoidance of overstimulation, followed by graded increases in usual activities with light to moderate intensity and with sufficient rest in between exposures provided the prescribed activities do not cause clinically significant symptoms. Symptom recrudescence may occur with increasing cognitive, physical, or even emotional challenges, and early expectation management and subsequent scaling of activity prescriptions may mitigate related distress, reluctance to engage in activity for fear of worsening injury, or any actual risk of injury exacerbation. It is important to note, however, protracted rest or abstinence from activities, if not clinically indicated, may lead to patient isolation and prolong symptom burden.

Prior dogma of strict physical activity limitations is also being challenged by emerging evidence supporting subthreshold aerobic exercise with escalating intensity, particularly in sports-related concussion/mTBI. One biologically plausible explanation in support of an exercise prescription relates to possible effects of aerobic exercise activity on cerebral blood flow. Autonomic nervous system function after concussion/mTBI may be impaired, especially if there are rotational forces transmitted through the brainstem during injury. These forces may cause microstructural changes affecting functionally connected processes such as altered peripheral and central sensitivity to the arterial partial pressure of carbon dioxide ($PaCO_2$), leading to inappropriate relative hypoventilation during exercise. Subsequent elevated $PaCO_2$ levels during aerobic activity increase cerebral blood flow (CBF) which may then exacerbate postconcussive symptoms, particularly early after injury. Training programs targeting subthreshold aerobic exercise may restore relevant sensitivity to $PaCO_2$, recalibrate CBF regulation, and ultimately reduce symptom exacerbation with increasing exercise intensity.[13] Aerobic exercise has thus been described as a treatment modality and a potential physiologic biomarker that parallels recovery (e.g., less postconcussive symptom recrudescence with ongoing training).[13] Most athletes presenting to clinic with concussion/mTBI should therefore be counseled to engage in graded light to moderate physical activity, after a brief period of initial rest, and should be referred to a physical therapist or other experienced professional for guidance with structured and studied programs such as the Buffalo Concussion Exercise Treatment Protocol.[3,13] Nonathlete patient populations may also benefit from this approach when supervised by an experienced therapist although this concept is not yet explicitly stated uniformly across position statements and practice guidelines. With careful counseling and safety screening, a patient may be able to conceptualize subthreshold aerobic exercise as a dose of medication even on days when prescribed physical activity has already occurred, or on days when the patient feels particularly unwell.[13]

The relationship between aerobic exercise and neuroplasticity is complex in patients with a history of acquired brain injuries of varying etiologies and severity. This is an active area of investigation targeted to identify periods of maximal benefit (and potential harm), establish frequency and intensity of exercise, and to more clearly characterize physiologic, neurobehavioral, and quality of life improvements. Exercise in general has clearly demonstrated powerful health advantages across disciplines for numerous medical conditions. Establishing a supervised exercise program with a goal toward an independent exercise routine and other usual activities may be a critical intervention with widespread benefits beyond concussion/mTBI treatment. Such a program provides additional structure to an active recovery approach and may empower the patient to self-administer treatments outside of prescribed therapy encounters. Counseling within the clinic, partnering with experienced therapists, and customizing plans for patients with a range of abilities or comorbid conditions will likely gain additional experimental support to enhance recovery. Screening for comorbid conditions is critical for harm reduction when prescribing exercise and should take into account an individual's medical history, medications, and functional abilities for prescription adaptation.

In addition to exercise as a treatment paradigm and the widely available educational material regarding graded activity exposure, customized return-to-activity plans should account for an individual's professional and personal obligations. As with exercise, a plan for a graded return to normal daily activity may be helpful.

Concussion Subtypes

Accumulating evidence supports distinct concussion/mTBI phenotypical subtypes characterized according to the primary symptomatic presentation. Subtypes include cognitive, ocular-motor, headache/migraine, vestibular, and anxiety/mood categories. Features of these subtypes are not mutually exclusive and may transition to other subtypes throughout recovery.[14] Current investigative strategies include using multimodal assessment techniques to fully characterize these proposed subtypes. Detailed clinical phenotypes may ultimately allow for earlier treatment target identification, more accurate prognostication, and refined treatment trial selection criteria. Position statements and guidelines do not yet discuss differences in management for these concussion subtypes, but in general targeting the most bothersome symptoms for diagnostic and treatment strategies is recommended.

SUBSEQUENT DEVELOPMENT OF NEURODEGENERATIVE DISEASE

Individuals who have sustained concussion/mTBI have common concerns related to prognosis, including the risk for developing neurodegenerative disease, particularly when cognitive impairment is a prominent presenting feature. More severe injuries have been linked with several neurodegenerative disorders including Alzheimer disease, Parkinson disease, and amyotrophic lateral sclerosis.[8,15] More recently, milder forms of head trauma including concussion/mTBI have been linked to increased risk for developing neurodegenerative disease. Patient-level factors that impact the link between TBI of any severity and neurodegenerative disease include genetics (e.g., APOE genotype status, α-synuclein genotype), age at which the injury was sustained, number and severity of repeated injuries, and various environmental exposures.[15] It is important to emphasize to the patient that many individuals with neurodegenerative conditions have not sustained head injuries, and many individuals with a history of head injury do not develop neurodegenerative disease. However, of equal importance is recognition of refractory cognitive and other neurobehavioral impairments beyond expected recovery curves following concussion/mTBI, particularly among certain presumably at-risk individuals (e.g., older adults, athletes, military personnel). These patients with refractory cognitive symptoms may warrant an expanded evaluation with relevant specialists in addition to usual concussion/mTBI clinical care.

A history of repetitive subconcussive or concussive head injuries has been identified as a risk factor for CTE. CTE is not a diagnosis that can occur during life but rather is a neuropathologic determination at autopsy. Determining the lifetime clinical correlates to CTE is an active area of investigation, and traumatic encephalopathy syndrome remains a research term used by investigators for related phenotyping studies. The neuropathology of CTE is unique among other neurodegenerative conditions and includes distribution of phosphorylated tau in perivascular neurons and astrocytes near cortical sulci, which are areas of particular vulnerability for axonal injury in head trauma. A large proportion of CTE cases also have other proteinopathies found in classic neurodegenerative diseases.[8] Precise impact quantity and severity thresholds and patient-level vulnerabilities that trigger the neuropathologic events leading to CTE are not yet known and are an area of active research. Regardless, there is an increasingly recognized framework that links repeat subconcussive and concussive injuries to clinical syndromes consistent with neurodegenerative disease, and ultimately a neuropathologic diagnosis of CTE. High-profile historical and recent literature has highlighted clinical syndromes among boxers thought to have CTE in retrospect, and confirmed CTE diagnoses have been made among other contact or collision sport athletes as well as military personnel.

Individuals with a history of multiple head injuries, head injuries in close succession, multiple subconcussive events, or sequentially more severe and more prolonged symptom burden following concussion/mTBI, should be engaged in discussions that weigh risks and benefits of ongoing exposure to the risk of subsequent injury. Currently, precise risk estimates of neurodegenerative disease are not available, but front-line clinicians are in a position to identify lingering or progressive neurobehavioral signs and symptoms despite appropriate and maximal medical management and then redirect diagnostic and treatment strategies accordingly. This approach should be considered in the appropriate clinical context even after a single concussion/mTBI, given compelling epidemiologic study results.[15]

CONCLUDING COMMENTS

Concussion/mTBI is a treatable entity despite highly variable clinical manifestations and is best addressed early after injury and with a systematic approach. Patient-level features may impact recovery trajectories. Persistent postconcussive symptoms may be approached in the same way as symptoms that occur in the acute or subacute period. Prolonged persistent postconcussive symptoms may also be complicated by, or even a result of, concurrent medical conditions, and caution should be used when attributing symptom profiles to a remote head injury. Currently, number and severity of immediate postinjury symptoms is the strongest predictor of prolonged recovery. Assessments should include clinical, cognitive, behavioral, and symptom burden measures to capture the entirety of treatable postconcussive sequelae and to gauge recovery in order to develop tailored return-to-activity guidance. Lingering or progressive cognitive or neurobehavioral symptoms may warrant expanded evaluation. Given the current lack of acute or prophylactic neuroprotective treatments for the moment of impact, select individuals at risk for ongoing exposure to subconcussive or concussive traumatic injury should be identified and engaged in a return-to-activity dialogue. Active recovery includes a multifaceted approach to gradual increase in usual activities until symptom resolution and avoids prolonged rest. Treatment paradigms are shifting toward increasingly evidence-based methods that will likely remain multifaceted. Biomarkers are needed to identify injury, track recovery and resolution, and flag risk for repeat or progressive injury despite optimal medical management, and a number of promising techniques are undergoing active investigation.

Acute bacterial infections of the central nervous system (CNS) include meningitis, brain abscess, subdural empyema, epidural abscess, and septic intracranial thrombophlebitis. The etiology, clinical presentation, diagnosis, and treatment of each of these bacterial infections are discussed in this chapter.

ACUTE BACTERIAL MENINGITIS

Bacterial meningitis is an acute purulent infection in the subarachnoid space, associated with an inflammatory reaction in the brain parenchyma and cerebral vasculature. During its treatment, not only must the meningeal pathogen be eradicated, but also the neurologic complications resulting from an often robust inflammatory reaction must be anticipated and managed. The most common causative organisms of bacterial meningitis are *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Staphylococcus aureus*, group B streptococci, and gram-negative bacilli. The current epidemiology of acute bacterial meningitis, the best diagnostic tests to perform on cerebrospinal fluid (CSF), the use of dexamethasone as adjunctive therapy, and the present recommendations for the use of chemoprophylaxis and vaccination are discussed here.

Etiology

The most common etiologic organisms of acute bacterial meningitis in children and adults are *S. pneumoniae* and *N. meningitidis*. Prior to the routine use of the *Haemophilus influenzae* type b conjugate vaccine,

Aminoff's Neurology and General Medicine, Sixth Edition.
© 2021 Elsevier Inc. All rights reserved.

H. influenzae type b was the most common cause of bacterial meningitis in children in the United States. Use of this vaccine has dramatically reduced the incidence of bacterial meningitis due to *H. influenzae* type b in children. *H. influenzae* type b, however, remains an important cause of bacterial meningitis in older adults, immunocompromised patients, and patients with chronic lung disease, splenectomy, leukemia, or sickle cell anemia. Children too young to have completed a primary *H. influenzae* type b vaccination course are also at risk.

S. pneumoniae is the most common cause of community-acquired meningitis in both children and adults in the United States and Europe. A number of predisposing conditions increase the risk of pneumococcal meningitis, the most common of which is pneumonia. Acute and chronic otitis media, sinusitis, immunodeficiency from alcoholism, diabetes, cancer, and immunosuppressive drugs are also important risk factors. Given the rise of multidrug-resistant strains of *S. pneumoniae* to both penicillin and third-generation cephalosporins, vancomycin is added to the initial empiric antimicrobial therapy, with specific antibiotic therapy based on culture susceptibilities.[1]

N. meningitidis is the second most common cause of meningitis in adults, but has a predilection for those younger than age 60. The quadrivalent (serogroups A, C, W-135, and Y) meningococcal glycoconjugate vaccine is recommended for all 11- to 18-year-olds, and is a requirement for attending most colleges and universities in the United States. A vaccine for serogroup B became available in 2015 and is increasingly recommended for college-bound students.

The Enterobacteriaceae (*Proteus* species, *Escherichia coli*, *Klebsiella* species, *Serratia* species, and *Enterobacter* species) cause meningitis in older adults; in adults with underlying diseases such as cancer, diabetes, alcoholism, congestive heart failure, chronic lung disease, and hepatic or renal dysfunction; and in neurosurgical patients.

L. monocytogenes is a cause of meningitis in individuals with impaired cell-mediated immunity from older age (adults greater than 55 years old), organ transplantation, pregnancy, malignancy, chronic illness, immunosuppressive therapy, and neonates. Outbreaks have occurred from eating contaminated foods. The incidence amongst pregnant women and neonates has decreased, likely from education on foodborne infections during pregnancy.[2] In addition, the routine use of trimethoprim-sulfamethoxazole as a prophylactic agent for the prevention of *Pneumocystis carinii* pneumonia in patients with the acquired immunodeficiency syndrome (AIDS) has the added benefit of reducing the risk of *L. monocytogenes* infection, including meningitis.

S. aureus and coagulase-negative staphylococci are the predominant organisms causing meningitis as a complication of invasive neurosurgical procedures, particularly shunting procedures for hydrocephalus and with subcutaneous Ommaya reservoirs or following lumbar puncture for the administration of intrathecal chemotherapy. Hematogenous spread accounts for 25 percent of *S. aureus* meningitis cases and is seen in patients with endocarditis, pneumonia, and skin or soft-tissue infections. Intravenous drug use accounts for an increasing number of methicillin-resistant (MRSA) infections.

Streptococcus agalactiae, or group B streptococcus, is a leading cause of bacterial meningitis and sepsis in neonates and is increasingly recognized in two groups of adults: puerperal women and patients with serious underlying disease.

Clinical Presentation

The classic triad of symptoms and signs of bacterial meningitis consists of fever, headache, and stiff neck. An altered level of consciousness, such as lethargy or stupor, may deteriorate rapidly, and should be added to the classic triad for potential bacterial meningitis. Approximately 95 percent of patients will have at least two of the four symptoms and signs of fever, stiff neck, headache, or altered mental status, but less than 50 percent will have all three components of the classic triad.[3] Nausea, vomiting, and photophobia are common complaints, which often reflect elevated intracranial pressure (ICP). Seizure activity occurs in approximately 20 percent of patients, although in neonates this can approach 40 percent, typically either at the onset or within the first few days of the illness; seizures are a poor prognostic indicator.[1]

A stiff neck, or meningismus, is the pathognomonic sign of meningeal irritation. Meningismus is present when the neck resists passive flexion. Kernig and Brudzinski signs are classic signs of meningeal irritation with high specificities but relatively low sensitivities, and therefore their absence does not exclude the diagnosis. Kernig sign is elicited with the patient in the supine position; the thigh is flexed on the abdomen, with the knee flexed. Attempts to passively extend the leg elicit pain when meningeal irritation is present. Brudzinski sign is elicited with the patient in a supine position and is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees.

Increased ICP is an expected complication of bacterial meningitis and is the major cause of obtundation and coma. The most common signs of increased ICP in bacterial meningitis are an altered level of consciousness and papilledema. Cerebral arteritis and septic venous thrombosis of the cerebral dural sinuses and cortical veins are also complications of bacterial meningitis, often presenting as focal neurologic deficits or as new-onset seizure activity.

The rash of meningococcemia begins as a diffuse erythematous maculopapular rash resembling a viral exanthem, but the lesions rapidly become petechial. This rash can be differentiated from the rash of a viremia in that petechiae are found on the trunk and lower extremities in meningococcemia. Petechiae may also be found in the mucous membranes and conjunctiva and occasionally on the palms and soles. Other infectious diseases that may manifest with a petechial, purpuric, or erythematous maculopapular rash resembling that of meningococcemia include enteroviral meningitis, Rocky Mountain spotted fever, West Nile virus encephalitis, bacterial endocarditis, echovirus type 9 viremia, and, more rarely, pneumococcal or *H. influenzae* meningitis.

Diagnosis

The diagnosis of bacterial meningitis is made by examination of the CSF. The necessity of neuroimaging prior to lumbar puncture has been debated for years. The presence of any of the following necessitate neuroimaging prior to lumbar puncture: an altered level of consciousness, papilledema, focal neurologic deficits, an immunocompromised state, or new-onset seizure activity. When the clinical presentation is suggestive of bacterial meningitis, two sets of blood cultures should be obtained and dexamethasone and empiric antimicrobial therapy initiated immediately. If the patient is being treated with antibiotics, there is no risk in delaying lumbar puncture until after neuroimaging has been performed. While antibiotics do decrease the likelihood of a positive CSF culture, the culture is still positive in approximately 75 percent of cases if obtained less than 4 hours after antibiotic initiation, since it takes time to sterilize the cultures once antibiotics have been initiated. Antibiotic therapy for several hours prior to lumbar puncture has little effect on CSF white blood cell count or glucose concentration, so even if the specific organism is not isolated, the overall suspicion of bacterial meningitis based on CSF abnormalities will remain. Blood cultures are positive at least 60 percent of the time, making them particularly helpful if CSF culture is negative. Serum procalcitonin is elevated in bacterial, but not viral, meningitis.

The classic CSF abnormalities in bacterial meningitis are: (1) an increased opening pressure (>18 cm water); (2) a pleocytosis of polymorphonuclear leukocytes (10 to 10,000 WBCs/mm^3); (3) a decreased glucose concentration (<40 mg/dL or CSF/serum glucose ratio of <0.31); and (4) an increased protein concentration. A CSF sample should be analyzed using Gram stain and bacterial culture, which can identify the causative pathogen in approximately 80 percent of patients. CSF PCR assays detect bacterial nucleic acid in CSF. A 16S rRNA conserved sequence broad-based bacterial PCR can detect small numbers of viable and nonviable organisms in the CSF, but this assay has been replaced by newer nucleic acid assays.

A commonly used PCR panel is the FilmArray Meningitis/Encephalitis panel which tests six bacterial meningeal pathogens, including *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, *E. coli*, group B streptococcus and *L. monocytogenes*. Specific advantages of this PCR panel are its rapid turnaround time, which can be as short as 1 hour, and that antibiotics do not interfere with its results. The sensitivity and specificity of the FilmArray Meningitis/Encephalitis panel for bacterial pathogens is not known at this time as further studies are still required for verification along with further refinements to reduce false-positive rates. Metagenomic next-generation sequencing (mNGS) is a newer nucleic acid assay to identify the meningeal pathogen.[4] A limitation to mNGS is that the results take time. Metagenomic next-generation sequencing is particularly helpful in those instances when the pathogen is difficult to detect. PCR assays have eliminated the need for previously used tests, such as the latex particle agglutination test, which had high specificities but variable sensitivities. A false-positive PCR is a possibility with meningitis/encephalitis panels and mNGS. The results of a PCR assay can be confirmed by a conventional test, such as culture, CSF IgM, acute and convalescent serology, or some combination of these tests. In clinical practice, when bacterial meningitis is a possibility, most physicians treat with empiric therapy until CSF analysis suggests an alternative diagnosis.

If there are petechial skin lesions, biopsies should be performed. While the occurrence of a rash is only modestly sensitive, it is highly specific for meningococcal meningitis if present. The rash of meningococcemia results from the dermal seeding of organisms with vascular endothelial damage, and biopsy may reveal the organism on Gram stain.

Lumbar puncture should be performed with a 22- or 25-gauge needle. The amount of CSF recommended for testing is 10 to 15 ml, which includes saving 5 ml for future testing. Cell count with differential, glucose and protein concentrations, Gram stain and culture, and viral culture and PCR assays all should be sent and more advanced testing including panels and mNGS should be considered as above in some clinical situations.

Differential Diagnosis

Viral meningitis and herpes simplex virus (HSV) encephalitis are the leading diseases in the differential diagnosis of bacterial meningitis. Arthropod-borne viral encephalitis should be considered during the summer and early fall months while mosquitoes are biting. Focal intracranial mass lesions and subarachnoid hemorrhage also need to be included in the differential diagnosis when approaching patients with suspected meningitis.

VIRAL MENINGITIS

In a patient with fever, headache, and a stiff neck, the leading consideration in addition to bacterial meningitis, is viral meningitis. The key difference is that patients with viral meningitis do not typically have an altered level of consciousness and are both awake and alert. Patients with viral meningitis will often be sitting up and concerned about the severity of their headache. Patients with viral meningitis also do not have seizures or focal neurologic deficits. In addition to clinical differences, viral meningitis will have a distinct CSF profile from bacterial meningitis. In comparison to the predominantly polymorphonuclear pleocytosis and low glucose concentration of bacterial meningitis, patients with viral meningitis will exhibit a lymphocytic pleocytosis with a modest white cell count (often 100 to 500 WBCs) and normal glucose concentration. Treatment for viral meningitis is largely supportive, except when the organism is herpes simplex virus (HSV) or varicella zoster virus (VZV), in which case acyclovir, valacyclovir, or famciclovir should be used. Viral meningitis is typically a self-limited disease, but the headache may take months to resolve.

HERPES SIMPLEX VIRUS ENCEPHALITIS

The clinical presentation of HSV encephalitis (discussed in detail in Chapter 42) often includes hemicranial headache, fever, behavioral abnormalities, focal or generalized seizure activity, and focal neurologic deficits (e.g., dysphasia, usually hemiparesis with greater involvement of the face and arm, and superior visual field defects). The symptoms of HSV encephalitis typically evolve over several days, and the presentation is often less acute than bacterial meningitis. In patients with HSV encephalitis, fluid-attenuated inversion recovery (FLAIR), T2-, and diffusion-weighted magnetic resonance imaging (MRI) sequences demonstrate lesions in the medial and inferior temporal lobe, inferior frontal lobe, and insular cortex that begin unilaterally and remain asymmetric if contralateral involvement occurs. Lesions will have associated edema, restricted diffusion (particularly early in the course), hemorrhage, or some combination of these features. The absence of an abnormality on MRI 48 hours after symptom onset should prompt consideration of another diagnosis.

There is a distinctive electroencephalographic (EEG) pattern in HSV encephalitis, consisting of periodic, stereotyped complexes from one or both temporal areas that occur at regular intervals of 1 to 2 seconds and are typically observed between day 2 and day 15 of the illness. Examination of the CSF reveals an increased opening pressure, a lymphocytic pleocytosis of 5 to 500 cells/mm^3, a mild to moderate elevation in the protein concentration, and a normal or mildly decreased glucose concentration. There may be red blood cells or xanthochromia, findings that reflect the hemorrhagic nature of the encephalitis but are neither sensitive nor specific markers of the disorder. Results of CSF viral cultures for HSV-1 are almost always negative.

HSV PCR is the gold standard for diagnosis with a sensitivity of 96 percent and specificity of 99 percent. Nonetheless, a false-negative PCR is possible within the first 72 hours of symptom onset. If an initial CSF HSV PCR is negative within the first 72 hours of symptoms and HSV remains a major diagnostic consideration, patients should be continued on empiric treatment and repeat lumbar puncture with HSV PCR should be performed 3 to 7 days later. CSF and serum samples can also be sent for HSV IgG antibody titers if neurologic symptoms are present for more than 1 week at the time of presentation, since the sensitivity of HSV PCR begins to decline after the first week and antibodies to HSV appear in the CSF approximately 8 to 12 days after onset of symptoms. A serum to CSF HSV-1 antibody ratio of less than 20 to 1 is considered diagnostic of intrathecal synthesis of antibodies and HSV encephalitis in the appropriate clinical context.

ARTHROPOD-BORNE VIRUS ENCEPHALITIS

During the summer and early fall months when mosquitoes are active, arthropod-borne virus (also known as arbovirus) encephalitis (see Chapter 42) should be included in the differential diagnosis of patients with meningitis. In the United States, the most common arbovirus is West Nile virus with the number of neuroinvasive cases ranging from a few hundred to a few thousand cases per year. The other arboviruses occur much less frequently, and include St. Louis encephalitis virus, Powassan virus, La Crosse virus, western equine encephalitis virus, Jamestown Canyon virus, and eastern equine encephalitis virus.[5] Eastern equine encephalitis virus causes the most severe arthropod-borne viral encephalitis, and the fatality rate is as high as 40 percent; recent outbreaks of this rare disease have raised awareness of the entity. Japanese encephalitis virus is the most common cause of arboviral encephalitis worldwide and occurs mainly in Asia. Venezuelan equine encephalitis virus is endemic in South America and is a rare cause of encephalitis in Central America and the southwestern United States, particularly in Texas.

The clinical presentation of arthropod-borne viral encephalitis, regardless of the specific virus, is fairly characteristic. The onset of encephalitic symptoms may be preceded by an influenza-like prodrome of fever, malaise, myalgias, nausea, and vomiting followed by headache, confusion, stupor, and occasionally convulsions. Focal neurologic deficits and focal seizure activity have been reported in cases of encephalitis caused by eastern equine encephalitis virus and La Crosse virus. Patients with West Nile virus encephalitis may have conjunctivitis or a maculopapular or roseolar rash. Patients with West Nile virus or St. Louis encephalitis virus may present with a polio-like acute asymmetric flaccid weakness or a syndrome of tremors, myoclonus, or parkinsonian features. The flaviviruses, including St. Louis encephalitis virus, Japanese encephalitis virus, and West Nile virus, tend to infect the basal ganglia and the thalamus, leading to tremors during the acute disease and a parkinsonian-like syndrome in survivors.

On neuroimaging, bilateral and symmetric T2-FLAIR hyperintensities with associated mass effect in the basal ganglia and thalamus are a characteristic finding in eastern equine encephalitis virus, St. Louis encephalitis virus, Japanese encephalitis virus, and West Nile virus encephalitis.

Examination of the CSF demonstrates a polymorphonuclear leukocytic pleocytosis if tested very early in the course, and this typically evolves to a moderate lymphocytic pleocytosis (i.e., several hundred cells). The CSF glucose concentration and protein concentration are usually normal. Based on criteria established by the US Centers for Disease Control and Prevention, a confirmed case of arboviral encephalitis is defined as a febrile illness with encephalitis during a period when arboviral transmission is likely to occur, plus at least one of the following: (1) fourfold or greater rise in serum antibody titer between the time of acute illness and 4 weeks later; (2) isolation of virus from tissue, blood, or CSF; or (3) a specific immunoglobulin M (IgM) antibody identified in the CSF. However, La Crosse virus has not been isolated from CSF and St. Louis encephalitis virus, eastern equine encephalitis virus, and western equine encephalitis virus are rarely isolated from CSF; therefore antibody titers are typically the diagnostic test of choice. A CSF PCR assay is available for the detection of West Nile virus nucleic acid and has a high specificity; however, it has a low sensitivity so a negative test does not exclude the disorder. The detection of West Nile virus IgM in CSF is considered the most sensitive diagnostic test for West Nile virus encephalitis. West Nile virus IgM antibodies may persist in serum (not the CSF) for a year or more after exposure to the virus and therefore cannot be used for definitive diagnosis of recent infection.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever is caused by the bacterium *Rickettsia rickettsii*. The disease begins with high fever, prostration, myalgias, headache, nausea, and vomiting. The rash is characteristic and presents initially as a diffuse erythematous maculopapular eruption appearing 2 to 4 days after the onset of symptoms, usually beginning at the wrist and ankles and then spreading distally, including to the palms and soles, and then proximally within a matter of a few hours. Diagnosis is made by immunofluorescent staining of skin biopsy specimens or by the detection of IgM and IgG antibodies. If a tick-borne etiology is suspected, then empiric treatment with doxycycline should be initiated.

Focal Infectious Intracranial Mass Lesions

Focal infectious intracranial mass lesions, including brain abscess, subdural empyema, and epidural abscess, are discussed later in this chapter but should be included in the differential diagnosis of bacterial meningitis. The presence of a focal infectious intracranial mass lesion is suggested by focal or generalized seizure activity or focal neurologic deficits on examination. This possibility is ruled out by neuroimaging.

Subarachnoid Hemorrhage

The possibility of a subarachnoid hemorrhage should also be included in the differential diagnosis of acute bacterial meningitis. The clinical presentation is characterized by the explosive onset of a severe headache or a sudden transient loss of consciousness followed by a severe headache. Because of the presence of blood in the subarachnoid space, nuchal rigidity is frequently present, leading to diagnostic confusion with infectious meningitis. A dilated nonreactive pupil is suggestive of a subarachnoid hemorrhage from an aneurysm of the posterior communicating artery. Computed tomography (CT) of the brain may demonstrate blood in the basal cisterns. If the CT scan is normal, the spinal fluid should be examined for red blood cells and xanthochromia. Red blood cells are present in the CSF within minutes of the rupture of an intracranial aneurysm and usually fail to clear in successive tubes of CSF. A sample of the blood-tinged CSF should be centrifuged; a yellow or xanthochromic color in the supernatant is present 6 to 12 hours following subarachnoid hemorrhage and lasts for 2 to 3 weeks. Xanthochromic spinal fluid may also be seen when the CSF protein concentration is elevated (above 150 to 200 mg/dL), and therefore it can be seen in bacterial meningitis.

Treatment

Empiric Antimicrobial Therapy

TABLE 38-1 ■ Empiric Therapy for Acute Bacterial Meningitis in Children and Adults

Community-acquired (immunocompetent child or adult)	Cefotaxime or ceftriaxone or cefepime *plus* Vancomycin *plus* Acyclovir
Community-acquired (immunosuppressed individual)	Cefotaxime or ceftriaxone or cefepime *plus* Vancomycin *plus* Acyclovir *plus* Ampicillin
Iatrogenic (associated with neurosurgery, epidural anesthesia, intrathecal chemotherapy)	Vancomycin *plus* Ceftazidime or meropenem

When bacterial meningitis is suspected, antimicrobial therapy is initiated immediately after blood cultures are obtained and before the results of CSF Gram stain, culture, and antimicrobial susceptibility tests are known. Empiric therapy should be based on the possibility that the patient has penicillin- and cephalosporin-resistant pneumococcal meningitis and should include a combination of a third- (ceftriaxone or cefotaxime) or fourth-generation cephalosporin (cefepime) plus vancomycin. Acyclovir is added to the empiric regimen to cover HSV (Table 38-1). Ampicillin should be added to cover *L. monocytogenes* if the patient is over the age of 55 years or is immunosuppressed. When the patient has been treated with trimethoprim-sulfamethoxazole for prophylaxis of toxoplasmosis or *P. carinii* pneumonia, it is less likely that the meningitis is due to *L. monocytogenes*. Meningitis that complicates a neurosurgical procedure, epidural anesthesia, head trauma with skull base fracture, or intrathecal chemotherapy should be treated empirically with a combination of vancomycin plus ceftazidime, cefepime, or meropenem. Vancomycin is used to cover staphylococci and ceftazidime, cefepime, or meropenem to cover gram-negative bacilli, specifically *Pseudomonas aeruginosa*. The doses of each of the antimicrobial agents are provided in Table 38-2, which shows both pediatric and adult dosing ranges.

Specific Antimicrobial Therapy

All CSF bacterial isolates should be tested for antimicrobial susceptibility. In experimental models of bacterial meningitis, the maximal bactericidal activity occurs when the antibiotic concentration is 10 to 30 times greater than the minimal bactericidal concentration of the microorganism in vitro.[6]

Pneumococcal Meningitis

Antimicrobial therapy for pneumococcal meningitis is initiated with a third- or fourth-generation cephalosporin

TABLE 38-2 ■ Doses of Antimicrobial Agents

Antimicrobial Agent	Total Daily Pediatric Dose (Dosing Interval)	Total Daily Adult Dose (Dosing Interval)
Acyclovir	30 mg/kg daily (every 8 h)	30 mg/kg daily (every 8 h)
Ampicillin	300 mg/kg daily (every 6 h)	12 g/day (every 4–6 h)
Cefepime	150 mg/kg daily (every 8 h)	6 g/day (every 8 h)
Cefotaxime	225–300 mg/kg daily (every 6–8 h)	12 g/day (every 4–6 h)
Ceftazidime	150–200 mg/kg daily (every 8 h)	8 g/day (every 8 h)
Ceftriaxone	80–100 mg/kg daily (every 12 h)	4 g/day (every 12 h)
Meropenem	120 mg/kg daily (every 8 h)	6 g/day (every 8 h)
Metronidazole	30 mg/kg daily (every 6 h)	2 g/day (every 6 h)
Nafcillin	200 mg/kg daily (every 6 h)	12 g/day (every 4 h)
Penicillin G	0.3 million U/kg/day (every 4–6 h)	24 million U/day (every 4–6 h)
Vancomycin	60 mg/kg daily (every 6 h)	45–60 mg/kg daily (every 6 h)
Intrathecal vancomycin	10 mg/day	20 mg/day

TABLE 38-3 ■ Specific Antimicrobial Therapy for Bacterial Infections of the Central Nervous System

Organism	Antibiotic
Streptococcus pneumoniae	
Sensitive to penicillin	Penicillin G *or* ceftriaxone *or* cefotaxime
Relatively resistant to penicillin	Ceftriaxone *or* cefotaxime
Resistant to penicillin	Vancomycin *plus*
	Cefotaxime *or* ceftriaxone +/− intraventricular vancomycin
Neisseria meningitidis	Ceftriaxone *or* penicillin G *or* ampicillin
Staphylococci	
Methicillin-sensitive	Nafcillin
Methicillin-resistant	Vancomycin
Listeria monocytogenes	Ampicillin
Enterobacteriaceae	Cefotaxime *or* ceftriaxone *or* cefepime
Pseudomonas aeruginosa	Ceftazidime *or* cefepime *or* meropenem
Haemophilus influenzae	Ceftriaxone
Streptococcus agalactiae	Ampicillin *or* penicillin G
Anaerobes	Metronidazole
Nocardia asteroides	Trimethoprim-sulfamethoxazole
Bacteroides species	Metronidazole

and vancomycin. Rifampin can be added to vancomycin for its synergistic effect because it is highly active against most penicillin-resistant pneumococci, but rifampin is inadequate as monotherapy because resistance develops rapidly. Some strains of pneumococci are sensitive to penicillin. Once the results of antimicrobial susceptibility tests are known, therapy can be modified accordingly (Table 38-3).

For pneumococcal meningitis, consideration should be given to using intraventricular vancomycin in patients not responding to parenteral vancomycin. The intraventricular route of administration is preferred over the intrathecal route because adequate concentrations of vancomycin in the cerebral ventricles are not always achieved with intrathecal administration. Intraventricular and intrathecal vancomycin is safe and is not associated with a risk of seizure activity. A 2-week course of intravenous antimicrobial therapy is recommended for pneumococcal meningitis.

Meningococcal Meningitis

Penicillin G or a third-generation cephalosporin (Table 38-3) remains the antibiotic of choice for meningococcal meningitis. Isolates of *N. meningitidis* with moderate or relative resistance to penicillin [defined as a minimal inhibitory concentration (MIC) of penicillin of 0.12 to 0.25 μg/mL] and decreased susceptibility to ampicillin have been reported from a wide variety of geographic locations. All CSF isolates of *N. meningitidis* should be tested for penicillin and ampicillin susceptibility. If antimicrobial susceptibility testing demonstrates that the isolate is a relatively penicillin-resistant strain, or if the patient is in an area with a high prevalence of meningococci with decreased susceptibility to penicillin, cefotaxime or ceftriaxone should be used. A 7-day course of intravenous antibiotic therapy is adequate for most uncomplicated cases of meningococcal meningitis. The index case and all close contacts should receive chemoprophylaxis with a 2-day regimen of rifampin (600 mg every 12 hours for 2 days in adults and 10 mg/kg every 12 hours for 2 days in children older than 2 years of age). Rifampin should not be used in pregnant women. Pregnant and lactating women and children less than 2 years of age may be given intravenous or intramuscular ceftriaxone, in a single injection of 250 mg for adults and 125 mg for children. Close contacts are defined as individuals who have had contact with nasopharyngeal secretions either through kissing or sharing toys, beverages, or cigarettes.

Staphylococcal Meningitis

Meningitis caused by *S. aureus* or coagulase-negative staphylococci is treated with nafcillin or oxacillin. Vancomycin is the drug of choice for methicillin-resistant staphylococci and for patients allergic to penicillin. Linezolid is the drug of choice for vancomycin-resistant strains (MIC $>$ 2.0 μg/mL). Treatment is for a minimum of 14 days. The CSF should be monitored during therapy, and if the spinal fluid continues to yield viable organisms after 48 hours of intravenous therapy, intraventricular vancomycin, 10 mg once daily for children or 20 mg once daily for adults, should be added.

Listeria monocytogenes Meningitis

Meningitis due to *L. monocytogenes* is treated with ampicillin for at least 3 weeks. Gentamicin should be added to ampicillin in critically ill patients. Meningitis caused by this organism is seen less often today in immunosuppressed patients than in the past because of trimethoprim-sulfamethoxazole administration in these patients as prophylaxis against *P. carinii* pneumonia and toxoplasmosis.

Enterobacteriaceae Meningitis

Meningitis caused by the Enterobacteriaceae, including *Proteus* species, *E. coli*, *Klebsiella* species, *Serratia* species, and *Enterobacter* species, is treated with a third- or fourth-generation cephalosporin, either cefotaxime, ceftriaxone, or cefepime, for 3 weeks.

Pseudomonas aeruginosa Meningitis

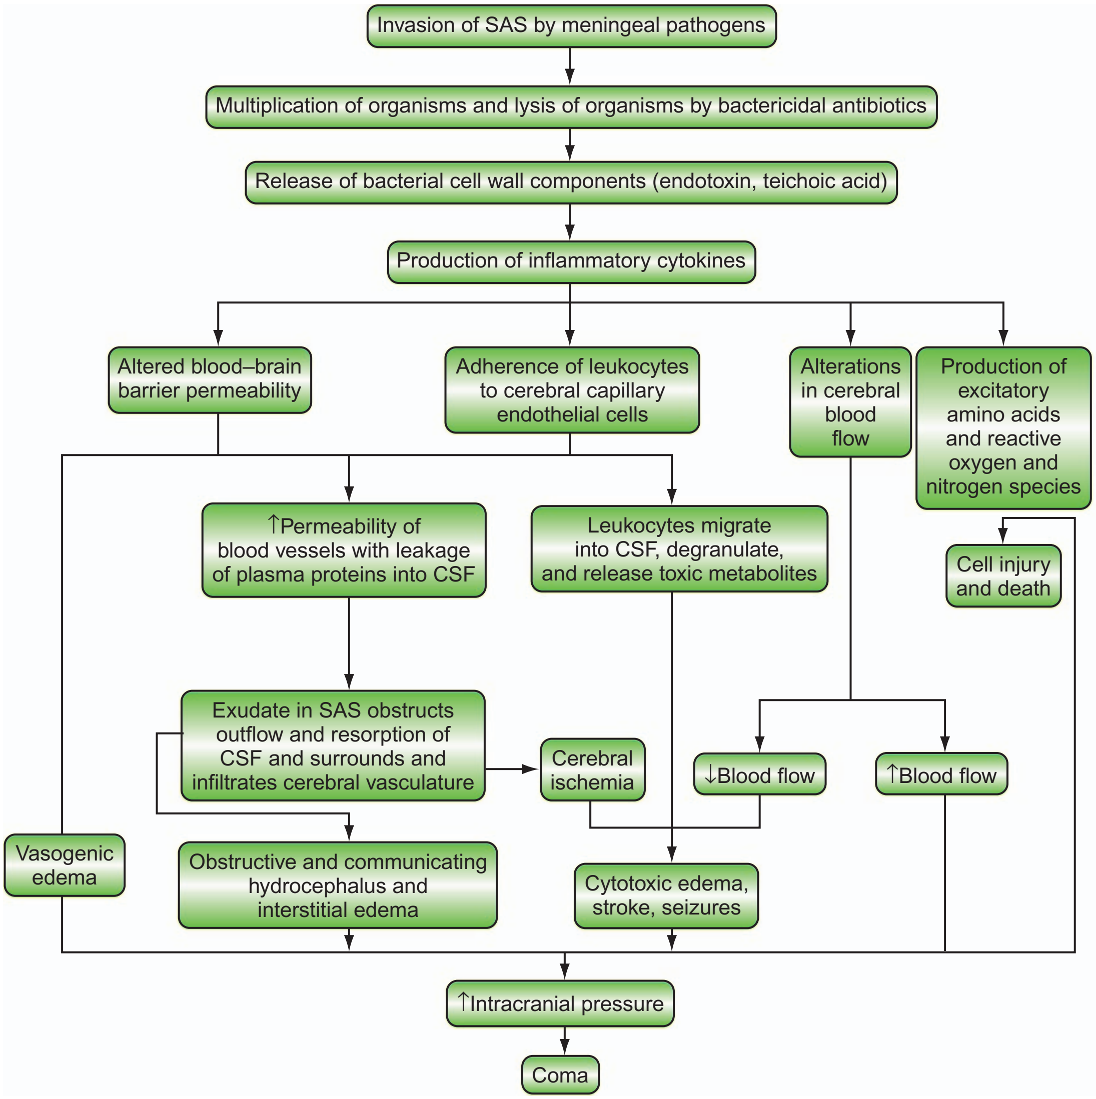
The third-generation cephalosporins, cefotaxime, ceftriaxone, and ceftazidime are equally efficacious for the treatment of gram-negative bacillary meningitis, with the exception of meningitis caused by *P. aeruginosa*. Meningitis resulting from infection with this organism is treated with ceftazidime, cefepime, or meropenem intravenously for 3 weeks.

DEXAMETHASONE THERAPY

The use of dexamethasone as adjunctive therapy in bacterial meningitis comes from the present understanding of the pathophysiology of the neurologic complications of bacterial meningitis. The critical event in pathogenesis is the inflammatory reaction in the subarachnoid space to the invading meningeal pathogen. The pathogen itself is not responsible for most neurologic complications. In bacterial meningitis, damage to the CNS progresses long after the CSF has been sterilized by antibiotic therapy.

Lysis of bacteria and release of bacterial cell wall components into the subarachnoid space are the initial steps in the induction of the inflammatory process and formation of a purulent exudate (Fig. 38-1). Components of bacterial cell walls, such as lipopolysaccharide molecules (endotoxin), a cell wall component of gram-negative bacteria, and teichoic acid and peptidoglycan, cell wall components of the pneumococcal species, induce meningeal inflammation by stimulating the production of inflammatory cytokines and chemokines by microglia (CNS macrophage-equivalent cells), astrocytes, monocytes, microvascular endothelial cells, and white blood cells in the CSF space. There are a number of consequences that result from the presence of inflammatory cytokines in CSF. Tumor necrosis factor (TNF) and interleukin-1 (IL-1) act synergistically to alter the permeability of the blood—brain barrier, allowing for the leakage of serum proteins and other molecules into the CSF and contributing to the formation of a purulent exudate. This purulent exudate may obstruct the flow of CSF through the ventricular system and diminish the resorptive capacity of the arachnoid granulations in the dural sinuses, leading to nonobstructive or communicating hydrocephalus and to interstitial edema. The exudate also surrounds and narrows the diameter of the lumen of the large arteries at the base of the brain with infiltration of inflammatory cells in the arterial walls (i.e., vasculitis). These inflammatory cytokines also recruit polymorphonuclear leukocytes from the blood stream and upregulate the expression of selectins on cerebral capillary endothelial cells and leukocytes, which allow for migration of leukocytes into the CSF.

Experimental models of meningitis suggest that bacterial eradication is not a leukocyte-dependent phenomenon. Neutrophils degranulate and release toxic metabolites that contribute to cytotoxic edema, cell injury, and death. The adherence of leukocytes to cerebral capillary endothelial cells increases the permeability of blood vessels, allowing for the leakage of



Invasion of SAS by meningeal pathogens
Multiplication of organisms and lysis of organisms by bactericidal antibiotics
Release of bacterial cell wall components (endotoxin, teichoic acid)
Production of inflammatory cytokines
Altered blood–brain barrier permeability
Adherence of leukocytes to cerebral capillary endothelial cells
Alterations in cerebral blood flow
Production of excitatory amino acids and reactive oxygen and nitrogen species
↑Permeability of blood vessels with leakage of plasma proteins into CSF
Leukocytes migrate into CSF, degranulate, and release toxic metabolites
Cell injury and death
Exudate in SAS obstructs outflow and resorption of CSF and surrounds and infiltrates cerebral vasculature
Cerebral ischemia
↓Blood flow
↑Blood flow
Vasogenic edema
Obstructive and communicating hydrocephalus and interstitial edema
Cytotoxic edema, stroke, seizures
↑Intracranial pressure
Coma

FIGURE 38-1 ■ Inflammatory cascade leading to the neurologic complications of bacterial meningitis. CSF, Cerebrospinal fluid; SAS, subarachnoid space. (Reprinted by permission of Karen L. Roos, MD, Indiana University Hospital, Indianapolis.)

plasma proteins into the CSF and further contributing to the inflammatory exudate in the subarachnoid space.

Dexamethasone exerts its beneficial effect by inhibiting the synthesis of IL-1 and TNF at the level of mRNA and through decreasing CSF outflow resistance and stabilizing the blood–brain barrier. The rationale for giving dexamethasone prior to antibiotic therapy is that dexamethasone inhibits the production of TNF if administered to macrophages and microglia before they are activated by endotoxin, both by diminishing the quantity of TNF mRNA in response to endotoxin and by preventing its translation. Dexamethasone is unable to regulate TNF production once induction occurs.

A meta-analysis of randomized, controlled trials of dexamethasone therapy in childhood bacterial meningitis published from 1988 to 1996 confirmed the benefit of dexamethasone for *H. influenzae* type b meningitis if begun with or before intravenous antibiotics and also suggested a beneficial effect for pneumococcal meningitis in children.[7] Maximal benefit from dexamethasone therapy is dependent on timing.

A common early criticism of the dexamethasone trials is that in the majority of cases, the causative organism of the meningitis was *H. influenzae* type b. However, this organism no longer is one of the more common etiologic agents of bacterial meningitis because of the success of the Hib conjugate vaccine. Present understanding of the molecular basis of the neurologic complications of bacterial meningitis, however, does not suggest that the pathophysiology of the neurologic complications varies with the meningeal pathogen, with the exception of how the microorganism gains access to the CNS.

In 2002, a prospective, randomized, double-blind, multicenter trial of dexamethasone in 301 patients with acute bacterial meningitis was published. *S. pneumoniae* was the causative organism in 37 percent of patients in the dexamethasone group and 44 percent of the placebo group. Among the patients with pneumococcal meningitis, 26 percent in the dexamethasone group had an unfavorable outcome, as compared with 52 percent in the placebo group.[8] After the introduction of nationwide dexamethasone therapy in adults with pneumococcal meningitis in the Netherlands, the case fatality rate declined from 30 to 20 percent; a total of 45 percent of cases of bacterial meningitis were pneumococcal.[9] In meningococcal meningitis, reduced rates of death and hearing loss have been reported with adjunctive dexamethasone.[10]

An additional concern regarding the use of dexamethasone in the treatment of bacterial meningitis is its effect on the penetration of antibiotics into the CSF. Meningeal inflammation appears to improve the penetration of vancomycin. By decreasing meningeal inflammation, dexamethasone could theoretically reduce the penetration of vancomycin into the CSF. However, in a prospective, randomized clinical trial of bactericidal activity against cephalosporin-resistant pneumococci in children with acute bacterial meningitis, vancomycin (60 mg/kg daily) reliably penetrated the CSF when the children were treated concomitantly with dexamethasone (0.6 mg/kg daily, divided into four doses for 4 days).[11] The third- and fourth-generation cephalosporins and rifampin penetrate the CSF extremely well, even in the presence of dexamethasone.

The American Academy of Pediatrics recommends the consideration of dexamethasone for bacterial meningitis in infants and children 6 weeks of age or older. The recommended dose is 0.6 mg/kg daily in four divided doses (0.15 mg/kg/dose) given intravenously for the first 4 days of antibiotic therapy. The first dose of dexamethasone should be administered 15 to 20 minutes before or at least with the first dose of antibiotics. Results of clinical trials of dexamethasone therapy in children have demonstrated its efficacy in decreasing meningeal inflammation and neurologic sequelae and in reducing the incidence of sensorineural hearing loss in bacterial meningitis from any cause.

The Infectious Diseases Society of America (IDSA) practice guidelines for the management of bacterial meningitis in adults recommend the use of dexamethasone with suspected or proven pneumococcal meningitis.[12] The recommended dose is 0.6 mg/kg daily in four divided doses for the first 4 days of antimicrobial therapy, with the first dose administered 15 to 20 minutes before or at least concomitant with the first dose of antibiotic. A favorable trend toward reduced rates of hearing loss and death with no evidence that dexamethasone is harmful has also been reported in patients with meningococcal meningitis.[10]

Prevention

It is recommended that college freshmen be vaccinated against meningococcal meningitis with the quadrivalent (A, C, W135, Y) meningococcal polysaccharide vaccine and with the serogroup B vaccine. During an outbreak of meningococcal disease, individuals who have not been previously vaccinated should be treated with chemoprophylaxis. Meningococcal disease can develop as quickly as within 2 to 5 days of presentation of the index case. Vaccination is not a substitute for chemoprophylaxis to prevent secondary disease, because there is an insufficient amount of time for development of the optimum effect of vaccination, which requires approximately 1 to 2 weeks for good antibody production. Adults and adolescents who have not been vaccinated but have been exposed to an individual with meningococcal disease can be treated with rifampin, 600 mg twice daily for 2 days. Children, older than age 2, can be treated with rifampin, 10 mg/kg twice daily for 2 days or a single injection of ceftriaxone 125 mg. Rifampin should not be used in pregnant women. Pregnant and lactating women and children under 2 years of age may be given intravenous or intramuscular ceftriaxone in a single injection of 250 mg for adults and 125 mg for children.

Vaccination against pneumococci is recommended for adults older than 65 years, adults with chronic underlying diseases (cardiopulmonary diseases, renal diseases, diabetes mellitus, splenectomy, and CSF fistula), and immunocompromised patients, including those infected with the human immunodeficiency virus (HIV).

BRAIN ABSCESS

A brain abscess is a focal suppurative infection in the brain parenchyma that typically begins as a localized area of cerebritis and develops into a collection of pus surrounded by a well-defined capsule. In a systematic review and meta-analysis of nearly 10,000 patients, brain abscess was found to develop from a contiguous suppurative focus of infection (e.g., frontoethmoidal sinusitis, chronic otitis media, mastoiditis, or meningitis) or hematogenous dissemination from a distant site of infection (e.g., lungs, skin, endocarditis, dental, or urinary tract infections) in the majority of patients.[13] Direct inoculation from head trauma or a neurosurgical procedure was a less common source. Nearly 20 percent of cases were polymicrobial, so overlap in the modes of dissemination was not uncommon. In another 20 percent of cases, no source of infection was identified. It should be noted that bacteria are not a common cause of brain abscess in immunosuppressed patients because of routine prophylaxis with antibiotics during episodes of neutropenia. The single exception to this is *Nocardia asteroides*, which is the causative organism in an increasing number of cases of brain abscess in patients with defects in cell-mediated immunity.

Etiology

The most common source of brain abscess is direct spread of infection from a contiguous suppurative focus of infection or hematogenous spread from a distant site of infection. Brain abscesses that arise from intracranial extension of paranasal sinus infections are caused usually by microaerophilic streptococci and anaerobic organisms (e.g., *Bacteroides* species, *Fusobacterium* species, and anaerobic streptococci), Enterobacteriaceae, and *Haemophilus* species. Bacterial infection in the paranasal sinuses spreads intracranially to the frontal or temporal lobe either by retrograde thrombophlebitis of the diploic veins or via a contiguous area of osteomyelitis. Brain abscesses associated with a dental procedure or dental abscesses are also typically due to microaerophilic streptococci and anaerobic organisms. A brain abscess may arise from direct extension of mastoid infection or via retrograde thrombophlebitis of the emissary veins within the temporal bone from mastoiditis. Middle ear infections can cause temporal lobe abscess by direct spread of infection through the tegmen antrum or petrous portion of the temporal bone. Brain abscesses that arise from middle ear infections are most often due to *Streptococcus* species, Enterobacteriaceae, *Bacteroides* species (including *B. fragilis*), and *P. aeruginosa*. A brain abscess may develop from hematogenous dissemination of microorganisms from a remote site of infection such as the heart, the lungs, the abdomen, or the urinary tract. Metastatic abscesses are often multiple and tend to form primarily in areas supplied by the middle cerebral artery (i.e., posterior frontal or parietal lobes) at the interface of gray and white matter, where capillary blood flow is slowest.

A common cause of brain abscess in infants and children is cyanotic congenital heart disease, with tetralogy of Fallot and transposition of the great vessels being the most frequent associated anomalies. As a general rule, a brain abscess in these patients develops only in an area of ischemic or devitalized brain tissue. Cyanotic congenital heart disease causes reduced rates of blood flow in the microcirculation of the brain resulting in hypoxia or infarction. Neonatal brain abscesses occur as a complication of meningitis, a predisposing condition that is uncommon in older children and adults; the most common causative organisms of bacterial brain abscess in neonates and infants are *Proteus* species and *Citrobacter* species. Brain abscess is an uncommon complication of neonatal group B streptococcal or *E. coli* meningitis.

When a brain abscess develops as a complication of penetrating head trauma, *S. aureus* is the most common pathogen found. Such abscesses are frequently multiloculated and may contain foreign bodies. A brain abscess following a neurosurgical procedure is typically due to staphylococci or gram-negative bacilli.

Clinical Presentation

Headache is the most common presenting complaint in patients with brain abscess, and fever occurs in fewer than 50 percent of patients. Up to 25 percent of patients present with new-onset focal or generalized seizures.[14] The findings on neurologic examination are related both to the site of the abscess and to the presence of increased ICP. Hemiparesis is a common localizing sign of a frontal or parietal lobe abscess. A temporal lobe abscess may be associated with dysphasia or a visual field deficit (e.g., upper homonymous quadrantanopia). A patient with a cerebellar abscess usually presents with nystagmus and ataxia. When the brain abscess is complicated by increased ICP, the clinical findings may include papilledema, deficits of the oculomotor (III) or abducens (VI) nerves, and an alteration in consciousness ranging from lethargy to irritability, confusion, or coma.

Diagnosis

Brain MRI is the best neuroimaging procedure for demonstrating a brain abscess, especially one that is in an early (i.e., cerebritis) stage. On T2-weighted images, cerebritis is evident as an area of hyperintensity. A mature brain abscess appears hypointense to CSF on T1-weighted sequences and demonstrates ring enhancement following administration of intravenous gadolinium. On T2-weighted images, a mature brain abscess has a central area of pus that is hyperintense, is surrounded by a well-defined hypointense capsule, and has a surrounding area of hyperintense edema. Diffusion-weighted MRI is helpful in differentiating a brain abscess from other types of cystic lesions as brain abscesses typically show restricted diffusion.

On contrast-enhanced CT, the mature abscess has the appearance of a low-density lesion with a sharply demarcated, dense ring of contrast enhancement surrounded by a variable hypodense region of edema. In both the early (i.e., cerebritis) and mature stages, a marginal ring of density is present on contrast-enhanced images; however, in the cerebritis stage, the enhancing ring forms an inhomogeneous "halo." As the abscess matures, its margin becomes more discrete and the associated enhancement more homogeneous. There may be leakage of contrast medium into the low-density center of an abscess in the cerebritis stage.

The etiologic organism of a brain abscess is determined by stereotactic needle aspiration. This procedure not only provides diagnostic specimens for Gram stain and culture but also permits therapeutic drainage of pus. Surgical resection can be considered for solitary abscesses that are superficial and not located in eloquent brain tissue. Lumbar puncture should be avoided in patients with known or suspected focal intracranial infections due to the danger of herniation and because the diagnostic yield is low. About 50 percent of patients with a brain abscess have a peripheral leukocytosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are elevated in the majority. Blood cultures should be drawn prior to initiation of empiric antimicrobial therapy, as a positive result is present in 25 to 50 percent of cases.

Differential Diagnosis

The differential diagnosis of a brain abscess includes focal structural or space-occupying lesions such as tumor, stroke, subdural empyema, and superior sagittal sinus thrombosis.

Treatment

Almost any brain abscess that measures greater than 1 cm in diameter can undergo stereotactic aspiration, regardless of location.[14] Antibiotic therapy is based on culture and sensitivity testing of the specific etiologic organism of the brain abscess. Empiric antibiotic therapy should be based on a knowledge of the organisms most frequently encountered with the suspected etiology of the brain abscess until the results of culture and sensitivity studies are available (Table 38-4).

Abscesses originating from the paranasal sinuses are caused predominantly by microaerophilic streptococci, anaerobic organisms (*Bacteroides* species, *Fusobacterium* species, and anaerobic streptococci), Enterobacteriaceae, and *Haemophilus* species. A combination of a third- or fourth-generation cephalosporin along with metronidazole is recommended for empiric therapy. The doses of these antimicrobial agents are provided in Table 38-2. A brain abscess associated with dental disease is treated with a combination of a third- or fourth-generation cephalosporin along with metronidazole to cover streptococci and *B. fragilis.* A brain abscess that complicates otitis media or mastoiditis may be caused by *Streptococcus* species, *Bacteroides* species (including *B. fragilis*), Enterobacteriaceae, or *P. aeruginosa.* A combination of metronidazole and ceftazidime or meropenem is recommended. Cerebral abscesses due to bacteremia from a pyogenic lung infection, urinary sepsis, or an intra-abdominal source of infection are treated with a combination of metronidazole and ceftazidime or meropenem until the results of culture and antimicrobial susceptibility tests are available. A brain abscess that develops in association with endocarditis is most often caused by *S. aureus* or microaerophilic streptococci; empiric therapy should include a combination of vancomycin plus a third- or fourth-generation cephalosporin (e.g., cefotaxime).

The most common organisms isolated when brain abscess complicates cyanotic congenital heart disease are *viridans* streptococci (microaerophilic streptococci), anaerobic streptococci, and occasionally *Haemophilus* species. A combination of cefotaxime plus metronidazole is recommended. Metronidazole has excellent bactericidal activity against strict anaerobes, adequate oral absorption, and good penetration into CSF and brain abscess cavities, but streptococci and aerotolerant anaerobes are resistant to metronidazole. Cefotaxime is added to cover *Haemophilus* species, and is the preferred third-generation cephalosporin because it and its lipophilic metabolite, desacetylcefotaxime, have

TABLE 38-4 ■ Etiologic Organisms of Brain Abscess and Empiric Therapy

Source	Organisms	Antibiotics
Paranasal sinuses	Microaerophilic streptococci *Bacteroides* species *Fusobacterium* species *Haemophilus* species Anaerobic streptococci *Staphylococcus aureus*	Third- or fourth-generation cephalosporin *plus* metronidazole *plus* vancomycin
Dental disease	Streptococci *Bacteroides fragilis*	Penicillin G *or* a third- or fourth-generation cephalosporin *plus* metronidazole
Otitis media or mastoiditis	*Streptococcus* species Enterobacteriaceae *Bacteroides* species (including *B. fragilis*) *Pseudomonas aeruginosa*	Metronidazole *plus* ceftazidime *or* meropenem
Pulmonary disease	*Streptococcus* species *Actinomyces* species *Fusobacterium* species	Metronidazole *plus* ceftazidime *or* meropenem
Endocarditis	*Staphylococcus aureus* Microaerophilic streptococci	Vancomycin *plus* cefotaxime
Intra-abdominal site	*Streptococcus* species Enterobacteriaceae Anaerobes	Metronidazole *plus* ceftazidime *or* meropenem
Urinary tract	*Pseudomonas* species Enterobacteriaceae	Metronidazole *plus* ceftazidime *or* meropenem
Cyanotic congenital heart disease	Anaerobic and microaerophilic streptococci (*viridans* streptococci)	Penicillin G *plus* cefotaxime *plus* metronidazole
Neonatal meningitis	*Proteus* species *Citrobacter* species	Ampicillin *plus* aminoglycoside *or* cefotaxime
Immunosuppressed state	*Nocardia asteroides* *Clostridium* species *Pseudomonas aeruginosa* *Xanthomonas maltophilia* *Enterobacter cloacae* Staphylococci Gram-negative bacilli	Trimethoprim-sulfamethoxazole *plus* ceftazidime *or* meropenem *plus* vancomycin
Penetrating head injury	Staphylococci Gram-negative bacilli Anaerobes	Vancomycin *plus* ceftazidime *or* meropenem *plus* metronidazole
Neurosurgical procedure	Staphylococci Gram-negative organisms Enterobacteriaceae *Pseudomonas aeruginosa*	Vancomycin *plus* ceftazidime *or* meropenem

excellent antibacterial activity and penetrate and accumulate within abscess cavities.

Brain abscesses complicating neurosurgical procedures are usually due to staphylococci or gram-negative organisms. Empiric therapy should be a combination of vancomycin plus ceftazidime, cefepime, or meropenem. The most common pathogens recovered from brain abscesses that complicate penetrating head injuries are staphylococci and gram-negative bacteria, but anaerobes and *Nocardia* species may also be found. Empiric therapy should include a combination of vancomycin, ceftazidime, and metronidazole.

Brain abscesses are treated with a 6- to 8-week course of parenteral antimicrobial therapy. During treatment, MRI can be performed every 2 weeks for 3 months or until clinical recovery is evident and should also be undertaken at any sign of clinical deterioration. If the abscess cavity is still visible on MRI following completion of parenteral antibiotics, oral antibiotics should be initiated and continued until there is complete resolution of the cavity on neuroimaging.

The majority of abscesses can be managed with stereotactic aspiration and therapeutic drainage in combination with antimicrobial therapy, with two exceptions. An abscess that is in the cerebritis stage and has not become encapsulated may respond to antimicrobial therapy alone. Brain abscesses due to *N. asteroides* usually require more extensive surgical excision and therapy with trimethoprim-sulfamethoxazole.

Corticosteroids are recommended only for those patients with significant cerebral edema and associated mass effect causing increased ICP. Corticosteroids should not be given routinely to patients with brain abscesses, as they delay the encapsulation of the abscess.

The use of prophylactic anticonvulsant therapy during the course of antimicrobial therapy is controversial. The risk for focal or generalized seizures is of concern. However, more recent studies do not show a decreased seizure rate with prophylactic treatment, and therefore, prophylactic treatment is now not routinely recommended in patients with brain abscess.[14] If seizures do occur, it is recommended to continue anticonvulsant treatment until resolution of abscess on neuroimaging, at which time tapering off of anticonvulsants can be attempted.

SUBDURAL EMPYEMA AND CRANIAL EPIDURAL ABSCESS

A subdural empyema is a collection of pus in the space between the dura and the arachnoid (Fig. 38-2).

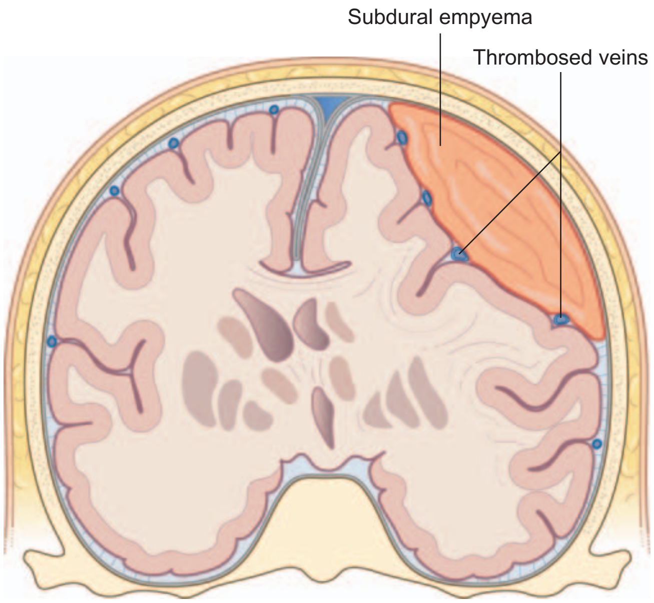


FIGURE 38-2 ■ Schematic appearance of a subdural empyema.

A cranial epidural abscess develops in the space between the dura and the inner table of the skull (Fig. 38-3). A subdural empyema is a more malignant and life-threatening infection than is a cranial epidural abscess.

Etiology

Paranasal sinusitis, especially frontal sinusitis, is the most common predisposing condition for subdural empyema. Septic thrombophlebitis of the mucosal veins of the sinuses results in retrograde extension of infection with drainage of bacteria into the dural venous sinuses and cortical veins and the formation of a subdural empyema. Subdural empyema may also result from direct infection of the subdural space during a neurosurgical procedure such as drainage of a subdural hematoma; as a complication of head trauma; or from infection of a subdural effusion. It only rarely develops from hematogenous dissemination of bacteria from a distant focus of infection.

A cranial epidural abscess may develop as a complication of a craniotomy or a compound skull fracture or as the result of spread of infection from the frontal sinuses, middle ear, mastoid, or orbit. When an epidural abscess develops as a complication of a craniotomy, it is either from direct infection of the epidural space or as a complication of a contiguous area of osteomyelitis that develops from infection of a wound or bone flap. A cranial epidural abscess rarely results from hematogenous seeding of the epidural space from a distant site of infection.

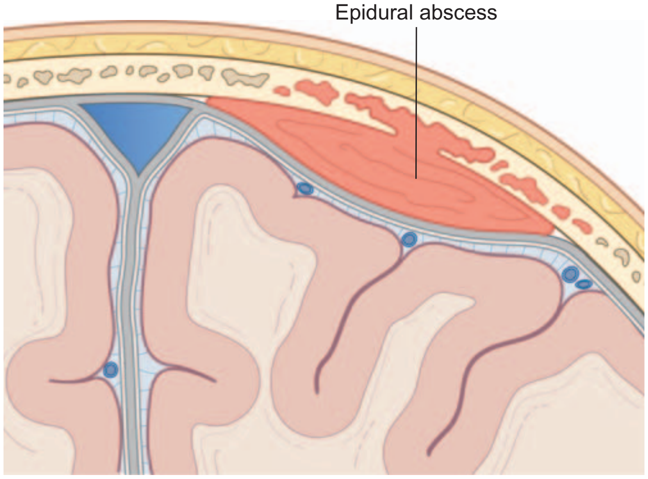

FIGURE 38-3 ■ Cranial epidural abscess located in the space between the dura and the inner table of the skull.

Aerobic and microaerophilic streptococci and anaerobic bacteria are the most common causative organisms of subdural empyema or epidural abscess that develops as a complication of sinusitis, middle ear infection, or mastoiditis. A subdural empyema or an epidural abscess that develops as a complication of craniotomy, compound skull fracture, or drainage of a subdural hematoma is usually caused by *S. aureus*, coagulase-negative staphylococci, or gram-negative organisms. A subdural effusion may be a complication of bacterial meningitis in infants and children. It is typically a self-limited process that resolves as the meningitis is treated. Occasionally, a subdural effusion may become infected, causing a subdural empyema—the causative organism is the organism responsible for the meningitis.

Clinical Presentation

Headache is the most common complaint with a subdural empyema and is initially localized to the side of the subdural infection. It may be accompanied by fever and symptoms of sinusitis or otitis media. The evolution of a subdural empyema tends to be remarkably rapid. There are no septations in the subdural space, and, as a result, the purulent exudate can spread quite extensively. The headache may become more severe and generalized as the infection spreads. Focal neurologic deficits or seizures may also occur. Contralateral hemiparesis or hemiplegia is the most common focal neurologic deficit. Seizures begin as focal motor type that then may become secondarily generalized. Over the course of a few days, the level of consciousness decreases from somnolence to stupor and finally to coma.[15] In a review of subdural empyema arising from sinusitis in 18 patients, headache was present in 15 patients (83%), fever in 17 patients (94%), focal neurologic signs in 17 patients (94%), nuchal rigidity in 14 patients (78%), altered level of consciousness in 10 patients (56%), seizures in 10 patients (56%), and sinus tenderness or periorbital swelling in 7 patients (39%).[15]

The clinical presentation of a cranial epidural abscess is distinctly different from that of a subdural empyema. The patient is not as ill, and there is rarely rigidity of the neck or focal neurologic signs.[15] Presentation is typically with an unrelenting hemicranial headache accompanied by persistent fever. Focal neurologic deficits, seizures, and signs of increased ICP do not typically develop until the infection spreads into the subdural space (i.e., becomes a subdural empyema).

Diagnosis

Cranial MRI is the procedure of choice for demonstrating these lesions because it is free from bony artifacts adjacent to the inner table of the skull and readily can demonstrate extracerebral fluid collections. T1-weighted postgadolinium and T2-weighted sequences are best for demonstrating subdural empyema or cranial epidural abscess. Subdural empyema is hyperintense on T1-weighted sequences. There is contrast enhancement of the rim of the empyema separating the empyema from the subjacent brain parenchyma. The empyema itself appears as a crescent-shaped lesion of hyperintensity on T2-weighted sequences.

On T1-weighted sequences, an epidural abscess has a signal intensity that is between that of normal brain parenchyma and CSF. Enhancement of the dura is seen on T1-weighted contrast-enhanced images. An epidural abscess appears as a lentiform or crescentic purulent fluid collection that is hyperintense on T2-weighted sequences.

Lumbar puncture should not be performed in patients with subdural empyema or epidural abscess. The etiologic organism is identified by Gram stain and culture of pus obtained either via burr hole or by craniotomy.

Treatment

Immediate neurosurgical drainage of a subdural empyema or a cranial epidural abscess is the definitive step in their management. At surgery, Gram stain and culture of the purulent material are performed. Empiric antimicrobial therapy pending the results of Gram stain and culture should cover aerobic and microaerophilic streptococci, anaerobic bacteria, staphylococci, and gram-negative bacilli and include a combination of a third- or fourth-generation cephalosporin (e.g., ceftriaxone, cefotaxime, or cefepime), metronidazole, and vancomycin. Ceftazidime or meropenem should be substituted for cefotaxime or ceftriaxone in neurosurgical patients because of better *Pseudomonas* species coverage. Antibiotics can be modified when the results of Gram stain and bacterial culture and sensitivity testing are known. A 4-week course of intravenous antibiotic therapy is recommended for subdural empyema, followed by a 2-week course of oral antibiotic therapy. A cranial epidural abscess is treated for 3 weeks with parenteral antibiotics in the absence of osteomyelitis, and for 6 to 8 weeks when it is a complication of a contiguous area of osteomyelitis.

SPINAL EPIDURAL ABSCESS

An epidural abscess may develop in the spinal epidural space (Fig. 38-4). The most common locations are either the posterior midthoracic region between the fourth and the eighth thoracic vertebrae (Fig. 38-5) or the lower lumbar epidural space. Anterior abscesses occur less often than do posterior abscesses and usually occur at the cervical level.

Etiology

A spinal epidural abscess develops in the space outside the dura mater but within the spinal canal as the result of hematogenous spread of bacteria from a remote site of infection to the epidural space (e.g., secondary to skin infection, urinary tract infection, intra-abdominal infection, pelvic inflammatory disease, pneumonia, endocarditis, or infections from intravenous lines); by direct extension from a contiguous infection (e.g., an area of osteomyelitis in an adjacent vertebral body); by direct infection of the epidural space during spine surgery or epidural anesthesia; or by direct extension of infection from decubitus ulcers, infected abdominal

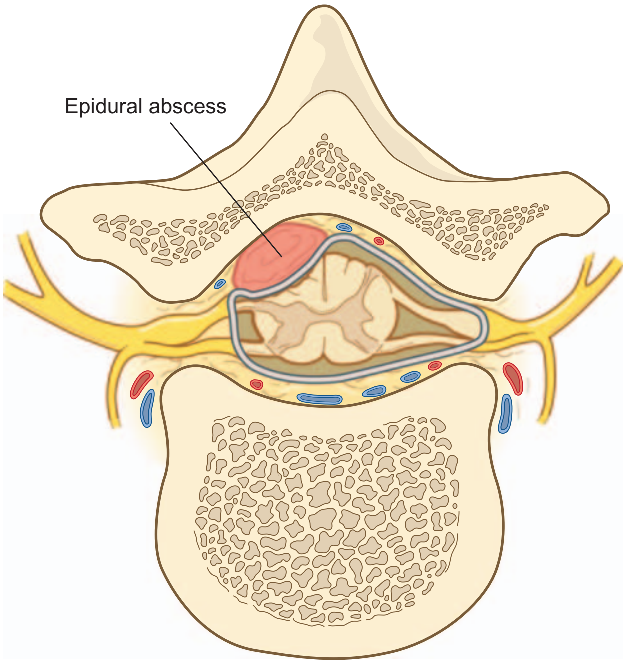

FIGURE 38-4 ■ An abscess in the epidural space posterior to the spinal cord.

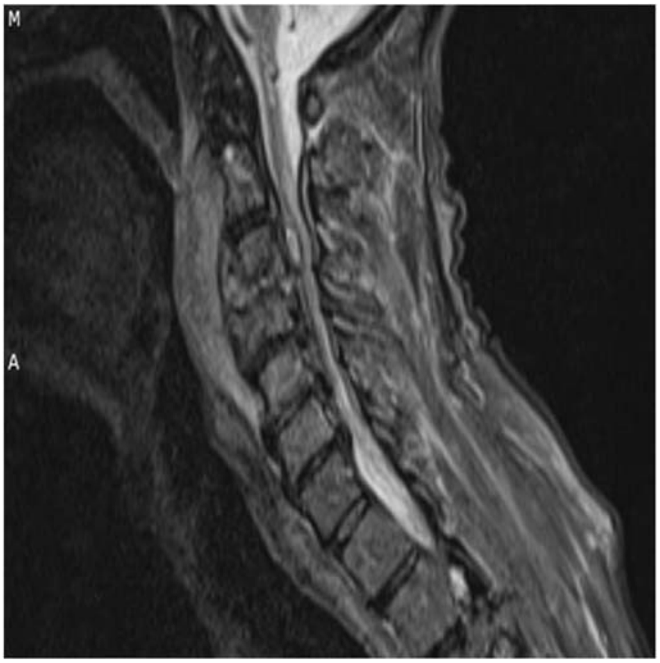

FIGURE 38-5 ■ Sagittal T2-weighted magnetic resonance imaging of the cervical spine demonstrating an epidural fluid collection (abscess) compressing the spinal cord.

wounds, retropharyngeal abscesses, or psoas muscle abscesses. Immunosuppression from chronic disease (such as diabetes or chronic renal insufficiency), HIV infection, corticosteroid therapy, and immunosuppressive therapies are increasingly reported as predisposing conditions.

The etiologic organism of the spinal epidural abscess is predictable from the predisposing condition. A spinal epidural abscess that arises from hematogenous dissemination from a skin infection or contamination of intravenous lines, or as a complication of spine surgery or epidural anesthesia, is caused in the majority of cases by *S. aureus*. Infection that reaches the epidural space by hematogenous spread of bacteria from a genitourinary infection or intra-abdominal infection to the paravertebral venous plexus is usually caused by gram-negative bacilli.

Clinical Presentation

Patients with a bacterial spinal epidural abscess present with a classic neurologic syndrome. Back pain is the initial symptom, followed within 2 to 3 days by radicular pain in the extremities or pain in an intercostal thoracic dermatomal distribution. As the disease progresses, weakness of appendicular muscles is associated with decreased sensation below the level of the lesion and loss of bowel and bladder control. Finally, there is complete paralysis of appendicular muscles and loss of all sensory modalities below the level of the lesion (i.e., a sensory level). The majority of patients also have an elevated temperature.

The possibility of a spinal epidural abscess should be considered in any patient with fever, back pain (especially with focal vertebral pain and tenderness), and radicular pain in the extremities or pain in a thoracic dermatomal distribution.

Diagnosis

Gadolinium-enhanced MRI is the diagnostic procedure of choice for spinal epidural abscess. MRI of the thoracic and lumbar region should be obtained to visualize the extent of the epidural abscess, and it is reasonable to obtain images of the cervical region as well, especially if the upper extremities are involved. A lumbar puncture should not be performed at the site of a possible abscess because of the risk of spread of infection from the epidural to the subarachnoid space. The majority of patients have an elevated peripheral white blood cell count, and blood cultures may demonstrate the organism.

Treatment

A spinal epidural abscess is treated with immediate laminectomy for decompression and drainage of the epidural space. Empiric therapy depends on the predisposing condition. Because *S. aureus* is the most common etiologic agent, and given the increasing incidence of community- and hospital-acquired methicillin-resistant *S. aureus*, empiric therapy should include vancomycin in addition to a third- or fourth-generation cephalosporin. In the postneurosurgical patient, ceftazidime (instead of ceftriaxone) or meropenem should be added to the empiric regimen to cover gram-negative bacilli. When a spinal epidural abscess is the result of local extension from an adjacent infection, such as a decubitus ulcer, empiric therapy should cover *S. aureus* and gram-negative bacilli. If the source is an abdominal infection, anaerobic coverage with metronidazole should be added. Once a specific organism has been isolated, the antibiotic regimen can be modified based on the results of sensitivity studies. The duration of intravenous antibiotic therapy is typically at least 6 weeks when the spinal epidural abscess is associated with vertebral osteomyelitis. If osteomyelitis is not present, intravenous antibiotic therapy is usually continued for 3 to 4 weeks.[16]

Prognosis is dependent on the mechanism of spinal cord injury. If the abscess is due to compression of the arterial blood supply, arterial or venous thrombosis, or septic thrombophlebitis, the outcomes are frequently poor. If the mechanism is spinal cord compression (the neurosurgeon will see pulsation of the spinal cord after decompression), outcomes are excellent if laminectomy is performed early in the course of the abscess, especially if the patient has back pain alone or back pain and radicular symptoms. If the patient is paretic (but not plegic) prior to surgery, the expectation is either no weakness or a lesser degree of weakness postoperatively. If the patient is plegic, some improvement is expected postoperatively if the surgery occurs within 36 hours of paralysis.[16]

SEPTIC INTRACRANIAL THROMBOPHLEBITIS

Septic intracranial thrombophlebitis is a bacterial infection of the cortical veins and sinuses with resultant venous thrombosis. It is a complication of bacterial meningitis, subdural empyema, epidural abscess, or infection in the skin of the face, paranasal sinuses, middle ear, or mastoid. Textbooks tend to treat septic intracranial thrombophlebitis as a distinct entity, but in reality clinicians probably underdiagnose it as it usually appears as a complication of bacterial meningitis or subdural empyema. The availability of noninvasive neuroimaging procedures, such as magnetic resonance venography and CT angiography, that demonstrate dural sinus thrombosis may increase the recognition of this complication.

Etiology

The superior sagittal sinus is the largest of the venous sinuses (Fig. 38-6), and it receives blood from the frontal, parietal, and occipital superior cerebral veins and the diploic veins, which communicate with the meningeal veins. Infection can spread from the meninges to the superior sagittal sinus via the diploic veins, especially in cases with purulent exudate near the superior sagittal sinus. The cerebral veins and venous sinuses have no valves; therefore, blood within them can flow in either direction. The superior sagittal sinus drains into the transverse sinus. The transverse sinuses also receive venous drainage from small veins

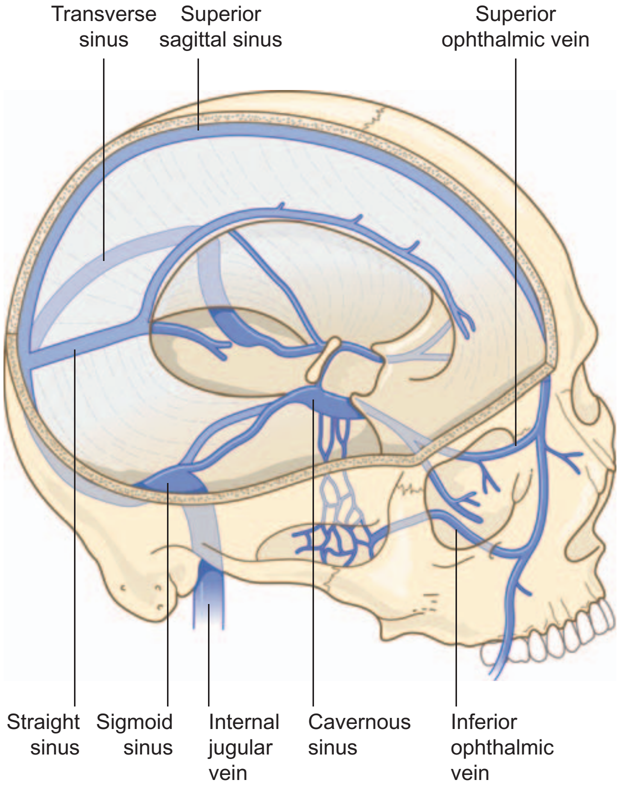

FIGURE 38-6 ■ The major cerebral venous sinuses.

from both the middle ear and the mastoid cells. The transverse sinus becomes the sigmoid sinus before draining into the internal jugular vein. Septic transverse or sigmoid sinus thrombosis can be a complication of acute and chronic otitis media or mastoiditis. Infection spreads from the mastoid air cells to the transverse sinus via the emissary veins or by direct invasion.

The cavernous sinuses are inferior to the superior sagittal sinus at the base of the skull (Fig. 38-6). Bacteria in the sphenoid and ethmoid sinuses can spread to the cavernous sinuses via the small emissary veins, causing septic cavernous sinus thrombosis.

Dehydration from vomiting and hypercoagulable states contribute to the formation of thrombosis in the cerebral venous sinuses. Immunologic abnormalities, including the presence of circulating antiphospholipid antibodies, can also serve as risk factors. Thrombosis of a dural sinus can be associated with thrombosis of the cortical veins that drain blood into and out of the sinuses, resulting in small parenchymal hemorrhages.

Clinical Presentation

Patients with septic thrombosis of the superior sagittal sinus have headache, nausea and vomiting, weakness of the lower extremities with bilateral Babinski signs, focal or generalized seizures, and an alteration in the level of consciousness. There may be a rapid development of stupor and coma.

The signs and symptoms of septic cavernous sinus thrombosis are fever, headache, and diplopia. The oculomotor nerve (III), trochlear nerve (IV), abducens nerve (VI), and ophthalmic and maxillary branches of the trigeminal nerve (V) all pass through the cavernous sinus; therefore, the classic signs of a septic cavernous sinus thrombosis are ptosis, proptosis, and extraocular dysmotility due to deficits of cranial nerves III, IV, and VI. Hypo- or hyperesthesia of the ophthalmic and maxillary divisions of the fifth cranial nerve and a decreased corneal reflex may be detected.

Patients with septic transverse sinus thrombosis may present with Gradenigo syndrome, which is characterized by otitis media, VI nerve palsy, and retro-orbital or facial pain.

Diagnosis

The diagnosis of septic venous sinus thrombosis is suggested by an absent flow void within the sinus on MRI and is confirmed by magnetic resonance venography, CT angiography, or the venous phase of cerebral angiography.

Treatment

Septic venous sinus thrombosis has traditionally been treated with antibiotics and hydration along with removal of infected tissue and thrombus. Anticoagulation with dose-adjusted heparin is reported to be beneficial in patients with aseptic venous sinus thrombosis and is used in the treatment of septic venous sinus thrombosis when patients are worsening despite antimicrobial therapy and intravenous fluids. Occasionally good clinical results have been reported with catheter-directed urokinase therapy and intrathrombus infusion of recombinant tissue plasminogen activator for aseptic venous sinus thrombosis that clinically progresses while on anticoagulation, but there has not been enough experience with these therapies for septic venous sinus thrombosis to make recommendations regarding their use. In patients with bacterial meningitis and lower extremity weakness or a decreased level of consciousness, the use of noninvasive magnetic resonance venography and CT angiography may increase the recognition of this complication.

LYME DISEASE
- Background
- Clinical Features
  - *General*
  - *Neuroborreliosis*
- Diagnosis
- Treatment and Outcome

Spirochetes cause a broad range of human illnesses, including relapsing fever, yaws, pinta, leptospirosis, and periodontal disease. Although leptospirosis and relapsing fevers can cause severe headaches and myalgias in conjunction with high fever and severe systemic illness, two spirochetal infections target the nervous system specifically: syphilis and Lyme disease. Both are the subject of popular mythology and have been blamed for far more than they could possibly have done. Syphilis swept Europe at a time when medicine had yet to understand such fundamental concepts as the germ basis of infection. Even early in the twentieth century, preeminent physicians referred to syphilis as the great imitator. Notably at that time, little was understood about cerebrovascular disease or other neurologic disorders. As late as the 1950s and beyond, anecdotal reports appeared about neurosyphilis having been diagnosed on the basis of silver stains of brain tissue—a highly problematic methodology since fibrillar structures normally present in the brain stain with silver and have a corkscrew-like appearance.

Similarly, Lyme disease has been blamed for innumerable “quality-of-life” ailments. At a time when science has sequenced the human genome, can detect subtle structural abnormalities with magnetic resonance imaging (MRI), and has developed an immense and powerful pharmacopoeia, many find it difficult to accept that medicine has limitations and, in particular, cannot provide simple biologic answers to and remedies for a constellation of common and distressing symptoms, variably known over the years by terms such as *neurasthenia*, *chronic fatigue syndrome*, and *fibromyalgia*, among others. In this setting, some have chosen to extrapolate from the known phenomenology of Lyme disease, emphasizing the areas of similarity between these symptom complexes and Lyme disease and ignoring the far more glaring differences.

There are fascinating similarities between syphilis and Lyme disease that deserve emphasis, as they presumably reflect basic biologic properties of spirochetes. Both infections can be chronic, despite the presence of easily demonstrable antibodies targeted against major epitopes. Presumably, this relates to the spirochetal predisposition to present a limited range of surface antigens, and then change the expressed epitopes over time, as conditions require. Both disorders are spread almost exclusively by intimate contact with a vector, reflecting the very limited ability of spirochetes to survive in vitro. Both begin with prominent, angry-looking cutaneous abnormalities that are surprisingly painless, the lack of pain presumably reflecting the peculiarities of the limited local host immune response.

Both disseminate widely and rapidly, easily broaching the blood−brain barrier, probably reflecting their own inherent motility and adherence to cell-surface molecules. Both seed the nervous system frequently but cause neurologic disease only in a subset of those seeded. Most important, both remain sensitive to fairly simple antibiotics. Although both are frequently described as

Aminoff’s Neurology and General Medicine, Sixth Edition.

presenting with protean manifestations, this reflects an approach to neurology based on phenomenology rather than pathophysiology. In fact, each infection usually causes a characteristic range of disorders. Specific manifestations in any given individual depend on the part of the nervous system involved, but the disorders are pathophysiologically related.

SYPHILIS

Background

Syphilis, caused by *Treponema pallidum*, became prominent in Europe shortly after the return of Columbus from the New World. Known at the time (in some circles) as "the French pox," the mode of transmission was recognized early on. The *Breviary of Health* of 1547 states clearly that "specially it is taken when one pocky person doth synne in lechery the one with another."[1] At that time, as with other newly introduced infectious diseases, the morbidity and mortality associated with syphilis were high. Then, presumably as the most susceptible hosts died and the bacteria self-selected for strains that could persist without killing or incapacitating their hosts, the bacteria and humankind settled into their current symbiotic relationship. Currently, there are about 31,000 cases of primary and secondary syphilis each year in the United States,[2] similar to the number of cases of Lyme disease confirmed by the Centers for Disease Control and Prevention (CDC).

Diagnosis

Diagnosis was originally clinical and rested on recognition of the characteristic chancre—a painless, ulcerated, indurated lesion at the site of primary infection that typically heals spontaneously. The lesion contains numerous spirochetes; one of the best methods of diagnosis is to scrape the lesion, place the scrapings in saline on a slide, and view the motile spirochetes with a dark-field microscope. In patients not seen at the time of the chancre, diagnosis initially rested on the recognition of one of the large number of clinical syndromes attributed to this disease.

More accurate diagnosis of later disease required advancements in laboratory techniques. Identification of the causative organism was an important first step, but diagnosis by culturing *T. pallidum* remains essentially impossible. The organism can be propagated by inoculation into susceptible animals but not cultured in vitro—hence the microbiologic approach traditionally used in clinical diagnosis of other bacterial infections is not useful.

The spirochete has now been very well characterized. Its length varies from 6 to 20 μm; its diameter is about 0.18 μm. It is shaped in a regular helix and exhibits corkscrew motility, propelled by its flagella. Its entire genome has now been sequenced. Despite this intimate knowledge of the spirochete, laboratory confirmation of infection, particularly after resolution of the chancre, remains dependent on serologic tests. These fall into one of two groups. Historically, screening has used nontreponemal tests, measuring "reaginic" antibodies—in essence, anticardiolipin antibodies. The reason that patients with this infection have high titers of anticardiolipin antibody remains unknown, but presumably reflects an interaction of the spirochete with host lipoproteins and other lipids.[3] Tests such as the Wasserman reaction, rapid plasma reagin (RPR), Venereal Disease Research Laboratory (VDRL), and Hinton tests all fall into this group. These tests have been thought to have very high sensitivity but, as indirect measures of infection, lack specificity. Patients with positive nontreponemal tests would then be further tested for specific antitreponemal antibodies, using the FTA-Abs (fluorescent treponemal antibody, absorbed against nonpathogenic treponemata to decrease cross-reactivity), the MHA-TP test (microhemagglutination for *T. pallidum*), or capture enzyme-linked immunosorbent (ELISA) or chemoluminescent assays (CIA).

Studies using CIAs or ELISAs for comparison suggest that reaginic tests are less sensitive than previously believed, leading to recommendations by some that direct tests be used for initial screening. Although the CDC still recommends the traditional sequence, it now also endorses the reverse sequence. In this approach the initial diagnosis starts with a specific treponemal test (ELISA or CIA), confirming positives with a nontreponemal test; discordant results are then further tested with a different specific treponemal test. To make matters even more confusing the European equivalent to the CDC recommends a different reverse approach, also starting with a specific treponemal test, but then confirming positives with a different specific test, testing discordant results with a nontreponemal test. Arguments in favor of each approach are based on assessments of positive and negative predictive values. Notably, a large study suggests that overall, both reverse approaches are equivalent,[4] although increasing evidence suggests the traditional method, starting with nontreponemal tests, is less sensitive.

Response to therapy is generally assessed by measuring titers of reaginic antibody. Typically, the serum titer in a VDRL or similar test declines steadily after successful treatment and eventually becomes negative in most cases, unlike specific assays, which remain positive indefinitely.

When serologic testing was introduced early in the twentieth century, seroprevalence rates of 8 to 14 percent were reported in major cities. It was at that time that the medical literature blossomed, attributing all manner of disease to syphilis. It may well be that at least some of this was misattribution due to coincidentally positive serologic tests, much as occurs in Lyme disease–endemic areas today (where, coincidentally, seroprevalence rates of 5 to 15% are common).

Diagnosis of nervous system disease relies heavily on examination of the cerebrospinal fluid (CSF), which is recommended in the assessment of any patient with primary or secondary syphilis and clinical suspicion of central nervous system (CNS) involvement or with tertiary syphilis. Invasion and infection of the CNS typically result in increased protein concentration or a CSF pleocytosis, with an increased proportion of B cells. Rarely there is mild hypoglycorrhachia. Active disease typically results in the presence of reaginic antibodies (VDRL) in the CSF. Chronic infection and stimulation of the immune response within the CNS generally result in increased CSF IgG concentration as well as production of oligoclonal bands. Synthesis of specific anti-*T. pallidum* antibody can often be demonstrated in the CSF. Interestingly, active infection leads to increased CSF concentration of CXCL13, a B cell–attracting cytokine, just as in nervous system Lyme disease.[5] Successful treatment usually leads to resolution of the CSF pleocytosis, with normalization of CSF protein, IgG concentration, CXCL13, and, usually, VDRL.

CSF-based diagnosis is usually straightforward but can sometimes be problematic, as reviewed elsewhere.[6] The CSF VDRL is considered highly specific—a positive CSF VDRL result is regarded as diagnostic of CNS syphilis. (The CSF RPR test has far more false-positive results.) The VDRL's specificity is probably related to the fact that the methodology is rather insensitive—a fairly high concentration of antibody is needed for the test to be judged positive. Thus, the presence of a positive VDRL in the CSF is unlikely to be an artifact of contamination of CSF with peripheral blood immunoglobulin. One potential diagnostic problem arises, however, in that although the CSF VDRL typically declines after successful treatment, it may remain positive for an extended period of time. In this circumstance, the return of the CSF white blood cell count and protein concentration to normal is usually taken as evidence of adequate treatment.

With the technically more sensitive methods used to detect antitreponemal antibodies (FTA-Abs, MHA-TP, ELISA, CIA), contamination is a more important issue. False-positive results can occur for one of at least three reasons. Antibodies against antigenically similar organisms (e.g., *Borrelia burgdorferi*) can cross-react. More important, if the lumbar puncture is traumatic, peripheral blood can contaminate the specimen, resulting in artifactual elevations in antibody titers. Probably most important, however, is the fact that some peripheral blood immunoglobulin always filters into the CSF. In the absence of CNS inflammation, there is minimal if any intrinsic production of antibodies within the CNS. However, CSF IgG concentration is typically 2 to 3 mg/dL, approximately 0.2 percent of peripheral blood IgG concentration, representing the small amount of serum immunoglobulin that normally passes through the blood–brain barrier. Just as in testing CSF Lyme serologies, standard testing conditions (diluting CSF 1:5 for the FTA-Abs, for example) are selected to compensate for this leakage. However, artifacts may arise in two important circumstances. In patients with high serum FTA-Abs titers, CSF titers may be positive simply by virtue of the small amount of specific antibody that normally filters in. Second, in the presence either of CNS inflammation or of blood–brain barrier breakdown for other reasons, the amount of peripheral blood immunoglobulin leaking into the CNS may be greater than assumed, resulting in an apparent increase in the concentration of the tested antibody but actually simply reflecting an overall and nonspecific increase in all antibody levels. These considerations notwithstanding, the CSF FTA is a highly sensitive if not entirely specific marker of neurosyphilis.

The absence of an absolute "gold standard" test for the diagnosis of neurosyphilis has resulted in controversy, differing recommendations for diagnostic strategies, and varying estimates of the sensitivity and specificity of different CSF tests. Whereas the CSF VDRL test is often said to be 100 percent specific, estimates of its sensitivity vary widely, depending on the alternative criteria used to define neurosyphilis. Screening CSF samples using the FTA-Abs and considering patients to have probable neurosyphilis if they have (1) a positive CSF FTA-Abs result, (2) a consistent clinical syndrome, and (3) elevation in either the CSF cell count, protein concentration, or both, leads to an estimated sensitivity of the CSF VDRL of 27 percent. Performing a similar analysis, but using the CSF MHA-TP as the primary criterion and comparing the CSF MHA-TP, CSF FTA-Abs, and CSF VDRL, suggests that the sensitivity of the CSF VDRL is about 40 percent, but that of the CSF MHA-TP is substantially greater than that of the FTA-Abs. However, there is evidence that as many as one-third of human immunodeficiency virus (HIV)–seronegative individuals with positive serum VDRL results will have inflammatory changes in the CSF, but no serologic (CSF VDRL or FTA-Abs) evidence of neurosyphilis, calling into doubt the assumptions underlying the first two conclusions.

Theoretically, a more definitive approach would be to determine whether antibodies targeted against *T. pallidum* are actually being produced within the CNS. Although a variety of techniques can be used, conceptually this is accomplished by measuring the antibody concentration in CSF and serum, normalizing for the relative total immunoglobulin concentrations in both, and determining whether specific antibody is disproportionately represented in the CSF. This approach, used in many other infections, should have very high specificity, although, again, sensitivity is difficult to define. Despite the intuitive appeal of this approach, sensitivity estimates have varied widely, depending on underlying assumptions, making its applicability uncertain at this time.

Clinical Features

After initial inoculation of spirochetes, the organism disseminates rapidly. Within weeks of infection the chancre develops at the site of infection. Chancres contain large numbers of spirochetes and are highly infectious. Untreated, they typically subside spontaneously over weeks. This early, localized disease constitutes primary syphilis. Over the ensuing few months, spirochetes disseminate, setting the stage for secondary syphilis. In this phase, there is a high antigen load, often with a significant spirochetemia. Spirochetes can invade any organ of the body but have a particular predilection for the skin (with secondary lesions, particularly involving the palms and soles), lymph nodes (particularly the epitrochlear nodes), kidney (with an immune complex–mediated glomerulonephritis), and CNS (seeded in between 25 and 40% of infected individuals). As many as 40 percent of untreated patients develop a lymphocytic meningitis. As in other basilar meningitides, the cranial nerves, particularly II to VIII, can be compromised. Intracranial pressure may be increased.

The disease then typically enters a latent phase, during which infection—and the immune response to it—persist. In the majority, the host immune response clears the infection. In a subset, late or tertiary complications develop. In some, this consists of disseminated granulomata, known as gummas, that can occur anywhere in the body, causing focal symptoms depending on location. Patients may develop gummas in the brain, causing local structural damage and symptoms. Gummas tend to be relatively benign but can be confused with neoplasms or other processes. Some patients develop an endarteritis obliterans affecting the vasa vasorum of the ascending aorta, causing characteristic aneurysmal dilatation.

Although neurologic involvement is generally divided into early or late (secondary or tertiary) manifestations, there is some variability in how different pathophysiologic entities are grouped. The acute meningitis, with or without cranial nerve involvement, typically occurs during acute spirochetal dissemination and is considered part of secondary (acute disseminated) disease. All other manifestations occur later in the disease, in what might be termed *late disseminated infection* ("tertiary syphilis"), although some tend to occur earlier in this "late" phase, others later.

Symptomatic nervous system involvement ultimately occurs in 4 to 6 percent of untreated patients and tends to take one of several forms. One of the earlier occurring late manifestations is meningovascular syphilis, in which the characteristic obliterative endarteritis involves the intracranial vasculature, causing strokes. Although the resultant clinical phenomena are described as protean, they are no more protean than in other cerebrovascular disease—differences reflect the site of damage, not the mechanism.

Several other characteristic abnormalities may occur. Those not due to vasculitis are collectively referred to as parenchymal neurosyphilis. Involvement of the upper brainstem and surrounding basilar cisterns may lead to Argyll Robertson pupils, small irregular pupils that do not react to light but do to accommodation. Optic atrophy may develop slowly, presumably owing to both increased intracranial pressure caused by the meningitis and local infiltration of the optic nerves. *Tabes dorsalis*, consisting of damage to the dorsal roots, the dorsal root ganglia, and the posterior columns, results in marked loss of proprioception, as well as "lightning-like" shooting radicular pain. Gait is typical of that in individuals with proprioceptive loss—slapping, with poor awareness of the location of the feet in space. Loss of the dorsal root ganglion neurons and dorsal roots leads to loss of reflexes and diminished pain awareness, potentially leading to repeated injuries to lower extremity joints with severe cumulative damage (Charcot joints).

One of the most fascinating disorders associated with late neurosyphilis is the late dementia, referred to as *general paresis of the insane*, or GPI. Initial symptoms are described as personality changes with delusions and hallucinations; seizures and myoclonus may occur. Involvement tends to be frontotemporoparietal, with a slowly progressive dementia. Considered a consequence of long-standing meningitis, the pathology is rather subtle. Inflammatory changes are seen in the ventricular walls (granular ependymitis). There is brain atrophy, ventricular enlargement, and neuronal loss, with some reactive gliosis. Parenchymal inflammation is usually rather limited, without evidence of multiple infarcts—in brief, the degree of CNS dysfunction seems out of proportion to the evidence of disease activity. MRI studies have demonstrated fairly widespread abnormalities.

Since the early 1980s, the HIV epidemic has led to a resurgence of neurosyphilis, raising new concerns about both the biology of the infection and its treatment. In HIV-infected individuals, early disease and asymptomatic disease each account for about one-third of the cases of co-existing neurosyphilis. Of patients with early disease, one-half have meningitis and one-fourth have meningovascular syphilis. Of those with late-stage disease, the majority has general paresis, and a small subset has tabes.

Finally, congenital infection still occurs. This happens most commonly during early stages of maternal infection, when spirochete dissemination is still actively occurring. Treatment during the first 4 months of gestation usually protects the fetus; after that, death of the fetus or newborn, or congenital infection, can result. The common manifestations of newborn infections include “snuffles” (rhinitis due to mucocutaneous involvement) and a diffuse rash that is unusual in that it involves the palms and soles as well as skin at mucoepithelial junctions. Involvement of the liver is common, as are osteochondritis and perichondritis, most typically manifested as a “saddle nose” and “saber shins.” Unusual, centrally notched, peg-shaped upper teeth (“Hutchinson’s incisors”) occur, as does frontal bossing. IgM assays can be useful for diagnosis.

Treatment

Treatment of early syphilis remains remarkably effective with simple regimens.[7] Primary, secondary, and latent syphilis (without CNS involvement and of less than 1-year duration) are generally treated with a single dose of intramuscular benzathine penicillin (2.4 million units). Treatment for 2 weeks with oral doxycycline (100 mg twice daily) has been recommended for patients allergic to penicillin, although few studies have evaluated this approach. Recommendations are usually for desensitization to penicillin if at all possible. When the nervous system is involved, high doses of intravenous penicillin are generally required (10 to 14 days, 3 to 4 million units every 4 hours). Curiously, for many years, weekly intramuscular injections of benzathine penicillin were used. This is still one of the recommended alternative regimens for neurosyphilis, even though the demonstrable levels in the CNS are subtherapeutic for *T. pallidum*, presumably reflecting the efficacy of this regimen outside the blood−brain barrier and the rather low incidence of late neurosyphilis in untreated individuals. An acceptable alternative is procaine penicillin 2.4 million units intramuscularly daily, with probenecid 500 mg orally four times daily for 10 to 14 days. Ceftriaxone has been suggested as an alternative in patients allergic to penicillin and may be useful.[8]

Treatment has been particularly challenging in patients coinfected with HIV. Not only may syphilis cause considerably more serious symptoms, it may be much more difficult to eradicate. Patients who have received full courses of usually curative doses of intravenous penicillin have developed clear-cut relapses, even when initial treatment was at a time when the patient was not severely immunocompromised.[9] This suggests that treatment may not eliminate these spirochetes entirely, but reduces the bacterial burden to a number that normally can be controlled by the patient’s immune system.

LYME DISEASE

Background

The term *Lyme disease* was coined in the mid-1970s to describe a disorder affecting children living near Lyme, Connecticut, who developed what appeared to be juvenile rheumatoid arthritis. Careful epidemiologic studies demonstrated that this disorder developed following bites by hard-shelled *Ixodes* ticks (Fig. 39-1), particularly when the bites were followed by a slowly enlarging erythroderm (Fig. 39-2), as reviewed in detail elsewhere.[6] It was soon recognized that this rash was identical to the one described early in the twentieth century in the European literature, known as

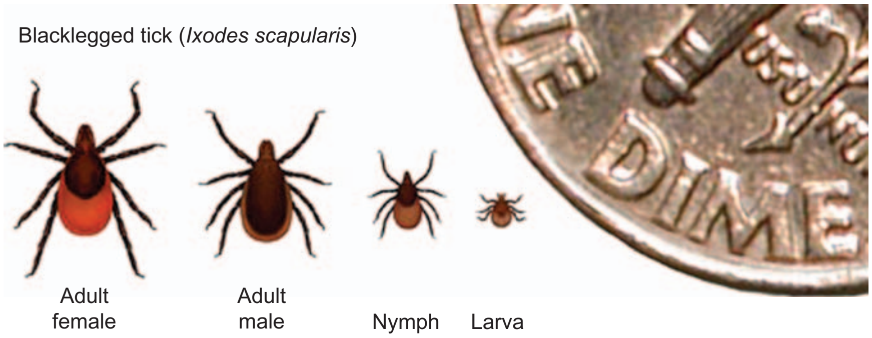

FIGURE 39-1 ■ Ixodes ticks. (Reproduced courtesy of Centers for Disease Control and Prevention: http://www.cdc.gov/lyme/transmission/. Accessed February 26, 2013.)

erythema chronicum migrans (ECM, now EM), also known to develop following bites of *Ixodes* ticks. Similarly, by the late 1970s it became apparent that affected individuals frequently developed all or part of a neurologic triad of lymphocytic meningitis, cranial neuritis, and painful radiculoneuritis, virtually identical to the disorder described in the 1920s by two French physicians and now known as Garin–Bujadoux–Bannwarth syndrome. A German report in 1941 even associated the disorder with "rheumatism." Although American patients appear to have more prominent rheumatologic symptoms and European patients more striking nervous system abnormalities, the European and American disorders are qualitatively similar.

In 1982, Willy Burgdorfer isolated a novel spirochete from *Ixodes* ticks collected on Shelter Island, New York (directly across Long Island Sound from Connecticut), and the following year it was clearly established that this organism, named *B. burgdorferi*, was the agent responsible for Lyme disease. Shortly thereafter, Eva Asbrink in Sweden identified a virtually identical organism as the agent responsible for European borreliosis. Subsequent studies have permitted the subdivision of this group of *Borrelia* (referred to collectively as *B. burgdorferi* sensu lato) into at least three subspecies. The strain responsible for North American disease has been termed *B. burgdorferi* sensu stricto, whereas European disease is attributed primarily to two strains, known as *Borrelia garinii*, responsible for most cases of neuroborreliosis, and *Borrelia afzelii*, responsible for several unique cutaneous abnormalities. These strain differences are believed to be responsible for the somewhat different range of presentations seen in Europe and North America. Several additional strains, *Borrelia mayonii* and *Borrelia miyamotoi*, have been identified in recent years, the former causing a Lyme disease-like illness, the latter one resembling relapsing fevers. Since both are quite uncommon and lack frequent nervous system involvement, they will not be discussed further here.

Interestingly, although Lyme arthritis was characterized only in the 1970s, identical cases of recurrent, nontraumatic knee arthritis were recognized years earlier in eastern Long Island, where this was known as Montauk knee. Some have conjectured that Lyme disease was introduced to the United States when a herd of deer was brought to Long Island, New York, from Europe early in the twentieth century, an interesting counterpoint to the theory that Columbus imported syphilis to Europe from the New World. The disease appears to have spread slowly from Long Island to Connecticut, and then to contiguous regions, and is now endemic along much of the eastern seaboard of the United States from Massachusetts to Delaware. A second endemic

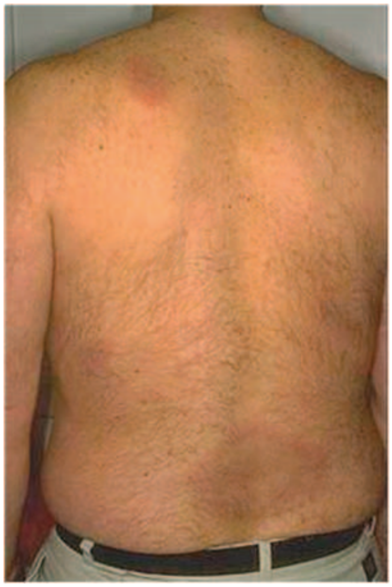

FIGURE 39-2 ■ Multifocal erythema migrans, extending across much of the back.

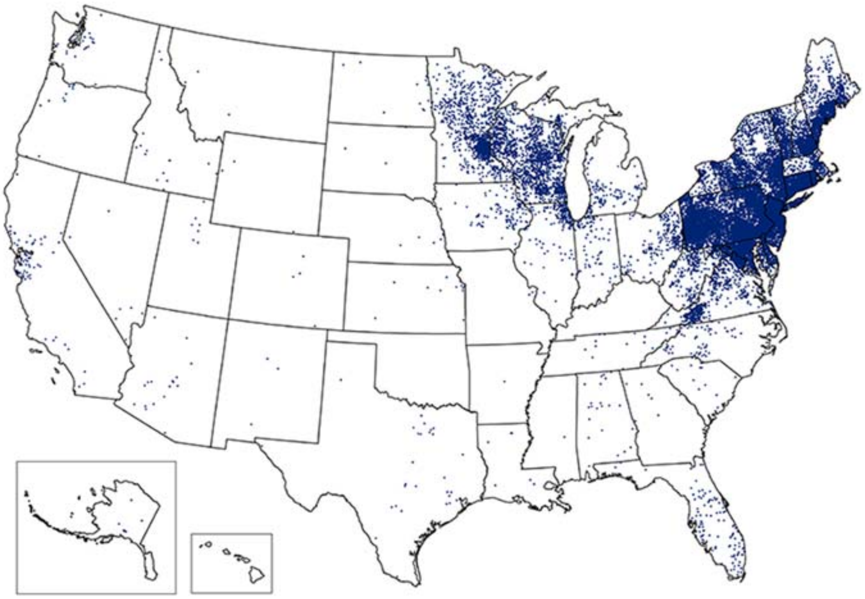

FIGURE 39-3 ■ Reported cases of Lyme disease in the United States, 2017. One dot is placed randomly within the county of residence for each confirmed case. Though Lyme disease cases have been reported in nearly every state, cases are reported based on the county of residence, not necessarily the county of infection. focus exists in the upper Midwest, and possibly a small third one in northern California. These three regions account for the vast majority of cases of Lyme disease in the United States (Fig. 39-3).

B. burgdorferi spirochetes differ somewhat morphologically from *T. pallidum.* They range in length from 10 to 30 μm and are 0.2 to 0.5 μm in diameter. Like treponemes, they are helical in shape and propel themselves through medium or tissue with flagella.

Lyme disease occurs worldwide, primarily in areas in which *Ixodes* ticks co-exist with a reservoir of infected animal hosts and potential human victims. In temperate climates the tick goes through a 2-year life cycle. After hatching into a larva (Fig. 39-1), it feeds once, typically on a small mammal such as a field mouse. If this host has previously been infected, the tick may ingest spirochetes and itself become infected. After feeding, the larva matures into a nymph, which will then have its next meal. As blood enters the infected tick's gut, spirochetes already present proliferate. Over a period of 24 to 48 hours, they migrate to the tick's salivary glands, from which they can be injected into the new host, again transmitting infection. Because of this process, tick attachment lasting less than 24 to 48 hours is highly unlikely to result in infection.

The tick ultimately partakes of one last meal, this time as an adult. This typically occurs on a larger mammal, such as a deer, bear, or sheep—the species of choice giving rise to the popular name given the tick. Since the tick responsible for Lyme disease in the northeastern United States (*Ixodes scapularis*) is most closely associated with deer, some control strategies have focused on reducing the deer population. Although this may be helpful in lowering tick density, host elimination must be nearly complete. Similar strategies are less practical elsewhere. In much of the world, sheep provide the predominant large host. Elimination of these commercially important animals would be impractical. Other control strategies, such as providing rodents—the principal reservoir host—with acaricide-containing nesting material, springtime acaricide spraying to eliminate nymphs, and creation of dry barriers between wooded and residential areas, have met with varying success. In most endemic areas, ticks feed primarily during warmer months, placing human victims at greatest risk of contracting this infection from spring through autumn. The more temperate California climate leads to less seasonal variation.

Clinical Features

GENERAL

Lyme disease typically begins with a virtually pathognomonic rash, erythema migrans, occurring at the site of the tick bite, generally developing several days after but within 1 month of infection. Although the rash is erythematous and occasionally swollen, it typically is remarkably asymptomatic. Untreated, it expands to become many inches in diameter, potentially spanning an entire limb or occupying much of the trunk (Fig. 39-2). Between one-half and two-thirds of adults with Lyme disease recall having such a rash; in children, who are presumably under the watchful eye of a parent, the rash is seen in as many as 90 percent of infected individuals. Since the rash may occur on parts of the body not readily seen and is often asymptomatic, it is not surprising that a significant number of patients have no recollection of having had a rash. Like the chancre, it can resolve spontaneously without treatment, although treatment speeds resolution. Also like the chancre, the rash contains innumerable spirochetes, particularly at the leading edge. Unlike *T. pallidum*, however, it is possible to culture *B. burgdorferi* in vitro, although this requires a specialized medium that is not commonly available in most microbiology laboratories.

The spirochetes typically disseminate rapidly after inoculation. This secondary spread differentiates acute localized Lyme disease, analogous to primary syphilis, from early disseminated infection, analogous to secondary lues. Dissemination is often accompanied by fever and diffuse myalgias and arthralgias, identical to those seen in other bacteremias, often referred to as a "flu-like" syndrome. Notably, this flu-like syndrome does not include upper respiratory or gastrointestinal symptomatology. With dissemination, the rash may become multifocal (Fig. 39-2), and other organ systems may become involved.

Other cutaneous abnormalities occur infrequently in North America, but more commonly in Europe. Acrodermatitis atrophicans develops late in European borreliosis and consists of "tissue paper—like" atrophy of the skin, which becomes reddish-purple in hue. *Borrelia* lymphocytoma, a thickening of the skin due to a dense lymphocytic infiltrate, typically involving the earlobe or the areola of the breast, similarly occurs frequently in Europe but rarely in the United States.

In early series about 5 percent of patients (fewer in later studies) developed cardiac conduction abnormalities—commonly heart block in an otherwise healthy young adult. Occasional cases of myositis have been described. Mild elevations of serum creatine kinase are not uncommon, although frank muscle weakness is distinctly unusual. The myositis is typically focal, presents particularly with pain and swelling, and tends to occur adjacent to areas of skin, joint, or nerve involvement.

As in virtually every other known infection, a certain number of individuals become infected but do not become symptomatic, or develop minor symptoms that are self-limited and indistinguishable from other summertime febrile illnesses. The precise frequency with which this occurs is indeterminate, but probably is substantial.

Unlike syphilis, congenital infection does not appear to be a significant problem. Despite anecdotal reports, no characteristic "congenital Lyme disease syndrome" has been identified. Epidemiologic studies have failed to demonstrate any increase in adverse outcomes among women with positive serologies who have not had clinical evidence of acute infection. In a few instances, infants born to women who had experienced acute infections during pregnancy have themselves been infected, so aggressive treatment in this circumstance is appropriate.

NEUROBORRELIOSIS

Among infected patients, 10 to 15 percent will develop neurologic abnormalities, most commonly a lymphocytic meningitis, cranial neuropathy, or painful radiculitis. The neurologic syndromes can be categorized (Table 39-1) as affecting primarily the peripheral nervous system or the CNS, although overlap occurs. Manifestations of each vary widely, depending on the specific site and severity of involvement. However, all share just a small number of pathophysiologic mechanisms.

TABLE 39-1 ■ Central Nervous System Manifestations of Neuroborreliosis

Infection in Subarachnoid Space (Abnormal CSF)
Meningitis
Radiculitis
Cranial neuritis
Infection in CNS Parenchyma (Abnormal Neurologic Examination, MRI, CSF)
Encephalitis
Myelitis
Some cases of severe encephalopathy
Toxic or Metabolic Encephalopathy (Normal MRI, CSF)
Encephalopathy

CNS, Central nervous system; CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

The CNS is often seeded early in infection. Precise estimates are difficult because patients do not routinely undergo CSF examination. However, it is likely that the CNS is seeded in many individuals, but the infection clears spontaneously. In many patients, acute infection is marked by an acute lymphocytic meningitis. Headache and neck stiffness are quite variable in severity and do not correlate well with the degree of CSF pleocytosis. Typically, the CSF contains 50 to several hundred lymphocytes per cubic millimeter, with mild (50 to 150 mg/dL) elevations in CSF protein concentration. CSF glucose concentration is usually normal. Although culture of *B. burgdorferi* is technically possible, generally CSF cultures are positive in no more than 10 to 20 percent of patients with unequivocal Lyme meningitis—with only a minimal increase in detection rates using nucleic acid−based detection—probably reflecting the very low number of spirochetes free in the CSF.

Although this meningitis typically is benign and manifests primarily as a headache, particularly in children a disorder resembling pseudotumor cerebri may occur, with increased intracranial pressure. This generally occurs either with or following Lyme meningitis and presumably relates to impaired CSF resorption, to increased vascular permeability mediated by cytokines and therefore increased pressure, or to both. On rare occasions, this has resulted in significant visual impairment.

Actual infection of the brain or spinal cord parenchyma (encephalomyelitis) is extremely rare, probably affecting fewer than 1 in 1,000 infected, untreated individuals. In these rare individuals, there is generally clear clinical and MRI evidence of focal parenchymal involvement, usually affecting the white matter preferentially (perhaps reflecting preferential binding of *B. burgdorferi* to oligodendroglia). Patients may present with focal signs that depend on the site of involvement, although a myelopathy tends to be more common. Anecdotal case reports have described a remarkable range of neurologic presentations. Establishing a causal relationship in such circumstances can be challenging. A number of case reports, primarily of European patients, has suggested that, as in meningovascular syphilis, strokes may be caused by Lyme disease, but the evidence of a causal relationship is limited; if a meningovascular form of Lyme disease exists, it must be much less common than in neurosyphilis. Similarly, several reports have suggested that optic neuritis may occur in neuroborreliosis, but this association similarly is unclear.

Despite the potential severity of CNS involvement, antimicrobial therapy is usually highly effective. As with any disorder of the nervous system, established damage may leave residual deficits, but treatment in most cases will arrest any further worsening and usually results in demonstrable clinical improvement.

The final and most controversial syndrome has been a chronic encephalopathic state, referred to as Lyme encephalopathy. In rare, more severely affected patients, this may reflect a mild encephalitis. In the latter individuals, the CSF is virtually always abnormal and brain MRI may demonstrate focal abnormalities. In most, who have prominent non-neurologic involvement (most typically active, recurrent oligoarthritis), a mild encephalopathy occurs that is similar to that seen in patients with other chronic inflammatory disorders in whom there is a sense of chronic fatigue and malaise with blunting of intellect and memory. An important corollary of this is that it is difficult to attribute mental status changes to Lyme disease in the absence of either systemic or CNS inflammation.

Unfortunately, this concept has been expanded to describe a disorder referred to as “chronic Lyme disease.” Such patients probably fall into one of at least three groups. Rare patients with true CNS infection will fail to respond to standard courses of antimicrobial therapy. In these, a second course may well end the symptoms. Other individuals who clearly have Lyme disease and are microbiologically cured continue to manifest chronic and nonspecific symptoms. The etiology of these symptoms is unclear. However, these patients do not respond to additional antibiotics, but often respond to treatment directed at their symptoms with various combinations of exercise, “wellness education,” and medications including anti-inflammatory and antidepressant agents. In some, a sleep disorder is a prominent part of this syndrome and correcting this can be beneficial. Finally, this group has been shown to include numerous patients whose symptoms were never caused by Lyme disease in the first place. These individuals require careful evaluation to determine the actual cause of their symptoms, then appropriate treatment. It needs to be emphasized in this context that no systematic study has ever indicated that Lyme disease causes psychiatric disease, beyond the usual difficulties associated with being ill; in fact, a systematic study of more than 900 psychiatric patients in a Lyme disease-endemic area found no evidence of any associations between any specific psychiatric disorder and this infection.

The peripheral nervous system (Table 39-2) is probably involved more frequently than the CNS. The cranial nerves are at particular risk, probably because they are vulnerable both within the subarachnoid space and along their peripheral course. As in syphilis and other

Demyelinating Polyneuropathy (Anecdotal, Rare)

basilar meningitides, cranial nerves VII and VIII are frequently affected, although cranial nerves III through VI may also be involved. The lower cranial nerves are sometimes impaired, although much less frequently. Lyme disease is one of the few disorders commonly associated with bilateral facial palsies (along with sarcoidosis and Guillain–Barré syndrome). Because these cranial neuropathies generally occur fairly early in infection and because, in the most commonly involved areas, climate dictates that ticks feed primarily from spring through autumn, patients presenting with facial palsies in summer and autumn in endemic areas should undergo serologic screening for Lyme disease. CSF examination may be helpful to address alternative diagnoses. However, numerous European studies have shown that Lyme meningitis and cranial neuritis respond well to oral doxycycline, so the CSF findings will likely not affect treatment directly.

The syndrome of Garin–Bujadoux–Bannwarth is probably under-recognized in the United States. Patients typically have severe radicular pain that can precisely mimic the symptoms of a mechanical radiculopathy. Weakness in the same nerve root distribution ranges from minimal to severe. Truncal radiculopathies occur and, as with painful diabetic truncal neuropathies, may lead to considerable diagnostic confusion. A clue to this atypical etiology may be involvement of more than one dermatome. CSF is often, although not invariably, abnormal.

Some patients develop a plexopathy or a typical mononeuropathy multiplex. Patients with more longstanding infection may develop a milder, more diffuse polyneuropathy. This usually is not painful, but presents as a more mundane distal sensorimotor neuropathic syndrome, with both positive and negative symptoms. Interestingly, electrophysiologic and pathologic studies indicate that all these syndromes are due to a mononeuropathy multiplex. Notably, in the rhesus macaque monkey, the only animal model of human neurologic Lyme disease, virtually all infected animals develop a mononeuropathy multiplex that subsides over time.

Finally, rare patients have been described with a disorder resembling Guillain–Barré syndrome. Clinically, these individuals have had a rapidly progressive polyneuropathy, with ascending paralysis, but many have had a more prominent CSF pleocytosis than typically occurs in Guillain–Barré syndrome. Electrophysiologic changes have been varied but only rarely demonstrate prominent demyelination.

Diagnosis

Accurate diagnosis requires recognition of the clinical syndrome, a reasonable epidemiologic likelihood of exposure, and laboratory confirmation. Although much has been said in the past about the inaccuracy of testing for Lyme disease, it is comparable, overall, with other serologic testing. There remain technical arguments about the best antigen and methodology to use, but it is likely that more of the difficulty arises from misinterpretation of test results than from inaccurate ones.

Laboratory diagnosis relies primarily on serologic diagnosis—the demonstration of antibody in peripheral blood that adheres to *B. burgdorferi*. The sensitivity of microbiologic culture remains low (except in erythema migrans, where it is unnecessary) and probably reflects the small number of spirochetes present in readily accessible clinical specimens. The polymerase chain reaction assay has remained problematic, probably for the same reason (in addition to contamination-related issues leading to false-positive results). Antigen detection methods have not been found to be reproducible. Immune complexes containing *Borrelia* antigens have been described, but do not appear to be a reliable independent marker of infection. Hence, most laboratories rely on ELISAs to quantitate immunoreactivity.

Several particular problems confront serologic testing for Lyme disease. First, the disease is focally endemic. In highly endemic areas, such as areas of Long Island, 10 percent or more of the population may have been exposed. In contrast, in nearby New York City, there were about as many cases of malaria in 2010 as of confirmed Lyme disease. This highly varying background prevalence has a major effect on the positive and negative predictive values of test results, which depend on the background prevalence. In areas with Lyme disease prevalence of 1 in 100,000 and a statistically defined negative cut-off of 3 standard deviations, 1 sample in 1,000 will be a false positive, but only 1 in 100,000 will be a true positive. Second, as with any antibody-based testing, it must be remembered that it takes several weeks or more to develop a detectable antibody response in blood. Thus, negative results are common at the time of the erythema migrans, but, as with the syphilitic chancre, the rash by itself is sufficiently diagnostic to mandate immediate antibiotic treatment. Third, unlike other serologic tests, most clinicians rely on a single Lyme disease ELISA value rather than comparing acute and convalescent titers. This may be reasonable in syphilis, where screening reaginic tests are typically positive only during active infection, and is understandable insofar as there is a desire to treat Lyme infection as soon as possible. However, it makes test interpretation difficult in patients who have had prior infection and have a persistently elevated titer. As in most infections, the immune system usually continues to generate detectable antibodies for an extended period after the infection has resolved, sometimes making the relevance of the positive serology to current symptoms difficult to judge.

Finally, as with most serologic tests, some cross-reactions occur. To address this a two-step test procedure is used, but unfortunately this too has produced confusion. Western blots are routinely used to confirm positive or borderline ELISAs. The criteria for interpreting these (Table 39-3) were defined in individuals with positive or borderline ELISA results; therefore, they can only be applied in individuals with negative ELISA results with extreme caution. Second, the criteria were derived statistically. Interpretation is based not on the uniqueness of any of the bands but on the statistical probability of accurate diagnosis. Importantly, just as in syphilis, testing algorithms are evolving. While the standard approach for over two decades has been to screen with an ELISA and confirm positive or borderline results with the more specific Western blot, the CDC now also endorses an alternative approach, testing with two independent ELISAs (i.e., testing for reactivity to different antigens, much like the European algorithm for syphilis testing) provides better test accuracy and eliminates much of the confusion associated with Western blot interpretation.[10]

TABLE 39-3 ■ Western Blot Criteria for Confirmation of Positive Serology in Lyme Disease

IgM (2 required)	Bands (kDa)	23, 39, 41
IgG (5 required)	Bands (kDa)	18, 23, 28, 30, 39, 41, 45, 58, 66, 93

As in syphilis, spinal fluid studies can be extremely useful, but they also are the source of considerable confusion. Most, if not all, patients with active CNS infection will have elevations in the CSF white blood cell count, protein concentration, or both. Chronic infection is often accompanied by increased local production of antibodies, resulting in an increased relative CSF IgG concentration and even oligoclonal bands. In most acute cases (about 90%) and in many patients with more longstanding CNS Lyme disease (at least 50% and possibly more), synthesis of specific anti–*B. burgdorferi* antibodies in the CNS can be demonstrated by appropriately comparing concentrations of specific antibody in CSF and serum. Simple measurement of antibody concentration in the CSF alone can be very misleading in individuals with blood–brain barrier breakdown, CNS inflammation from other causes, or positive peripheral blood Lyme disease serologies, as discussed previously in considering CSF serologies in syphilis. Mounting evidence suggests that measurement of the B cell–attracting cytokine, CXCL13, in CSF may be useful in clarifying the diagnosis.[11,12]

Treatment and Outcome

As with any infection, prevention is usually simpler than treatment. Infected ticks occur in relatively restricted locales, and avoidance is therefore a feasible strategy. Those who cannot or choose not to adopt this strategy can limit their risk by wearing light-colored clothing that covers as much of the body as possible, making it easier to spot the very small, responsible ticks. Because ticks must be attached and feeding for 24 to 48 hours before infection is likely, a careful tick check at the end of the day is highly effective. Attached ticks should be removed by placing a fine forceps between the tick and the skin, and gently pulling back. Efforts to suffocate ticks in petroleum products or burn them with a lit cigarette are counterproductive. Use of acaricides can help, but repeated exposures, particularly in children and with higher-concentration products, may lead to significant systemic absorption and may be neurotoxic. A vaccine was available but was withdrawn from the market, primarily because of poor sales.

Antimicrobial therapy is highly effective, regardless of disease duration and severity. Popular mythology about the organism hibernating invisibly, only to resurface years later, is an intriguing theoretical possibility, but from a practical perspective is irrelevant. Patients with the characteristic rash should be treated immediately with oral

TABLE 39-4 ■ Treatment Regimens

Medication and Route of Administration (Duration)	Adults	Children*
Parenteral (2–4 weeks)		
Ceftriaxone†	2 g daily	50–75 mg/kg daily
Cefotaxime	2 g every 8 h	150–200 mg/kg daily in 3–4 divided doses
Penicillin	20–24 million units daily	300,000 units/kg daily, divided every 4 h
Oral (3, possibly 4, weeks)		
Doxycycline‡	100 mg twice to four times daily	4 mg/kg daily in two divided doses
Amoxicillin§	500 mg three times daily	50 mg/kg daily in three divided doses
Cefuroxime axetil§	500 mg twice daily	30 mg/kg daily in two divided doses

Modified from Treatment of Lyme disease. Med Lett 42:37, 2000, with permission.

*Pediatric dosage should not exceed adult recommendation.

†Ceftriaxone should probably not be used late in pregnancy.

‡Although prior guidance recommended against use of any tetracyclines in children younger than age 8, recent pediatric guidelines have relaxed that recommendation. That notwithstanding, there is no evidence of "breakthrough" neuroinvasive disease in children treated for EM with amoxicillin or cefuroxime axetil.[13] Doxycycline should probably not be used in pregnant women.

§Limited data but probably effective.

medication (Table 39-4), regardless of the results of serologic testing. Those with more disseminated disease may well respond to oral regimens, and there are excellent data that Lyme arthritis and meningitis will usually respond well to oral regimens, particularly with doxycycline. Although US practitioners tend to be reluctant to use oral regimens when there is evidence of CNS involvement (particularly CSF abnormalities), such patients—if there is no parenchymal CNS involvement—can be treated effectively with oral doxycycline (Table 39-4). The optimal duration of treatment remains unclear. No randomized trial has demonstrated any advantage of prolonging parenteral treatment beyond 2 weeks. However, anecdotal evidence from all major centers treating patients indicates that occasionally this is insufficient. As a result, courses of 3 to 4 weeks are used not uncommonly and, under exceptional circumstances, repeated. Despite common practice at some centers, available data do not support longer courses or the use of more toxic antimicrobials. Multiple studies have addressed the role of longer courses of antimicrobial therapy in patients with continuing but nonspecific symptoms; no sustained benefit has been found over conventional treatment.[14,15]

Several studies from Lyme disease–endemic areas should be highly reassuring. Systematic case-control studies from Connecticut and Nantucket Island, Massachusetts, both areas highly endemic for Lyme disease, provide clear evidence that long-term outlooks of treated patients are excellent. Many patients who have been diagnosed as having Lyme disease and have undergone treatment appear to develop the same transient symptoms as do normal control subjects; however, they attribute them to Lyme disease and therefore find them more distressing. As also supported by several prospective studies from endemic areas in New York State,[16,17] by all objective measures, treated patients appear indistinguishable from healthy, uninfected individuals.

PROGNOSIS AND OUTCOME

CONCLUDING COMMENTS

Tuberculosis in all its forms remains a challenging clinical problem and a public health issue of considerable magnitude. Each year there are an estimated 10 million new cases of active disease worldwide and 1.3 million deaths attributable to tuberculosis. In 2018, 9,029 new cases of active tuberculosis were reported in the United States, an incidence rate of 2.8 cases per 100,000 persons.[1] Pulmonary tuberculosis accounts for 70 percent of active cases, isolated extrapulmonary disease 20 percent, and combined extrapulmonary and pulmonary disease 10 percent.

Tuberculosis of the central nervous system (CNS) accounts for approximately 1 to 2 percent of reported patients with active infection and 8 percent of all forms of extrapulmonary tuberculosis in immunocompetent individuals. While pulmonary tuberculosis in the United States has declined gradually in recent decades, the number of reported cases of meningeal tuberculosis has changed little and the case fatality rate remains high despite the availability of effective antituberculous therapy. CNS tuberculosis may be considered as comprising three clinical syndromes: meningitis, intracranial tuberculoma, and spinal tuberculous arachnoiditis.[2,3] All three forms of CNS infection are encountered with near equal frequency in regions of the world where the incidence of tuberculosis is high. In Europe and North America, where the incidence is lower and extrapulmonary tuberculosis is seen primarily in adults with reactivation disease, the large majority of cases present with meningitis.

MENINGITIS

Pathogenesis

Current understanding of the pathogenesis of CNS tuberculosis is based on a series of careful clinicopathologic correlations that date to the early part of the last century.[3] Conceptually, there is a two-phase process, beginning with the hematogenous dissemination of *Mycobacterium tuberculosis* (bacillemia) that follows primary pulmonary infection or late reactivation elsewhere in the body. During this hematogenous phase, small numbers of bacilli are scattered throughout the substance of the brain, meninges, and adjacent tissues, leading to the formation of multiple granulomatous foci of varying size and degree of encapsulation (tubercles). In

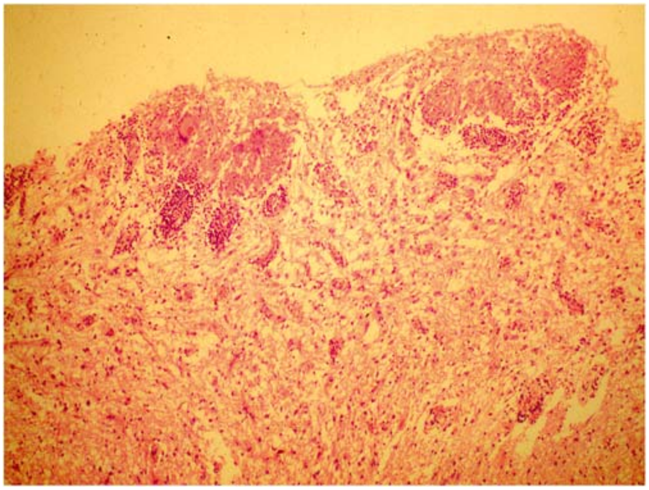

FIGURE 40-1 ■ Section from an autopsied case of tuberculous meningitis showing fresh granulomas beneath the surface of the brain, having eroded through the pia membrane into the subarachnoid space. (Hematoxylin and eosin, × 400.)

the second phase, such lesions coalesce to form larger caseous foci, some of which may lie just beneath the pia mater (the thin vascular membrane consisting of blood vessels and lymphatics that covers the entire surface of the brain) or beneath the ependyma (the thin nucleated epithelial membrane that lines the surface of the ventricles). With time and circumstance, a subpial or subependymal tuberculoma may destabilize and erode into the subarachnoid space, producing meningitis (Fig. 40-1). It follows that the propensity for developing clinical disease is determined by the number of tubercles and their proximity to the surface of the brain, the rapidity of progression, and the rate at which encapsulation follows acquired immunity.

The widespread and dense distribution of tubercles that occurs in progressive miliary tuberculosis greatly increases the chance that a juxtapial granuloma will be established and, from this critical location, break through into the subarachnoid space. This is the usual sequence in childhood tuberculous meningitis, as infants and young children are especially susceptible to progressive hematogenous dissemination following primary infection. Adult cases also develop in association with the bacillemia of progressive miliary disease or other less apparent or entirely hidden foci of chronic organ tuberculosis. Secondary hematogenous dissemination may be intermittent or chronic and progressive. In either circumstance, the spread of bacilli to distant organs produces scattered tubercles of varying size and encapsulation. Subpial tuberculous foci arising in this manner may remain quiescent for months or years, then destabilize when local injury or a depression in host immunity supervenes. Risk factors include advanced age, alcoholism, drug-induced immunosuppression, lymphoma, and infection with human immunodeficiency virus (HIV), all of which impair cellular immunity and, in persons with smoldering chronic organ tuberculosis, can lead to generalized tuberculosis including meningitis.

A significant proportion of adult cases of tuberculous meningitis have no demonstrable extracranial infection or apparent defect in host immune function. Occasionally, there is a history of head trauma some weeks or months prior to the onset of symptoms, suggesting that intracranial caseous foci may be destabilized by physical factors.

Pathology

The pathologic changes observed in the CNS result from an intense, cytokine-mediated hypersensitivity reaction induced by the presence of organisms and associated antigenic material in the substance of the brain and subarachnoid space. Three features dominate the pathologic process and account for the clinical manifestations: (1) a proliferative, predominantly basilar, arachnoiditis; (2) vasculitis of the arteries and veins traversing this exudate; and (3) disturbance of cerebrospinal fluid (CSF) circulation or resorption leading to hydrocephalus.

Proliferative arachnoiditis is most marked at the base of the brain and, in a matter of days or weeks, produces a thick, gelatinous exudate extending from the pons to the optic chiasm. With chronicity, the optochiasmic zone of arachnoiditis comes to resemble a fibrous mass encasing nearby cranial nerves and blood vessels.

Vasculitis with resultant thrombosis and hemorrhagic infarction develops in vessels that traverse the basilar or spinal exudate or those that are located within the brain substance itself. The vascular inflammatory reaction is initiated by direct invasion of the adventitia by mycobacteria or by secondary extension of adjacent arachnoiditis. An early polymorphonuclear reaction followed by infiltration of lymphocytes, plasma cells, and macrophages leads to progressive destruction of the adventitia, disruption of elastic fibers, and extension of the inflammatory process to the intima. Eventually, fibrinoid degeneration in small arteries and veins produces aneurysms, multiple thrombi, and focal hemorrhage in some combination. Depending on the location and extent of the vasculitis, a variety of stroke syndromes may result. Multiple lesions are common, and areas of ischemic injury that simulate lacunar infarctions most frequently involve the basal ganglia, cerebral cortex, pons, and cerebellum. Intracranial vasculitis and multiple infarcts are a common feature of autopsy studies and account for much of the residual neurologic disabilities observed in patients who survive.

Extension of the inflammatory process to the basilar cisterns impedes CSF circulation and resorption, leading to *communicating hydrocephalus* in most cases that have been symptomatic for longer than 2 to 3 weeks. Obstruction of the aqueduct develops less frequently from contraction of exudate surrounding the brainstem or from a strategically placed brainstem tuberculoma. In far-advanced cases, increased intracranial pressure may lead to brainstem compression and tentorial herniation.

TABLE 40-1 ■ Presenting Symptoms and Signs of Tuberculous Meningitis

Symptoms/Signs	Frequency (%)
Fever	60–90
Headache	40–90
Vomiting	30–60
Neck stiffness	40–80
Lethargy/drowsiness	25–80
Confusion	10–30
Stupor/coma	5–30
Focal neurologic signs	15–40
Cranial nerve palsy	20–40
Hemiparesis	10–20
Seizures	
Children	40–50
Adults	5

Clinical Presentation

SYMPTOMS AND SIGNS

Typically, tuberculous meningitis begins with a prodrome of insidious onset characterized by malaise, lassitude, personality change, intermittent headache, and low-grade fever. This is followed, usually within 2 to 3 weeks, by more prominent neurologic symptoms and signs such as meningismus, protracted headache, vomiting, confusion, cranial nerve palsies, and long-tract signs. The pace of illness may accelerate rapidly at this stage; confusion gives way to stupor and coma, seizures may occur, and multiple cranial nerve palsies and hemiparesis or hemiplegia are common. In most untreated cases, death supervenes within 5 to 8 weeks of the onset of illness although in occasional patients the illness follows a more indolent, slowly progressive course over weeks or months. In children, the condition is characterized early by irritability, loss of interest in play, restlessness, and anorexia; headache is less common and vomiting often much more prominent, especially in the very young. Seizures are more common in children and are likely to be an early or presenting symptom. Table 40-1 lists common symptoms and signs at presentation.

For purposes of prognosis and treatment, it is useful to categorize disease severity on presentation in reference to mental status and focal neurologic signs. *Stage I* comprises patients who have normal mental state, with or without meningismus but with no focal neurologic signs or evidence of hydrocephalus; *stage II* patients exhibit lethargy and confusion and may have mild focal neurologic signs such as single cranial nerve palsies and hemiparesis; *stage III* includes signs of advanced disease such as stupor and coma, seizures, multiple cranial nerve palsies, dense hemiplegia, and paraplegia. Some patients progress rapidly from one stage to the next within a few days of observation. The response to treatment is influenced significantly by the stage of disease at the time therapy is initiated, with better outcomes achieved when treatment is started early before the illness progresses from one clinical stage to the next.

ATYPICAL FEATURES

Adult patients may also present with a slowly progressive dementia over many months, characterized by personality change, social withdrawal, and memory deficits. At the other end of the spectrum are patients who present with an acute, rapidly progressive meningitic syndrome indistinguishable from pyogenic bacterial meningitis; at times, this accelerated form is superimposed on a chronic dementing illness. Seizures and focal neurologic disturbances such as cranial nerve palsies or hemiparesis may occur early and dominate the clinical presentation. Of the cranial nerves, the sixth is the most commonly involved, followed by the third and fourth. Occasionally the symptoms and signs of hydrocephalus with raised intracranial pressure (e.g., headache, papilledema, diplopia, and visual disturbance) precede signs of meningeal inflammation. Movement disorders, including tremor, myoclonus, chorea, and ballismus, may follow basal ganglia infarction secondary to vasculitis.

TUBERCULOUS MENINGITIS AND HIV INFECTION

CNS manifestations of tuberculosis are encountered with greater frequency in persons with tuberculosis who are coinfected with HIV. In a study of 455 HIV-positive patients with tuberculosis, 10 percent developed meningitis compared with 2 percent of HIV-negative patients, and HIV-positive patients accounted for 59 percent of all cases of tuberculous meningitis seen during the study period.[4] In comparison to non-HIV infected patients with tuberculous meningitis, coinfection with HIV has little impact on presenting clinical features, laboratory findings, or early response to therapy, though intracerebral tuberculomas are observed more commonly on neuroimaging studies in this population.

The initiation of antiretroviral therapy (ART) in treatment-naïve individuals coinfected with HIV and tuberculosis may lead to complications from the immune reconstitution inflammatory syndrome (IRIS) that follows restoration of immune responsiveness. Tuberculosis IRIS presents with signs of rapidly progressive extrapulmonary infection (e.g., fever, lymphadenopathy, respiratory symptoms, and meningitis) or clinical deterioration in patients previously improving on antituberculous therapy. In a series of 279 patients with tuberculosis-associated IRIS, progression to CNS tuberculosis developed in 12 percent, and excess mortality attributable to IRIS was observed in 30 percent of patients.[5] Manifestations of progressive CNS disease associated with IRIS include meningitis, brain abscess/tuberculoma, and rediculomyelitis.

Diagnosis

Few problems in medicine so critically challenge the physician's diagnostic acumen and clinical judgment as a patient with CNS tuberculosis. Once the possibility of tuberculous meningitis has been considered, the central task is rapid and thorough assessment of clinical and laboratory features followed by a prompt decision regarding empiric therapy.[6] Clues to the diagnosis include a positive family history of tuberculosis, recent exposure to others with active tuberculosis (especially in cases involving children and immunosuppressed adults), a history of recent head trauma, and alcoholism. Evidence of active tuberculosis elsewhere in the body, observed in 20 to 70 percent of cases, provides the most reliable basis for the presumptive diagnosis in patients with CNS disease. A meticulous physical examination should include looking for lymphadenopathy, spinal and other joint lesions, splenomegaly, scrotal masses, and draining fistulas. In patients with generalized (miliary) infection, careful funduscopic examination often shows choroidal tubercles on the retina: multiple, ill-defined, raised yellow-white nodules (granulomas) of varying size near the optic disc.

Abnormalities on chest radiography are seen in most childhood cases and in approximately 50 percent of adults presenting with CNS tuberculosis. Common findings include hilar adenopathy, a miliary interstitial pattern, apical scarring, or upper lobe nodular infiltrates. Computed tomography (CT) of the chest likely has a higher yield for these findings.

Patients with tuberculous meningitis may exhibit mild anemia and leukocytosis, but often the complete blood count and even the erythrocyte sedimentation rate are entirely normal. Hyponatremia related to inappropriate secretion of antidiuretic hormone occurs commonly and is a helpful, though nonspecific, clue to the diagnosis. The tuberculin skin test is more useful in childhood cases than in adults. A positive skin test supports the diagnosis but a negative skin test is relatively common in all forms of tuberculosis and thus does not exclude the diagnosis. Quantiferon gold serum testing is commonly used to assess for systemic infection but is neither sensitive nor specific for CNS disease.

CEREBROSPINAL FLUID EXAMINATION

Careful examination of the CSF is the key to diagnosis in most instances.[6] The opening pressure is usually elevated, the fluid is clear or "ground glass" in appearance, and, on standing, a delicate, web-like clot often forms. The typical CSF formula shows elevated protein and low glucose concentrations as well as a mononuclear pleocytosis.

The CSF protein concentration ranges from 100 to 500 mg/dL in most patients, is less than 100 mg/dL in 25 percent, and is more than 500 mg/dL in 10 percent. Patients with subarachnoid block may exhibit extremely high protein concentrations, in the range of 2 to 6 g/dL, associated with xanthochromia and a poor prognosis.

The CSF glucose concentration is usually low, being less than 45 mg/dL in approximately 80 percent of cases. The CSF cell count is between 100 and 500/mm^3 in most patients, less than 100 cells/mm^3 in approximately 15 percent, and between 500 and 1,500 cells/mm^3 in 20 percent. Although the characteristic cellular reaction is lymphocytic, early in the course of meningitis there may be only a few cells, a mixed pleocytosis, or polymorphonuclear predominance. This pattern will usually evolve in the direction of typical findings on repeat CSF examination. On occasion, an initial mononuclear pleocytosis may briefly change in the direction of polymorphonuclear predominance after therapy is initiated ("therapeutic paradox"), a change that may be associated with clinical deterioration.

Bacteriology

Specific diagnosis rests on the demonstration of *M. tuberculosis* in the CSF. Cultures are positive in approximately 70 percent of cases but often require weeks for detectable growth. Consequently, the careful examination of a stained smear for acid-fast bacilli (AFB) is the most effective means of making a prompt diagnosis. The importance of repeated, careful examination and culture of CSF specimens cannot be overemphasized; the diagnostic yield by smear and culture is enhanced when multiple CSF specimens from repeated lumbar punctures are submitted to the laboratory. In a prospective study designed to evaluate the effectiveness of careful bacteriologic technique, AFB were seen on smear in 77 of 132 adult patients (58%) and cultured from 94 of 132 (71%); the overall sensitivity of smear and culture was 82 percent.[7] This study confirmed earlier observations regarding the importance of high CSF volume and meticulous microscopy in the bacteriologic diagnosis of tuberculous meningitis.

In suspect cases, it is recommended that at least two CSF samples from separate lumbar punctures be obtained for stain and culture. It is best to submit 5 to 10 ml of the last portion removed; the AFB stain should be examined for 30 minutes. It is not necessary to defer treatment, as the yield remains high for several days after initiation of therapy.

Nucleic Acid Amplification Test

Molecular diagnostic techniques offer the promise of rapid and specific identification of mycobacteria in clinical specimens, thereby speeding the time to diagnosis and facilitating management decisions. Over the past decade, nucleic acid-based amplification (NAA) techniques have become increasingly utilized for the early diagnosis of tuberculous meningitis and for detection of drug resistance. In a recent meta-analysis of 63 studies comprising 1,300 patients with tuberculous meningitis confirmed by culture, the NAA test sensitivity and specificity were 82 and 99 percent, respectively.[8] CSF should be submitted for NAA testing whenever clinical suspicion is sufficiently high to warrant empiric therapy and initial stains for AFB are negative, recognizing that a negative NAA test result neither excludes the diagnosis nor obviates the need for continued treatment.

NEURORADIOLOGIC EVALUATION

CT and magnetic resonance imaging (MRI) have greatly enhanced the understanding of the pathogenesis, clinical assessment, and management of all forms of CNS tuberculosis.[9,10] CT can define the presence and extent of basilar arachnoiditis, the presence of cerebral edema and infarction, and the presence and course of hydrocephalus. In a study of 289 cases (214 children and 75 adults), hydrocephalus was demonstrated in 80 percent of patients, basilar meningeal enhancement in 39 percent, cerebral infarcts in 15 percent, and tuberculomas in 5 percent.[10] Hydrocephalus was associated with a longer duration of symptoms prior to treatment and was seen more often in children than adults. The CT findings are of prognostic significance and useful to monitor the effectiveness of adjunctive therapy such as corticosteroids and neurosurgical shunting procedures. In patients presenting with tuberculous meningitis, approximately 30 percent of those with stage I and 8 percent with stage II disease have a normal CT scan. Virtually all stage III patients have abnormalities, including hydrocephalus. Hydrocephalus alone without other features is uncommon and carries a good prognosis. Any degree of basilar meningeal enhancement combined with hydrocephalus is strongly suggestive of tuberculosis, and the combination is indicative of advanced disease, correlates well with the presence of vasculitis, and portends serious risk for basal ganglia infarction.[10]

MRI is the preferred imaging modality for defining lesions of the basal ganglia, midbrain, and brainstem.[9] It is superior to CT in delineating focal infarcts of the basal ganglia and diencephalon and in defining the presence of associated brainstem lesions. The character and severity of brainstem abnormalities correlate well with clinical signs of brainstem disease.

Differential Diagnosis

A variety of inflammatory, vascular, and neoplastic conditions of the CNS may mimic tuberculosis. In most cases, the differential diagnosis involves a patient presenting with clinical features of a granulomatous meningitis syndrome: fever, headache, meningeal signs, altered mentation, and a CSF profile showing lymphocytic pleocytosis, lowered glucose concentration, and high protein content. In addition to tuberculosis, the other primary infectious considerations include fungal disease (principally cryptococcosis), brucellosis, and syphilis. On occasion subacute aseptic meningitis with these CSF findings may be encountered in patients with unrecognized parameningeal suppurative infection such as sphenoid sinusitis, brain abscess, and endocarditis. Patients with herpes simplex virus and mumps meningoencephalitis may present with fever, rapid neurologic deterioration, and mild lowering of the CSF glucose concentration (see Chapter 42). Noninfectious etiologies to be considered include neurosarcoidosis and lymphomatous or carcinomatous meningitis. An evaluation for tuberculosis is warranted in every patient suspected of any of the diagnoses listed in Table 40-2.

TABLE 40-2 ■ Differential Diagnosis of Tuberculous Meningitis

Fungal meningitis (e.g., cryptococcosis, coccidioidal, histoplasmosis, blastomycosis)
Neurobrucellosis
Viral meningoencephalitis (e.g., herpes simplex virus, mumps)
Partially treated bacterial meningitis
Neurosyphilis
Focal parameningeal infection (e.g., sphenoiditis, brain abscess, endocarditis, spinal epidural abscess)
Central nervous system toxoplasmosis
Neoplastic meningitis (e.g., lymphoma, carcinoma)
Stroke
Neurosarcoidosis

TUBERCULOMA

Tuberculomas are conglomerate caseous foci within the substance of the brain that develop from deep-seated tubercles acquired during a recent or remote period of bacillemia. Centrally located, active lesions may reach considerable size without producing signs of meningeal inflammation. Under conditions of poor host resistance, this process may result in focal areas of cerebritis or frank abscess formation, but the more usual course is coalescence of caseous foci and fibrous encapsulation (tuberculoma). The characteristic CT finding is a nodular enhancing lesion with a central hypodense region.[9,11] Early-stage lesions may be isodense, often with edema out of proportion to the mass effect and with little encapsulation. As they mature, well-encapsulated tuberculomas appear as isodense or hyperdense lesions with peripheral ring enhancement. CT is useful for assessing the presence of cerebral edema, the risk of herniation, and the response to therapy. The MRI appearance depends on the stage of tuberculoma: focal cerebritis is manifest by nonspecific edema on T2-weighted images and ill-defined enhancement, whereas a caseating lesion typically shows central hypointensity and peripheral enhancement.

Clinically silent, single or multiple, small parenchymal tuberculomas are seen commonly in cases of tuberculous meningitis and often in miliary tuberculosis without meningitis. These lesions usually disappear with medical therapy, although cases have been reported in which tuberculomas enlarged early during the course of antituberculous therapy.

In contrast to small, incidental lesions that produce few or no symptoms, clinical tuberculomas presenting as symptomatic intracranial mass lesions are encountered frequently in areas of the world where the prevalence of tuberculosis is high. The usual patient is a child or young adult with headache, seizure, focal neurologic deficits, or signs of raised intracranial pressure. Symptoms of systemic illness and meningeal inflammation are usually lacking. The diagnosis is made with clinical, epidemiologic, and radiographic data or via needle biopsy.

Surgery for purposes other than diagnosis may be required when the location of the tuberculoma leads to obstructive hydrocephalus or compression of the brainstem. Corticosteroids aid in selected cases in which cerebral edema disproportionate to the mass effect contributes to altered mental state or focal neurologic deficits; however, this may mask the characteristic pathology of other diagnostic mimics such as CNS lymphoma, and therefore should be reserved for patients in whom the diagnosis is secure.

SPINAL TUBERCULOUS ARACHNOIDITIS

Tuberculous arachnoiditis or tuberculoma may arise at any level of the spinal cord in association with breakdown of a tubercle in the spinal cord or nearby meninges, or through extension from an adjacent area of inapparent spondylitis. The resultant inflammatory process gradually produces partial or complete encasement of the spinal cord in a gelatinous or fibrous exudate. In other cases, tuberculomas of the extradural, intradural, or intramedullary space may produce symptoms resembling local tumor.

Patients usually present with signs of nerve root and spinal cord compression secondary to impingement by the advancing arachnoiditis. The clinical manifestations are more neurologic than infectious, protean in nature, and often take the form of an ascending or transverse radiculomyelopathy of variable pace involving single or multiple levels.[12] Common symptoms and signs include pain, hyperesthesia or paresthesias in the distribution of the nerve root, lower motor neuron paralysis, and urinary or fecal incontinence. On occasion, the granulomatous mass or abscess may be confined largely to the epidural space, producing symptoms of spinal cord compression with no evidence of meningeal inflammation. Localized vasculitis can lead to thrombosis of spinal arteries and infarction of the spinal cord.

The diagnosis of spinal tuberculous arachnoiditis should be considered in the patient with any combination of the following clinical and laboratory features: subacute onset of spinal or nerve root pain; rapidly ascending transverse myelopathy or multiple-level myelopathy; increased CSF protein concentration and cell count; signs of arachnoiditis or epidural space infection by MRI; and evidence of tuberculosis elsewhere in the body. Surgical intervention and tissue biopsy are often required for diagnosis.

THERAPY

Antituberculous Chemotherapy

The decision to begin antituberculous chemotherapy should be made promptly and on the basis of strong clinical suspicion and presumptive diagnosis rather than waiting for confirmation of mycobacterial infection, as the prognosis is influenced greatly by the clinical stage at which treatment is initiated. There are no randomized trials to establish the optimal drug combination, dosage, and duration of treatment for tuberculous meningitis; the principles of treatment are those that govern the management of pulmonary tuberculosis. The use of multidrug regimens is designed to enhance the bactericidal effect, cover the possibility of drug resistance, and reduce the risk of emerging resistance while on therapy.

Isoniazid, rifampin, and pyrazinamide are each bactericidal, can be administered orally, penetrate inflamed meninges, and achieve CSF concentrations required for activity against sensitive strains. These drugs, in combination with ethambutol or streptomycin, are considered first-line therapy.

Isoniazid diffuses readily into CSF and achieves concentrations many times that required for bactericidal activity. The recommended daily dose is 10 mg/kg for children and 300 mg for adults. Pyridoxine, 25 or 50 mg daily, should be given concurrently to avoid the neurologic complications of isoniazid-induced pyridoxine deficiency, including peripheral neuropathy.

Rifampin is active early against rapidly dividing organisms and achieves reliable CSF concentrations only in the presence of meningeal inflammation. The daily dose in children and adults is 10 mg/kg (maximum 600 mg), and an intravenous formulation is available.

Studies of pulmonary tuberculosis have demonstrated that the addition of *pyrazinamide* to regimens that include isoniazid and rifampin produces a more powerful antituberculous effect without increasing the incidence of hepatotoxicity, as long as the duration of pyrazinamide therapy is restricted to 2 months or less. CSF penetration is excellent in the presence or absence of inflammation, and the drug is highly active against intracellular mycobacteria. It is recommended that pyrazinamide be included in the treatment regimen for meningitis during the first 2 months of therapy. In children, the daily dose is 15 to 20 mg/kg (maximum 2,000 mg). In adults, the dose is based on weight: 40 to 55 kg, 1,000 mg; 56 to 75 kg, 1,500 mg; 76 to 90 kg, 2,000 mg.

Ethambutol is a weak drug that reaches the subarachnoid space in moderate concentration. Its major toxicity, optic neuropathy, occurs in as many as 3 percent of patients receiving 25 mg/kg daily but is rare at the recommended dose of 15 mg/kg. When ethambutol is used, it is advisable to check baseline and then serial visual acuity, red-green color vision, and visual fields if possible.

RECOMMENDED REGIMEN

Clinical practice guidelines published jointly by subspecialty societies and the Centers for Disease Control and Prevention recommend an initial intensive phase of treatment with four drugs for 2 months followed by a prolonged continuation phase with two drugs for 7 to 10 months.[13] The initial four-drug regimen consists of isoniazid, rifampin, pyrazinamide, and either ethambutol or streptomycin, administered for 2 months. This is followed by isoniazid and rifampin alone if the isolate is fully susceptible and the clinical course satisfactory. If pyrazinamide is omitted or not tolerated initially, the total duration of treatment should be extended to 18 months.

In managing ART-naïve HIV patients, the initiation of ART should be delayed until after 8 to 10 weeks of antituberculous therapy, regardless of CD4 count.[13] This is to avoid the enhanced risk of serious neurologic complications and excess mortality associated with IRIS in patients coinfected with CNS tuberculosis.

The possibility of drug-resistant tuberculosis should be anticipated in high-risk individuals such as those from areas of the world where tuberculosis is endemic, the homeless, patients who have received previous antituberculous drugs, and individuals with known exposure to persons harboring resistant organisms. The impact on therapeutic outcome is variable, depending on whether the isolate is resistant to isoniazid or rifampin or both. The best drug combination for resistant infection is uncertain and to some extent depends on the particular sensitivity pattern of a given isolate. Fluoroquinolones (levofloxacin and moxifloxacin) are bactericidal against mycobacteria and exhibit good CNS penetration. In regions where the incidence of isoniazid-resistant tuberculosis is high, or for any case where drug resistance is considered likely, it is advisable to intensify the initial regimen by increasing the dose of rifampin to 15 mg/kg per day and adding levofloxacin (or moxifloxacin) 20 mg/kg per day.[14] The duration of treatment for drug-resistant CNS tuberculosis should be extended to 18 to 24 months, taking into consideration severity of illness and clinical response.

Adjunctive Therapy

CORTICOSTEROIDS

The role of corticosteroids in the management of tuberculous meningitis has long been a matter of uncertainty. Older studies were limited by small numbers of patients and the failure to stratify severity of illness according to neurologic manifestations. There is however a growing body of clinical data demonstrating that adjunctive corticosteroid therapy reduces neurologic complications and improves survival in children and adults with CNS tuberculosis. A 2016 Cochrane systematic review and meta-analysis of published trials concluded that corticosteroids increase survival in non-HIV-infected patients with tuberculous meningitis, but is of uncertain benefit in individuals coinfected with HIV.[15]

Adjunctive corticosteroid therapy is recommended for patients with convincing clinical evidence of CNS tuberculosis.[13] Complications for which corticosteroids are thought to be most beneficial include increased intracranial pressure or cerebral edema, stupor, focal neurologic signs, and spinal block. Specific clinical indications based on urgent warning signs include the following: progression from one clinical stage to the next at or before the start of specific treatment, CT evidence of marked basilar enhancement, moderate or advancing hydrocephalus, spinal block or incipient block (CSF protein ≥ 500 mg/dL), and intracerebral tuberculoma when edema is out of proportion to mass effect with clinical signs.

There is no established protocol for corticosteroid administration in patients with CNS tuberculosis. A commonly used regimen for adolescents and adults is dexamethasone: 0.3 to 0.4 mg/kg per day for 2 weeks, then 0.2 mg/kg per day for 1 week, then 0.1 mg/kg per day for 1 week, then 4 mg/day orally while tapering 1 mg off the daily dose each week, total duration 8 weeks.

The decision to use corticosteroids should rest on a strong presumptive or positive diagnosis. Caution is advisable in the face of diagnostic uncertainty, especially for cases in which fungal CNS infection is considered a strong possibility. The expected benefit from corticosteroids must be weighed against the potential for adverse consequences, bearing in mind that initial improvement may be nonspecific for tuberculosis. In select cases, systemic antifungal therapy should be administered concurrently until an etiologic diagnosis has been reached.

SURGERY

The management of hydrocephalus may require surgical decompression of the ventricular system in order to prevent neurologic complications of sustained elevated intracranial pressure. The indications for surgery are failure to respond to medical management and noncommunicating hydrocephalus. In patients with communicating hydrocephalus at clinical stage II disease, serial lumbar punctures combined with corticosteroids, diuretics, and osmotic agents may suffice while awaiting the early response to chemotherapy. However, surgical consultation should not be delayed when these measures fail or when the clinical course is one of progressive neurologic impairment.

Surgical removal of intracranial tuberculoma may be necessary in the patient with clinical features of a single space-occupying lesion, midline shift, raised intracranial pressure, and lack of satisfactory response to chemotherapy and corticosteroids.

PROGNOSIS AND OUTCOME

The clinical outcome in any individual case is greatly influenced by age, duration of illness, clinical stage at the initiation of therapy, the extent and character of optochiasmic arachnoiditis, and vascular complications. In general, when antituberculous treatment is started before patients progress beyond stage I or during early stage II disease, cure rates of 85 to 90 percent may be achieved. Ages younger than 5 years and older than 50 years are associated with a poorer prognosis. The observed mortality rate exceeds 50 percent in patients older than 50 years, in persons coinfected with HIV, and in any patient with stupor and coma.

The incidence of residual neurologic deficits after recovery from tuberculous meningitis varies from 10 to 30 percent in recent series. Late sequelae include cranial nerve deficits, gait disturbance, hemiplegia, blindness, deafness, learning disability, dementia, and various syndromes of hypothalamic or pituitary dysfunction.

CONCLUDING COMMENTS

Tuberculosis of the CNS, principally meningitis, remains the most devastating form of active mycobacterial infection. The natural untreated history is that of insidious onset and subacute progression, prone to rapid deterioration once focal neurologic deficits occur, leading to stupor, coma, and death within 5 to 8 weeks of the onset of illness. Antituberculous chemotherapy is effective, and the best clinical outcomes are realized when treatment is started in the early stages of disease. Patients with a subacute meningitis syndrome and CSF findings of low glucose concentration, elevated protein level, and mononuclear pleocytosis should be treated promptly if there is evidence of tuberculosis elsewhere in the body or if initial evaluation fails to establish an alternative, more likely diagnosis. Serial sampling of the CSF for culture and stained smears combined with molecular diagnostic testing provides the best means for reaching a bacteriologic diagnosis. Treatment need not be delayed as culture and stain for AFB remain positive for some days after antituberculous therapy has been started. In the patient with compatible clinical features, CT or MRI evidence of basilar meningeal enhancement combined with any degree of hydrocephalus is strongly suggestive of tuberculous meningitis. Serial imaging is useful for following the course of therapy and for managing hydrocephalus. The treatment regimen for presumed drug-susceptible infection is isoniazid and rifampin in all patients, combined with pyrazinamide and ethambutol for the first 2 months. Adjunctive corticosteroids can ameliorate complications and reduce mortality. Surgical shunting should be considered early in the patient with advancing hydrocephalus and symptoms or signs attributable to raised intracranial pressure.

CONCLUDING COMMENTS

INTRODUCTION

Leprosy is one of the oldest diseases known to afflict humans, with descriptions of the disease present in sixth century BCE Indian texts. It is caused by *Mycobacterium leprae* (*M. leprae*), the organism first identified by the Norwegian physician, Gerhard Hansen, in 1873. It is an obligate intracellular acid-fast bacillus, which is detected in tissues by the modified Fite-Faraco stain (Fig. 41-1). In 2008 a new species, *M. lepromatosis*, was identified in Mexico and is now known to cause a syndrome that is clinically equivalent in all respects to classic leprosy. Neither species grows in culture, and with the exception of armadillos, certain primates such as the chimpanzee and macaque, and red squirrels, humans are the primary reservoir and source of infection. The genome of the organism was sequenced in 2001 and has undergone reductive evolution, with only 49.5 percent of its genes being involved in coding.[1] The route of transmission is primarily through nasal droplets. Skin-to-skin contact is not thought to be an important route of infection. Other modes of transmission have been documented and are rare; they include contact with infected soil and direct dermal implantation such as occurs during tattooing. In susceptible individuals, the organisms rapidly gain access to cooler dermal tissues, primarily to cutaneous and subcutaneous nerves, and neural networks, skin appendages, sweat glands, and erector pili muscles. Scollard and colleagues demonstrated that endoneurial vessels in the armadillo serve as the route of entry into the nerve, by demonstrating extensive infection of endothelial cells of endoneurial, epineurial, and perineurial blood vessels.[2]

Leprosy is the leading cause of infectious neuropathy in the developing world. The considerable social stigma that has been associated with this diagnosis through the ages has persisted and can prevent early detection and effective treatment. Not only does *M. leprae* have a predilection for Schwann cells, but the immunologically mediated reactions seen during antimicrobial therapy cause significant damage to the peripheral nervous system and contribute substantially to disability.

EPIDEMIOLOGY

The prevalence of leprosy, defined by the World Health Organization (WHO) as those who are on active mycobacterial treatment, has declined by 96 percent over the last 20 years. This is largely due to the worldwide implementation since 1982 of progressively shorter courses of multidrug therapy (MDT). By 1982, the incidence of leprosy had already declined significantly in countries such as China and Mexico, coinciding with improvement in nutrition and living conditions, and with widespread bacille Calmette-Guérin (BCG) vaccination, which is variably protective against leprosy.

Since the year 2000, however, some 200,000 new cases of leprosy have been detected every year. Although these new cases include individuals who acquired their infection years earlier, there is evidence that transmission of leprosy is continuing unabated, with delays in diagnosis and treatment. At least 9 percent of new cases over the past decade have been in children, and high rates of disability have been seen in new cases in several countries. The latest WHO target for 2020 includes decreasing the number of new patients diagnosed with deformities to less than one per million, and the number of children with disabilities to zero. The decreased incidence numbers do not take into account patients who have significant residual disabilities that require ongoing treatment or rehabilitation after completion of MDT. Furthermore, clinicians taking care of patients with leprosy will continue to treat relapses and reactions for years after completion of MDT.

HOST FACTORS

The clinical spectrum of leprosy correlates with the cell-mediated immunity of the patient. This is the basis for the Ridley-Jopling classification, which includes indeterminate leprosy (I), tuberculoid (TT), borderline tuberculoid (BT), borderline (BB), borderline lepromatous (BL), and lepromatous leprosy (LL) forms (Table 41-1). Patients with tuberculoid leprosy have an excellent cell-mediated immune (Th1) response to *M. leprae*. This manifests as few skin lesions, which histologically have well-organized granulomas (in which bacteria are rarely found) with CD4-predominant T cells. Patients who have less effective cell-mediated immunity have more aggressive clinical and bacteriologic expression of the disease, known as borderline disease. Finally, patients with LL are anergic to *M. leprae*, with predominant T-helper 2 (Th2) response, resulting in uncontrolled growth of bacilli and disseminated skin lesions. The reduced cell-mediated immunity to *M. leprae* in LL is specific for this organism and does not represent a generalized immune deficiency against other pathogens. Interferon-gamma (IFN-γ) production by T cells is another key component of the protective response against mycobacteria, as this

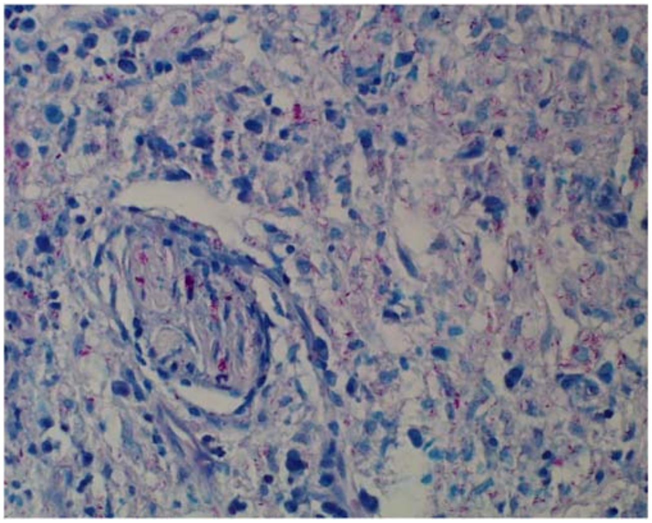

FIGURE 41-1 ■ Fite-Faraco stain reveals acid-fast bacilli in the nerve, seen in skin biopsy at 100× magnification.

cytokine stimulates infected macrophages to kill intracellular *M. leprae*. In TT leprosy there is increased expression of type-1 cytokines IFN-γ and tissue necrosis factor-alpha (TNF-α), whereas in LL disease there is a predominance of the type-2 cytokines such as interleukin-10 (IL-10). Histologic examination of LL lesions reveals sheets of foamy macrophages in the dermis, containing large numbers of bacilli in microcolonies packed in parallel, like cigarettes in a packet, called "globi" with small numbers of $CD8^+$ T cells. In the WHO's simplified clinical classification scheme, TT and BT types are identified as "paucibacillary" (PB, 2 to 5 skin lesions) and types BB–LL as "multibacillary" (MB) (Table 41-1).

Genetic susceptibility to leprosy has been postulated as an important factor in the acquisition and manifestation of leprosy.[3] HLA genes may also influence the type of leprosy that develops; for example, tuberculoid leprosy develops more frequently in individuals with HLA-DR3, whereas LL is more prone to develop in those with HLA-DQ1 or HLA-MT1. Toll-like receptor (TLR) activation plays an important role in innate immunity to pathogens by the upregulation of antigen-presenting molecules and secretion of cytokines. Toll-like receptor 1 and 2 (TLR1 and TLR2) expression in monocytes has been found to correlate with the clinical presentation of leprosy, especially TLR2 microsatellite polymorphisms and TLR2 SNP. Patients with tuberculoid leprosy strongly express these receptors, whereas patients with LL express them weakly.

BACTERIAL FACTORS

M. leprae's affinity to Schwann cells is mediated by Fc receptors, complement receptors, the fibronectin binding protein, and TLR2.[4] Phenolic glycolipid 1 (PGL-1), which is an *M. leprae*-specific antigen, has been shown to bind to laminin of Schwann cells. PGL-1 also binds to complement (C3), and this complement–*M. leprae* complex in turn binds to macrophages and monocytes via complement receptors (CR1, CR3, and CR5), resulting in a three-component receptor–ligand–acceptor molecule for mediating phagocytosis of the organism by human monocytes. *M. leprae* attaches to Schwann cells via PGL-1, binding specifically to the G domain of the α-2 chain of laminin-2 (a protein constituent of the extracellular basal lamina) that, in turn, binds to α-dystroglycan on the plasma membrane of the Schwann cells.

In a classic series of experiments, Rambukkana and colleagues showed that *M. leprae* preferentially invades nonmyelin-producing Schwann cells where the organisms multiply in large numbers, serving as a reservoir for organism growth.[4] After attachment of the organism, myelin-producing Schwann cells undergo significant loss of myelination by an immune-independent mechanism. Dystroglycan complexes link the basal lamina to the cytoskeleton of Schwann cells through membrane-associated linker proteins called dystrophins or utrophins, which are believed to transduce signals from the exterior to the interior of the cells. Myelin-producing Schwann cells contain a third complex, dystrophin-related protein 2 (DRP2), the disruption of which results in demyelination of nerves. It is hypothesized that the loss of myelin production by infected Schwann cells in leprosy may be due to the interaction of PGL-1 with the DRP2–dystroglycan complex. This is followed by dedifferentiation of the Schwann cells to the nonmyelin-producing phenotype that is very vulnerable to invasion by the bacteria.

The survival of *M. leprae* within Schwann cells is greater at 33°C and therefore it has an affinity for nerves at superficial, cooler sites. The Schwann cells are also altered by infection, producing metabolic and functional changes that trigger the immune system in recruiting cytotoxic cells, T lymphocytes, and macrophages. The end result is unrestrained multiplication of the organism within Schwann cells, destruction of myelin, inflammatory changes, and secondary destruction of the nerve architecture. The discovery that demyelination can be induced in vivo by the bacterial cell-wall antigen alone may explain the ongoing neurologic damage that can occur in leprosy after treatment.

Nerve growth factor (NGF) is a neurotrophin produced by multiple cell types, including neurons, Schwann cells, lymphocytes, and mast cells. The role of NGF in leprosy is not fully understood but it is likely that it is involved in the nerve damage and ensuing neuropathic pain.[5] Studies have shown that higher levels of NGF are associated with LL and low levels are associated with tuberculoid forms of the disease. NGF may also play a role in neuropathic pain, and this may be an important pathway in developing future remedies for pain.

The genome of *M. leprae* is the smallest among mycobacteria, with approximately 1,605 genes encoding proteins and 1,300 pseudogenes. Compared to the bacterium causing tuberculosis, *M. leprae* reveals extreme reductive evolution with less than half of the genome containing functional genes. Reductive evolution, gene decay, and genome downsizing may explain the

TABLE 41-2 ■ Clinical and Histologic Aspects of Leprosy

	Tuberculoid Leprosy (TT)	Borderline Leprosy	Lepromatous Leprosy (LL)
Dermatologic features	Single or few anesthetic macules or plaques with well-defined borders.	Many anesthetic lesions with ill-defined to indistinct borders. Satellite lesions around larger lesions.	Multiple, nonanesthetic symmetrically distributed macules or papules progressing to diffuse infiltration of skin.
Clinical features of neuropathy	Asymmetric nerve enlargement usually found proximal to skin lesion.	Multiple nerves may be involved. Involvement is earlier and more rapid than in LL.	No neural lesions until late, when bilateral symmetric distal neuropathies occur.
Histopathology	Destruction of nerve architecture with granulomas in nerves. Bacilli rarely seen.	Findings range from those seen in TT to those in LL with variable presence of bacilli.	Greater preservation of nerve structure with sheets of foamy cells in the perineum resembling onion skins. Numerous bacilli are seen.

unusually long generation time and the inability to culture the organism in vitro. The genome is also highly conserved, with <300 single-nucleotide polymorphisms (SNPs) observed between distantly related strains, and only a few SNPs between closely related strains. Only 16 SNP subtypes have been defined. Genotyping *M. leprae* strains from around the world has enabled detailed phylogenetic and phylogeographic comparisons to be made, new mutations associated with antimicrobial resistance to be detected, and the likely origin of leprosy to be proposed. It has allowed the identification of the new species, *M. lepromatosis*, and the study of the presence of zoonotic leprosy in armadillos in the southern United States.

CLINICAL MANIFESTATIONS

The incubation period ranges from 3 months to 40 years, with an average of 7 years. The onset of the disease is insidious, with the skin and peripheral nervous system primarily being involved.[4] Three cardinal signs remain the mainstay for the diagnosis of leprosy in clinical practice: anesthetic skin lesions, enlarged peripheral nerves, and acid-fast bacilli demonstrated by Fite-Faraco staining in skin smears or skin biopsies (Fig. 41-1). The bacilli favor the cooler areas of the body, such as the chin, malar areas of the face, earlobes, buttocks, knees, and distal extremities. Skin lesions range from the asymptomatic, ill-defined, slightly hypopigmented, macule of indeterminate leprosy to the diffuse infiltration seen in LL that causes thickening of the skin of the face and earlobes (leonine facies). Approximately 5 percent of patients present with nerve involvement without skin lesions; this is called primary neuritic leprosy (PNL), the diagnosis of which may require nerve biopsy and polymerase chain reaction (PCR) assistance. The clinical and histopathologic features of the main types of leprosy are shown in Table 41-2.

Lepromatous Leprosy

The initial manifestations of leprosy are due to direct infection of dermal nerves resulting in anesthetic patches. The nerve damage extends from this early lesion with involvement of a small superficial nerve twig and skin anesthesia to infection of many nerves and involvement of larger skin areas. Patients may subsequently develop more widespread neuropathies with greater sensory and motor deficits, sometimes preceded by pruritus, paresthesias, and rarely pain. In untreated cases, this type of leprosy becomes widespread and symmetric within superficial skin tissues and peripheral nerves. Because the immune response to the bacilli in LL is very indolent, neuropathy usually evolves over many years. As in tuberculoid disease, neuropathies involving larger, superficially located nerve trunks in the face, arms, and legs may also occur.

Initially, there is loss of thermal sense followed by sequential loss of nociceptive and pressure sensations. The affinity of *M. leprae* for Schwann cells and their predilection for cooler parts of the body have made certain segments of nerve trunks vulnerable. The nerves most likely to be involved are the ulnar nerve at the elbow, the median nerve immediately proximal to the carpal tunnel, the radial nerve at the spiral groove, the peroneal nerve at the fibular head, the tibial nerve proximal to the ankle, and the facial nerve at the region of the zygomatic bone. Sensory nerves such as the superficial peroneal, posterior auricular, sural (Figs. 41-2 and 41-3),

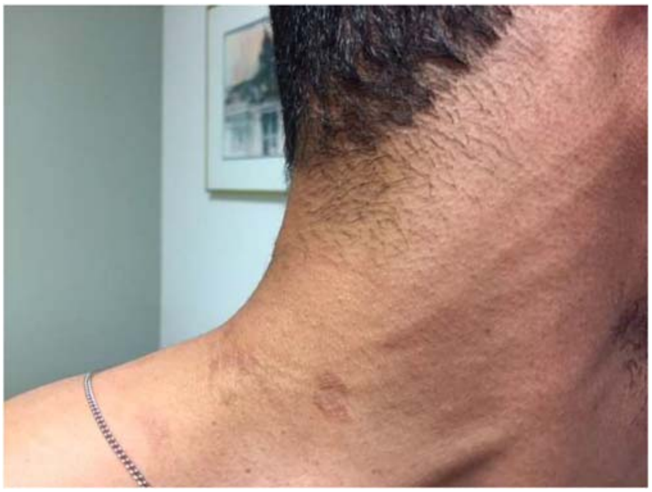

FIGURE 41-2 ■ Patient with tuberculoid leprosy and an enlarged posterior auricular nerve.

and superficial radial nerves and the dorsal branch of ulnar nerve may also be involved. Unperceived trauma secondary to sensory loss further aggravates the nerve damage.

Mycobacteria also invade the anterior chamber of the eye, upper respiratory tract, lymph nodes, periosteum, and testes. Eyebrows and eyelashes may be lost (madarosis), and anesthesia of affected areas is extensive and accompanied by anhidrosis. Sensory loss is largely due to destruction of intracutaneous nerve endings and first appears in cool areas, but with initial sparing of the soles of the feet and palms of the hands. There is also involvement of superficial facial nerve twigs, causing lagophthalmos and paralysis of some segments of the orbicularis oris and frontalis muscles. The sensory loss spares warmer areas including the intergluteal fold, the perineum, and the areas of the scalp covered by hair. Despite the appearance of an extensive sensorimotor neuropathy with clawed toes, foot drop, and clawed hands, preserved muscle stretch reflexes are the rule. Nerves that are grossly enlarged and infiltrated with abundant bacilli may still function well but are more susceptible to recurrent trauma.

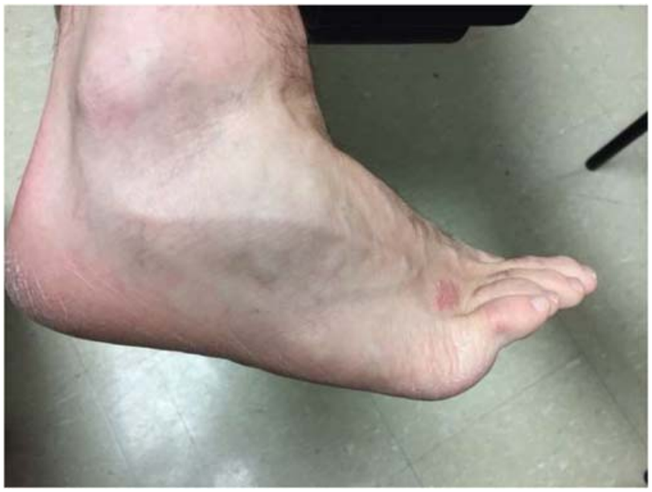

FIGURE 41-3 ■ Enlarged sural nerve with tuberculoid lesion.

Tuberculoid Leprosy

Nerve damage in tuberculoid leprosy is usually asymmetric and is often confined to the nerves underlying or near a skin lesion. Dermal nerves are infiltrated by granulomas composed of epithelioid cells and lymphocytes, with destruction of Schwann cells and secondary axonal damage. Nerves may be palpably enlarged and painful; calcification of nerves sometimes occurs in long-standing disease. The picture is generally one of a clearly visible skin lesion that is usually hypopigmented, with an elevated border (Fig. 41-3) and with a corresponding demarcated patch of sensory loss and absent sweating. Local bacillary invasion of nerves (although acid-fast bacilli are rarely seen on biopsy) and a robust immune response are the two factors that result in focal, limited, and asymmetric disease. Motor, sensory, or mixed nerves near a solitary tuberculoid patch may be affected. Subcutaneous sensory nerves near the tuberculoid patch are often enlarged. The tissue response within nerves may be so intense that there is necrosis and formation of a "cold" abscess. Enlarged nerves may be palpated or demonstrated on ultrasound.

Borderline Leprosy

Neuropathy in borderline leprosy can produce the most deformity as multiple nerves may be involved. Nerve damage occurs more rapidly than in LL and irreversible nerve destruction may occur. Borderline leprosy is immunologically unstable and movement along the spectrum may occur: either an upgrading response to the tuberculoid or a downgrading to lepromatous forms. When the clinical illness is toward the tuberculoid spectrum (BT), there may be a single lesion with asymmetric nerve involvement, but as the disease moves towards the lepromatous pole (BL) multiple symmetric skin and nerve lesions may be seen (Fig. 41-4).

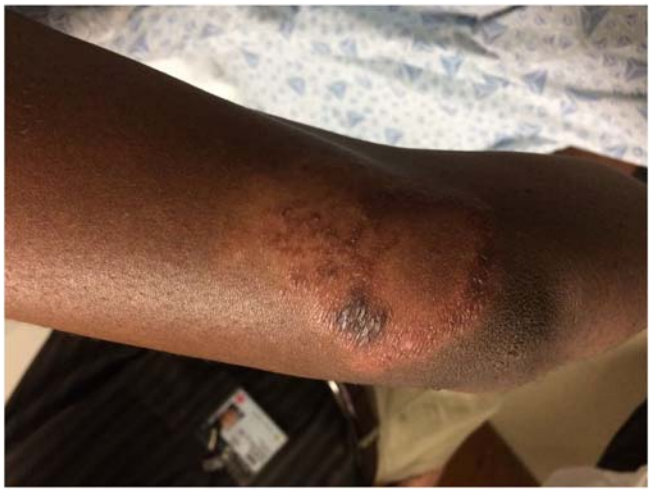

FIGURE 41-4 ■ Borderline lepromatous lesion.

Primary Neuritic Leprosy

This form is characterized by the presence of a neurologic deficit and nerve thickening (with or without tenderness) in the absence of clinical involvement of the skin or mucosa. This presentation is seen in 5 to 20 percent of patients at leprosy treatment centers in India. The clinical diagnosis of PNL may be difficult, as these patients do not have characteristic anesthetic skin lesions. However, blind biopsies of the skin near enlarged nerves often show the histologic changes of leprosy. Most of these patients present with a clinical picture consistent with mononeuritis multiplex, although in one-third a single nerve is affected. Nerve trunks may be significantly thickened and nodular. Ulnar and common peroneal nerves are commonly involved, although any nerve may be affected. Electrophysiologic studies reveal sensory and motor dysfunction of affected nerves, usually with demyelinating features early in the disease, and axonal injury in later stages. Nasal mucosal smears may show abnormalities including inflammation, epitheloid granulomas, and bacilli in half of the patients. Skin and nerve biopsies may show changes of leprosy (ranging from BT to LL), with bacilli in about 50 percent of patients. If nasal and skin pathology are nondiagnostic, nerve biopsies should be undertaken in patients suspected of having PNL. A positive PCR increases the sensitivity of detection of *M. leprae* in cases of probable PNL when Fite stain is negative.

Autonomic Neuropathy in Leprosy

Autonomic dysfunction occurs early in leprosy, especially in multibacillary disease, but it is often overlooked. Involvement of the small, unmyelinated, autonomic nerve fibers results in hypohidrosis and alopecia of the anesthetic, hypopigmented skin patches. Reduced sweating can often lead to dry, cracked skin that is prone to injury and infection. With more extensive skin involvement, there may be widespread impairment of sweating, resulting in heat intolerance. Impaired capillary blood flow due to involvement of autonomic fibers in blood vessels can result in stasis and impaired wound healing. Systemic symptoms from autonomic dysfunction may also be seen, including erectile dysfunction, heat intolerance, cardiac arrhythmias, and ankle edema. Testing will show vasomotor reflex impairment as measured by Doppler velocimetry, and absent sympathetic skin responses. Involvement of the parasympathetic system can be demonstrated by reduced heart rate variability on deep breathing and by the Valsalva maneuver. Autonomic dysfunction may impair the quality of life even after treatment, as patients may have persistent symptoms such as impaired sweating, heat intolerance, and severe xerosis.

Pain in Leprosy

Neuropathic pain is frequent in leprosy and may occur at all stages of the disease. Pain persists even after the patient has been fully treated. Studies have shown that the majority of patients have pain that is moderate to severe in intensity; this has a significant negative effect on their quality of life. Patients should be asked about their pain and treated for this with analgesic medications.

DIAGNOSTIC STUDIES

Electrodiagnostic Studies

Electrodiagnostic studies have contributed significantly to understanding the pathogenesis of the disease.[4] They also help in establishing a baseline against which response to treatment can be measured. Leprosy initially causes segmental demyelination of peripheral nerves with secondary axon loss. Early electrodiagnostic findings in the disease therefore include prolongation of distal latencies and segmental slowing of conduction velocities, particularly when measured across vulnerable sections of the nerves. If there is significant weakness on clinical examination, there may be evidence of conduction block or changes consistent with axonal loss, that is, a reduction in amplitude of compound muscle action potentials. Ulnar motor conduction studies reveal significant slowing of conduction across the elbow segment, with relative sparing of the forearm, wrist, and humeral segments. This selective involvement of the elbow segment reflects the predilection of the pathogen for cooler regions of the body. Median motor studies reveal slowing in the distal third of the forearm, usually proximal to the carpal tunnel. In the lower extremities, peroneal studies are usually abnormal, with slowing in conduction velocity in the segment between the popliteal fossa and the fibular head, and distally below the ankle, with prolongation of distal latency. Facial motor studies may also be abnormal, revealing prolonged latencies or reduced or absent responses of the orbicularis oculi or frontalis muscles. Even the phrenic nerve may be affected.

Needle electromyography may reveal reduced recruitment early in the disease, when there is weakness due to focal demyelination. Later, increased insertional activity and polyphasic, large-amplitude, long-duration motor unit potentials with reduced recruitment may be seen due to axonal loss and reinnervation. Late responses such as the F response and H reflex are often abnormal even without evidence of overt disease involving the nerves. Electrodiagnostic studies are sometimes used to monitor response to therapy or to monitor drug toxicity, particularly of thalidomide, which is known to be associated with neuropathy.

Ultrasonography

High-resolution ultrasonography is increasingly useful in leprosy.[6] This is a relatively inexpensive diagnostic method that is readily available, causes no discomfort, and can be used to obtain information that is static (size of the nerve, echo texture, nerve abscess) and dynamic (Doppler studies of neural blood supply). Studies have shown close correlation between abnormalities on ultrasound and nerve conduction studies in leprosy. While electrodiagnostic abnormalities may show evidence of nerve dysfunction, ultrasonography shows evidence of nerve enlargement, abnormal echo texture, and often increased epineural and endoneural blood flow. Additionally it sometimes pinpoints the site of maximum inflammation, which may help to determine the site of a nerve biopsy. In PNL, it may show nerve involvement that is more extensive than occurs in other mononeuropathies (such as entrapment neuropathies), nerve abscesses that are rare complications of PNL, and evidence of asymptomatic involvement of other nerves. A unique sonographic pattern of nerve enlargement is noted in patients with ulnar neuropathy; the enlargement starts at the ulnar sulcus and is maximal 4 cm above the medial epicondyle. Asymmetric increase of the cross-sectional area of the nerve at the same point between right and left sides is an important feature of leprosy. Finally, serial measurement of nerve thickness and echo texture as well as vascularity measurements by Doppler may help monitor response to treatment, and changes in these measurements may be early harbingers of relapse or the development of leprosy reactions.

Nerve Biopsy and Pathology

Nerve biopsies are rarely necessary in the right clinical and epidemiologic setting as the diagnosis is usually made clinically and confirmed by skin smears or skin biopsies.[2] However, nerve biopsies are sometimes necessary to confirm a diagnosis of leprosy, especially in PNL, or to exclude other causes of neuropathy. The nerve of choice is a sensory cutaneous nerve that is enlarged, such as the greater auricular (Fig. 41-2), superficial radial, dorsal ulnar, or sural nerve (Fig. 41-3). The histologic findings in nerve biopsies depend on the nature and severity of the leprosy as well as on the presence or absence of reactions.

In the tuberculoid (TT) and borderline (BT) subtypes, light microscopy of nerve biopsies may reveal a well-localized, intraneural granulomatous lesion involving a few nerve fascicles. Central caseous necrosis may be present, surrounded by inflammatory cells consisting of lymphocytes, epitheloid calls, and Langhans-type giant cells sometimes surrounded by regenerating myelin (Figs. 41-5 and 41-6). Bacilli are not seen commonly in TT or BT types and when present are usually

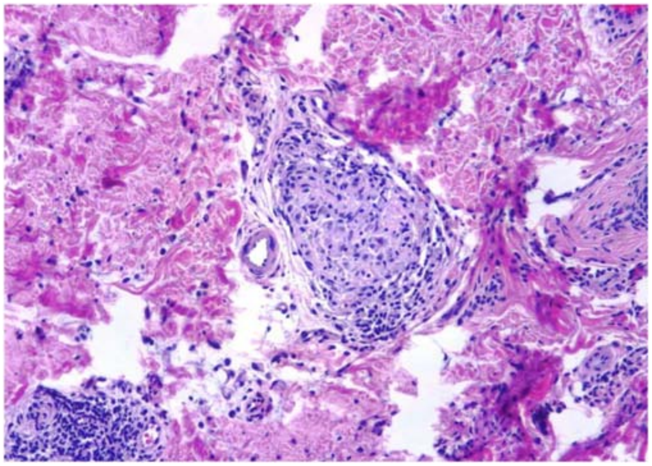

FIGURE 41-5 ■ Leprosy granuloma surrounded by lymphocytes.

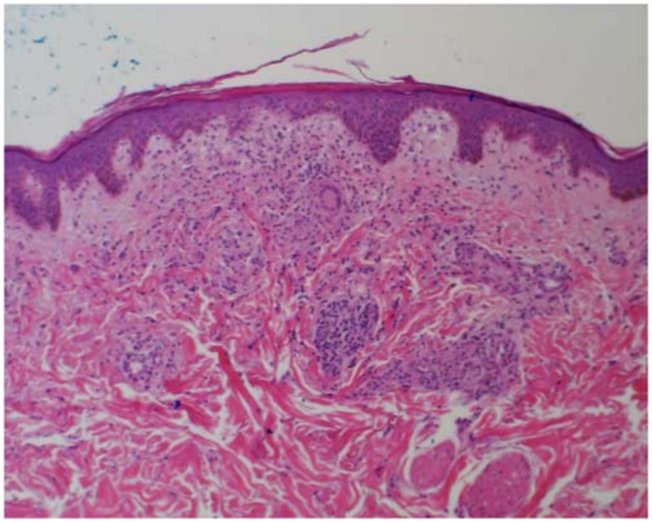

FIGURE 41-6 ■ Skin biopsy showing skin surface and non-caseating granulomas (with one multinucleate giant cell).

found in Schwann cells. Granulomas extend from the perineurium to the endoneurium and sometimes also involve the epineurium. Axon stains reveal significant axonal loss that is sometimes confined to certain fascicles of the nerves. In late stages, significant fibrosis and hyalinization of the endoneurium may occur and the nerve architecture may be destroyed completely.

In the BL and LL subtypes, there is usually greater histologic preservation of nerve structure than in the tuberculoid type; axon stains may reveal some axonal loss. Bacilli are numerous in Schwann cells and foamy macrophages (globi), and, to a lesser extent, in the endothelial cells of endoneurial and perineurial vessels. Plasma cells are characteristic of the lepromatous subtypes; histiocytes are seen in the early stages of infection while the presence of foamy macrophages indicates chronic infection. Epithelioid cells and nerve abscesses are usually not seen in the BL and LL subtypes (except when there is a change in the grade to a BT/TT subtype). The perineurium may be split into layers by edema or sheets of foamy cells, giving the appearance of an onion-skin. However, as the disease progresses, more significant destruction of the nerve architecture and matrix may occur; fibrosis may supervene with nerve destruction. Bacilli may be found in nerves for many years, even after treatment. Nerve biopsies may show active disease with intact organisms in some patients who are thought to have inactive disease clinically.

In borderline leprosy, nerve deformity may be significant. Multiple nerves may be involved as in lepromatous forms and there may be extensive nerve destruction as in tuberculoid leprosy.

PCR is very useful in diagnosing PNL when nerve biopsies have nonspecific changes and bacilli are not seen. PCR was positive in about 62 percent of all patients with PNL in an Indian study in which nerve biopsies were obtained in patients with mononeuritis multiplex. The positive and negative predictive values of PCR were 54.5 and 92.3 percent, respectively, in this population.[7]

MYCOBACTERIAL TREATMENT

In 1982, MDT was first recommended by the WHO to replace dapsone monotherapy to prevent the emergence of drug resistance.[5] The key component of these regimens was the bactericidal drug rifampicin. Since 1982 the recommended duration of treatment has decreased. The 2018 WHO guidelines (Table 41-3) recommend a three-drug regimen of rifampicin, dapsone, and clofazimine for all leprosy patients, to be given for 6 months for PB leprosy and 12 months for MB leprosy.

Patients with any nerve involvement (including primary neural leprosy) are treated as MB disease. This represents a change from the prior treatment for

TABLE 41-3 ■ **WHO Recommended Treatment Regimens**

			Duration	
Age Group	**Drug**	**Dosage and Frequency**	**MB (months)**	**PB (months)**
Adult	Rifampicin	600 mg once a month	12	6
	Clofazimine	300 mg once a month and 50 mg daily		
	Dapsone	100 mg daily		
Children (10–14 years)	Rifampicin	450 mg once a month	12	6
	Clofazimine	150 mg once a month, 50 mg on alternate days		
	Dapsone	50 mg daily		
Children <10 years or <40 kg	Rifampicin	10 mg/kg once a month	12	6
	Clofazimine	100 mg once a month, 50 mg twice weekly		
	Dapsone	2 mg/kg daily		

Note: The treatment for children with body weight below 40 kg requires single formulation medications since no MDT combination blister packs are available. For children between 20 and 40 kg, it would be possible to follow the instructions of the Operational Manual, Global Leprosy Strategy 2016–2020 on how to partly use (MB-Child) blister packs for treatment.
MB, multibacillary disease; PB, paucibacillary disease.

PB leprosy (which was rifampicin and dapsone for 6 months) due to evidence indicating better clinical outcomes with a three-drug, 6-month regimen. Published studies for patients treated with the prior two-drug PB regimen for 6 months showed that 2 to 44 percent of patients had clinically active skin lesions at the end of treatment. Nerve impairment occurred during treatment in 2.5 percent of patients, and visible disabilities increased from 4 percent at enrollment to 7 percent at 8 to 10 years of follow-up. Relapse rates ranged from 0 to 2.5 percent. For patients treated with the MB regimen for 24 months, one study in Thailand found that 29 percent of lesions were still active after 3 years and that visible disabilities increased from 5 percent at enrollment to 13 percent at 8 to 10 years of follow-up. Relapse rates were low, from 0.15 to 0.2 percent, but several reports have indicated much higher rates in subgroups of patients with high bacteriologic indexes (BI > 4 +), usually occurring 5 to 7 years after treatment is stopped. Relapsed patients responded to retreatment with the same drug combination, indicating that the relapse was not usually secondary to development of resistant organisms. Viable bacteria have also been demonstrated in patients who relapsed up to 13 years after MDT for MB disease.

A retrospective survey of 40 documented patients who relapsed showed that leprosy relapse after MDT usually occurred late and all had new skin lesions. Most relapsed with a positive skin smear after previously reaching negative BI status. The histologic features of relapsed BB-LL patients included granulomas containing macrophages or epithelioid cells, with sparse lymphocytes and acid-fast bacilli. PB patients require 2 years, and MB patients at least 5 to 10 years of monitoring after treatment. It may be difficult, however, to differentiate clinically between relapse, reactions, and recurrent infection. Immunologically mediated reactions occurring after completion of MDT are more frequent usually within the year after treatment completion. In addition, there may be persistent infection in nerves and eyes. DNA-based PCR-positivity and the presence of acid-fast bacilli by microscopic examination persist in some cases for years after treatment but do not necessarily reflect mycobacterial viability.

A promising new assay of *M. leprae* viability has been developed using 16S rRNA levels on skin biopsy specimens and may assist in differentiating between relapse and reactions after completion of MDT. Whole-genome sequencing techniques have also revealed that patients can be reinfected and did not relapse in recurrent leprosy cases. Many clinicians in resource-rich countries such as the United States have continued to use MDT for 24 months for MB disease until definitive data about relapses rates are available.

Side Effects of Multidrug Treatment

Although treatment with MDT is very effective, with over 95 percent cure rates, medications may occasionally cause serious adverse effects. The most common adverse effects reported are for dapsone, and include hemolytic anemia, methemoglobinemia, toxic hepatitis, photosensitivity, psychosis, and sulfone syndrome, currently described as DRESS syndrome (drug reaction with eosinophilia and systemic symptoms). Peripheral neuropathies have been observed among patients using dapsone in higher doses for dermatologic disorders. They develop painless distal motor axonal degeneration, most commonly involving the ulnar and median nerves. Usually only motor nerve involvement is seen, although sensory loss may also occur; this is usually reversible when dapsone is discontinued.

Clofazimine has rare serious adverse effects; the most common ones involve cutaneous hyperpigmentation (the most common cause of discontinuation of this drug), xerosis, ichthyosis, nausea, vomiting, diarrhea, and abdominal pain. In doses higher than 300 mg/day, clofazimine can be deposited in the intestinal wall, causing acute gastrointestinal obstruction. Rifampicin has been associated with toxic hepatitis, thrombocytopenia, flu-like syndrome, respiratory failure, hemolytic anemia, shock, and renal insufficiency.

Drug Resistance and Treatment of Relapses

The worldwide prevalence of drug resistance to *M. leprae* has not been established but reports from the WHO indicate a low level of resistance in some relapsed cases. Dapsone-resistant, rifampin-resistant, and multidrug-resistant (MDR) leprosy have been reported in different parts of the world, usually in association with relapse after insufficient therapy. Primary rifampicin resistance has also been reported, but clofazimine-resistant strains have not been demonstrated. PCR-based DNA sequence analysis of the *rpoB* gene of *M. leprae*, which is associated with rifampin resistance (Table 41-4), presents a cost-effective way for the study of drug resistance.

Dapsone resistance does not require a change of therapeutic regimen. If rifampicin resistance is proven, a WHO Expert Committee has recommended the regimen to follow (Table 41-5). Rifampicin resistance

TABLE 41-4 ■ Mutations in *Mycobacaterim leprae* Associated With Drug Resistance

Drug	Resistance Gene Mutation	Percent Resistant in Relapsed Cases
Dapsone	*folp* gene	5.9
Rifampicin	*rpoB* gene	4.1
Ofloxacin	*gyrA* gene	1.2

remains rare except in Brazil; therefore standard WHO-recommended MDT regimens remain the treatment of choice for relapsed leprosy everywhere. But primary multidrug resistance to rifampin and dapsone can also occur, as was described in a patient in the United States who originated in American Samoa.

Quinolone resistance in *M. leprae* is an increasing concern, especially in India; it may occur if ofloxacin is used for other acute infections. High dropout rates and a search for regimens with fewer side effects have led to trials with monthly rifampicin, ofloxacin, and minocycline (ROM). In a 2001 study, PB patients treated with either ROM or MDT for 6 months had similar cure rates of 97 percent. Both groups had similar relapse rates after follow-up for 5 to 8 years, but the rate of adverse effects was much lower in the patients receiving ROM.

Newer agents such as rifapentine (RPT) and moxifloxacin (MXFX), which are significantly more bactericidal than rifampicin, may represent other therapeutic alternatives. The bactericidal activity of a single dose of MXFX is identical to that of a single dose of rifampicin; both killed 92.1 percent of the viable *M. leprae*. The most promising new drug is bedaquiline, which is comparable to rifampicin in potency but has an entirely new mechanism of action and a long half-life. An international network of sentinel sites for drug-resistant leprosy was established in 2007 to share data and technical expertise, including trends in development of new drugs of relevance to leprosy.

TABLE 41-5 ■ Recommended Regimens for Drug-Resistant Leprosy

	Treatment	
Resistance Type	**First 6 Months (Daily)**	**Next 18 Months (Daily)**
Rifampicin resistance	Ofloxacin 400 mg* + minocycline 100 mg + clofazimine 50 mg	Ofloxacin 400 mg* OR minocycline 100 mg + clofazimine 50 mg
	Ofloxacin 400 mg* + clarithromycin 500 mg + clofazimine 50 mg	Ofloxacin 400 mg* + clofazimine 50 mg
Rifampicin and ofloxacin resistance	Clarithromycin 500 mg + minocycline 100 mg + clofazimine 50 mg	Clarithromycin 500 mg OR minocycline 100 mg + clofazimine 50 mg

*Ofloxacin 400 mg can be replaced by levofloxacin 500 mg OR moxifloxacin 400 mg.

LEPROSY REACTIONS

Leprosy reactions are immunologically mediated episodes of acute or subacute inflammation that may occur in any type of leprosy and result in increasing nerve damage and worsening disability. The two main types of reactions are type 1 and type 2 reactions (also known as erythema nodosum leprosum or ENL).[8] There is currently no cheap, accurate diagnostic test to detect reliably leprosy reactions or to predict which patients will develop these immunologic exacerbations, but various research strategies aimed at identifying biomarkers to diagnose these reactions are being pursued.

Type 1 Lepra Reactions (Reversal Reactions)

Type 1 reaction is seen almost exclusively in the borderline forms of leprosy (BT, BB, or BL) and is a manifestation of an improvement in the patient's immune response to the infection, commonly as a result of treatment. The incidence of reversal reactions is highest 6 to 12 months after initiating treatment but reactions may occur up to 5 years after diagnosis. They may be the presenting feature, especially during pregnancy or after the initiation of antiretroviral therapy (ART) in patients infected with human immunodeficiency virus. Clinical features of a type 1 reaction usually include an acute worsening of the swelling and erythema of preexisting skin lesions and development of acute, painful nerve palsies commonly involving the ulnar or peroneal nerve. Histologic features of a type 1 reaction are those of a delayed hypersensitivity response with $CD4^+$ lymphocytes, macrophages, and expression of IL-2 in the lesions. Intraneural caseous necrosis in tuberculoid disease and microabscesses in lepromatous disease can occur during reversal reactions. It is postulated that the lysis of mycobacteria by antibacterial treatment causes a release of antigen that mediates the immunologic response. *M. leprae* antigens and a diffuse extracellular infiltrate have been found in macrophages and

Schwann cells during reversal reactions, suggesting that these antigens are initiating factors in the reaction. Other studies indicate a strong Th1-like cytokine profile within reactional lesions. TNF-α, which has been shown to directly cause the destruction of myelin and oligodendrocytes in vitro, is also overproduced during reactions.

Corticosteroids are the treatment of choice for severe type 1 reactions, especially those involving ulcerations and neuritis.[9] Severe neuritis is treated promptly with prednisone at doses of 1 mg/kg daily, with increasing doses if there is no response within 24 to 48 hours. Corticosteroid therapy should be tapered slowly, especially in severe cases, to reduce the risk of relapse of the neuritis. Studies have indicated that moderate doses of corticosteroids given for 20 weeks are better than high-dose corticosteroids for 12 weeks in reducing the risk of relapse of neuritis. The approximately 60 percent success rate of corticosteroids in salvaging nerve function in reversal reactions is related to the promptness of initiation of therapy, as irreversible damage can ensue within hours to days. Corticosteroids have an immediate anti-inflammatory effect in reducing intraneural edema. More sustained benefit is probably due to its genomic effect, which affects cytokine production at various levels. The principal mechanism of action is thought to be inhibition of transcription of TNF-α—induced cytokine mRNA. A number of cytokine genes have the same TNF-α binding sites in their promoter regions, and corticosteroids downregulate the production of several proinflammatory cytokines, including TNF, IL-2, and IFN-γ.

Occasional patients with severe, protracted reactions require extended corticosteroid treatment for several additional months due to severe nerve pain. However, a Cochrane review of clinical trials has demonstrated that prolonged corticosteroid regimens of many months do not provide long-term functional neurologic benefits for most patients.[9] A more recent multinational randomized controlled trial comparing 45 to 60 mg methylprednisolone daily for 20 weeks versus 32 weeks for early ($<$6 months) nerve function involvement showed 78 percent improvement in both treatment arms. However, around 15 percent of the patients (comprising significantly more MB patients) in both groups required further individualized treatment because of reactions or deteriorating nerve function involvement, both of which occurred primarily in the first few weeks after corticosteroid treatment had ended. It appears that corticosteroids should be started as early as possible with acute neuritis but moderate doses should be continued for 20 weeks. Patients with higher BI should be monitored closely for recurrent reactions or deteriorating nerve function involvement for a few weeks after stopping, as they may need resumption of corticosteroid therapy.

Patients with pre-existing neuropathy have an increased risk of nerve function involvement and reversal reactions with treatment and this is not prevented by prednisone in the first 4 months of MB treatment. In contrast, a strong protective effect on neuritis was observed in those without significant loss of nerve function during the 4 months of prophylactic corticosteroid treatment and MDT, but this was not sustained at 1 year. Multiple or large lesions on the face overlying the distribution of the facial nerve may therefore benefit from low-dose prophylactic corticosteroids at the onset of MDT to prevent facial palsy, lagophthalmos, and ensuing exposure keratitis. Both cyclosporine and azathioprine have also been tried with varying success for their steroid-sparing effect. Corticosteroids have to be used in the first 5 days in patients treated with cyclosporine, until this drug reaches a steady state. Acute neuritis in reversal reactions that have not responded to high-dose corticosteroids for 6 weeks may be considered for surgical decompression (neurolysis) to relieve the pressure and preserve function, although there have been no large-scale controlled studies of this modality of treatment. Thalidomide has not been successful in the treatment of reversal reactions, perhaps because T-cell activation appears to be a significant component of reversal reactions and thalidomide stimulates T-cell activation.

Type 2 Reactions

ENL reactions occur almost exclusively in patients at the lepromatous end of the spectrum (BL and LL) and continue to be the most common cause of hospitalization. They usually occur within 2 years of the start of therapy, but rarely may be the presenting symptom. Risk factors for ENL reactions include antibacterial therapy, female sex, pregnancy, and high bacterial loads. Clinically, presentation is with crops of new painful erythematous papules that may resolve spontaneously. Other features include severe fatigue, fever, acute neuropathy, lymphadenopathy, uveitis, orchitis, mastitis, periostitis, and glomerulonephritis. Laboratory tests may reveal anemia, leukocytosis, and abnormal liver function tests. In contrast to type 1 reactions, patients tend to develop chronic recurring bouts of ENL reactions. In the MDT era, ENL occurs in 16 to 47 percent of LL patients and 2 to 11 percent of BL patients. ENL reactions are thought to be associated with the release of *M. leprae* antigens from dead and dying bacilli, inducing humoral immune mechanisms and immune complex formation, accompanied by high levels of circulating concentrations of TNF. These complexes result from an antigen–antibody reaction involving activation of the complement system and may resemble the Arthus phenomenon, resulting in systemic vasculitis and panniculitis.

The management of ENL is aimed at controlling the acute inflammation and neuritis, providing pain relief, saving vision, and preventing further attacks. Mild symptoms in the absence of neural and ophthalmologic symptoms may be treated with comfort measures and nonsteroidal anti-inflammatory drugs. Clofazimine at high doses up to 300 mg per day, with slow tapering over a year, can be effective for more severe cases of ENL without neural involvement. The drug of choice for treating the severe systemic symptoms associated with ENL is thalidomide. This drug accelerates the degradation of mRNA encoding TNF-α, resulting in its decreased production by monocytes and macrophages, without significantly reducing the production of other monocytic cytokines. Fever, fatigue, and skin lesions respond within a few days to thalidomide but neuritis accompanying ENL may take up to a week to respond.

Corticosteroids, with their more rapid effect in reducing intraneural edema, are often added to treat severe neuritis and prevent further nerve damage. High-dose pulse dexamethasone and azathioprine have been utilized in cases of recurrent ENL unresponsive to standard prednisone therapy. Successful treatment with methotrexate, in corticosteroid- and thalidomide-resistant ENL has also been reported. Methotrexate exerts anti-inflammatory and immune-suppressive effects.[10] It has direct inhibitory effects not only on the proliferation of cells involved in inflammatory reactions but also on proinflammatory cytokines. The immunomodulatory activity of thalidomide mainly lies in its capability to alter the secretion and activities of various cytokines including iL-6, IL-10, IL-1, and TNF-α; these cytokines are also targeted by methotrexate. The newer TNF-α blockers such as infliximab have been reported to precipitate the development of clinical symptoms in latent leprosy in some patients with rheumatoid arthritis. Chronic steroid-dependent ENL has also been found to be due to rifampin resistance and responded to an alternate regimen of minocycline, ofloxacin, and clofazimine.[11]

In addition to severe teratogenicity, which limits its use in women of child-bearing age, thalidomide may cause an axonal, length-dependent, sensorimotor neuropathy which presents with painful paresthesias or numbness. The incidence rate is maximal during the first year of treatment and is dose dependent.

In a study in which patients underwent neurologic examination and nerve conduction studies during treatment, thalidomide-induced neuropathy was seen in 25.2 percent of patients. The risk of neuropathy was highest when the daily dose exceeded 75 mg. No neuropathy was observed when daily doses of less than 25 mg were used. A recent review of the literature from 1965 to 2017 found thalidomide toxicity in less than 5 percent of patients.[12] Sural nerve biopsies have shown evidence of Wallerian degeneration and loss of myelinated fibers in thalidomide toxicity. Monitoring sensory nerve action potential amplitudes by nerve conduction studies may be useful for the early detection of thalidomide neuropathy, a decline in amplitude of 40 percent compared to the baseline usually being associated with clinical symptoms of neuropathy. Monitoring F waves may also be useful to detect early thalidomide neuropathy; F-wave chronodispersion may occur before changes in sensory amplitudes. Other adverse effects associated with thalidomide include deep venous thrombosis in 14 percent of patients.

LEPROSY AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The interaction of leprosy and HIV coinfection is an evolving picture and has been significantly impacted by more widespread ART.[13] HIV affects cell-mediated immunity, and it was initially thought that the decrease in CD4 cells may result in an increase in disseminated leprosy. However, to date there are no clinical data to suggest that leprosy may worsen HIV infection or that HIV infection increases the risk of leprosy. All types of leprosy have been reported in HIV-infected patients, suggesting that HIV infection does not increase the rate of lepromatous disease. Coinfected patients treated with standard-length WHO-MDT regimens have responded adequately but in one study a 3.4 percent relapse rate occurred in coinfected patients compared to 1.0 percent in HIV-negative patients. This suggests that patients with coinfection should be monitored more closely for relapse after treatment. There are some data in coinfected patients that suggest that they may be at a higher risk of developing acute and recurrent reactions, especially when they are on ART.

In 1995, before widespread ART use, patients with AIDS and BT leprosy had lesions with well-formed granulomas and normal CD4 cell numbers in their lesions even though they had low circulating CD4 counts. Coinfected patients with LL had lesions with loose infiltrates comprising heavily parasitized macrophages and a small number of almost exclusively CD8 lymphocytes, which was similar to HIV-negative patients.

When a coinfected cohort treated with ART was followed prospectively, BT leprosy was the most common clinical form studied. Coinfected patients who present with BL leprosy and AIDS may shift to BT disease after implementation of ART and MDT, which suggests that, in some patients, granuloma formation might be altered by an ART-induced increase in the $CD4^+$ T-cell count. Histopathologic follow-up of these patients has revealed that on initiation of ART and MDT foamy histiocytes containing numerous acid-fast bacilli are replaced by granulomas consisting of lymphocytes and epithelioid cells with scant or no acid-fast bacilli. These findings demonstrate the true impact of HIV infection, ART, and MDT on leprosy granuloma formation. Immunostaining techniques revealed the absence of $CD4^+$ T cells in all granuloma specimens from the patients with BT disease, but $CD3^+$ T cells, macrophages, and natural killer cells were observed within the granulomas. These observations indicate that cell types other than $CD4^+$ and $CD8^+$ T lymphocytes may be playing a role in granuloma formation under the conditions observed for individuals with leprosy and HIV infection receiving ART. Further studies aiming to investigate this possibility are currently ongoing.

Another consequence of ART-induced $CD4^+$ T-cell count improvement is the development of immune reconstitution inflammatory syndrome (IRIS). IRIS is a paradoxical deterioration in clinical status after starting ART, a deterioration that is attributable to the recovery or reactivation of the immune response to a latent or subclinical process. This syndrome was first associated with leprosy in 2003 and usually develops within 6 to 10 months after initiating ART. Risk factors include advanced HIV disease with CD4 counts below 50 before ART. BT leprosy was the commonest form detected and type 1 (reversal) reaction was always present. Ulceration, a highly unusual feature in leprosy lesions, was commonly observed.

The neuropathies associated with HIV have been well described. A few small studies in the 1990s did not find increased nerve damage in coinfected patients. Subsequently it was found that leprosy patients coinfected with HIV (87% on ART) when compared to patients with leprosy alone had a greater rate of overall nerve function involvement, especially in MB disease. The most frequent onset of leprosy in relation to ART was within 12 months of the introduction of therapy. Nerve function involvement improved over time using MDT and ART. Neuritis was treated with prednisone at doses recommended by the WHO, and coinfected patients had the highest rate of clinical improvement in the first 60 days.

PREVENTION

Prevention of leprosy with vaccines directed against *M. leprae* or other mycobacterial antigens has thus far not proved to be too effective in large-scale clinical trials. BCG appears to be protective against leprosy in some populations but not in others. Repeated doses of BCG vaccine may be more effective, but this approach has limited clinical application, because of the cost of implementation and the potential for adverse reactions in immunosuppressed patients. Mapping of the *M. leprae* genome and the discovery of the armadillo as a good animal model for leprosy pathogenesis have led to better understanding of immunology with potential for identification of candidate antigens for vaccine development.

LepVax, a defined subunit vaccine that provides effective pre-exposure and postexposure prophylaxis of *M. leprae* infection, is in early clinical trials.[14] It appears safe and, unlike BCG, alleviates and delays the neurologic disruptions caused by *M. leprae* infection. MDT does not eliminate transmission in households, and early detection of subclinical leprosy or the carrier state is difficult. The identification by PCR (or other methods) of high-risk household contacts who may benefit from vaccination or chemoprophylaxis deserves further study. The 2018 WHO guidelines recommend the use of single-dose rifampicin as preventive treatment for adult and child (2 years of age and older) who are close contacts of leprosy patients, after excluding leprosy and TB disease.[15] This is based on the COLEP2 randomized controlled trial that found single-dose rifampicin in leprosy contacts led to a

57 percent reduction in the risk of leprosy after 2 years and 30 percent after 5 to 6 years.

CONCLUDING COMMENTS

The discovery that demyelination can be induced by dead *M. leprae* or its bacterial cell wall alone, both in vitro and in vivo, and the use of armadillos as animal models to study the pathogenesis of nerve damage have provided new insights into the underlying causes for continuing neurologic injuries in patients who have been bacteriologically cured of leprosy after MDT. Leprosy will continue to occur in endemic and nonendemic countries where physicians are becoming less familiar with the clinical presentation of a disease for which early diagnosis and MDT treatment are crucial to prevent new and ongoing nerve damage. Successful application of modern molecular methods using current knowledge of the bacterial genome and host susceptibility factors, should lead to better identification of target *M. leprae* antigens for improved diagnostic testing, vaccine development, identification of new antimicrobial agents, and detection of relapses after therapy. An improved understanding of nerve damage and reactions should lead to better preventive and therapeutic modalities.

  Approach to Patients With Postinfectious Neurologic Injury

Invasion of the central nervous system (CNS) by viruses typically produces a meningoencephalitis in which either meningitis or encephalitis may predominate. Viruses may also infect cranial or spinal blood vessels leading to ischemic injury. Systemic or CNS infection by viruses or other infectious agents may elicit a host immune response that is cross-reactive with components of neural tissue, resulting in autoimmune encephalitis, demyelinating or hemorrhagic encephalomyelitis, transverse myelitis, injury to peripheral nerves, or optic neuritis. A few viruses, such as rubella, cytomegalovirus, or Zika virus may, in the course of maternal infection, cross the placenta to produce systemic fetal infection and CNS injury.

PATHOGENESIS OF VIRAL CENTRAL NERVOUS SYSTEM INFECTIONS

Before a virus can infect the CNS, it must first breach the cutaneous or mucosal barriers that protect the patient from the outside environment and then penetrate the blood—brain barrier to gain access to susceptible cells in the meninges, brain, or spinal cord. At each step, the virus must infect specific cell populations and produce progeny virus in order to continue the infection. Viruses can enter the body through ingestion, as in enterovirus infections; by the respiratory route, as in influenza or chicken pox; by inoculation across skin, as in arthropod-borne encephalitides or rabies; or across mucosal membranes, as in human immunodeficiency virus (HIV) infection. Virtually all viruses capable of infecting the CNS do so via hematogenous spread; exceptions are rabies virus and herpes simplex viruses types 1 and 2 (HSV-1, HSV-2), all of which travel from the periphery to the CNS within peripheral nerves. Varicella zoster virus (VZV) is transported within nerves during reactivated infection.

Infection at the cellular level may occur through several mechanisms. Herpesviruses are taken into the cell following fusion of the viral envelope to the host cell. The human polyomavirus, JC virus (JCV), the etiologic agent of progressive multifocal leukoencephalopathy (PML), binds to cellular serotonin and other receptors. Alphaviruses, such as St. Louis encephalitis virus, recognize

cell surface laminin and heparan molecules. Viral replication within the host cell may result in various outcomes including lytic infection with cell death; productive infection with budding of viruses across the cell membrane without death of the host cell; or persistent infection, with the virus remaining latent over time. Classic examples of viruses causing latent infection include HSV-1, HSV-2, and VZV, all of which persist in sensory ganglia and may reactivate to cause several syndromes including cutaneous lesions and CNS disease.

Host response to viral infections initially involves innate immune responses and natural killer cells. Resolution of infection, however, involves both production of antibody and development of specific T-cell-mediated immune responses. Antibody is required to control and clear enteroviruses, and failure of antibody response may result in progressive enteroviral encephalitis. In contrast, immune control of West Nile virus (WNV) involves both B and T cells. Failure of host T-cell response is a major factor in the pathogenesis of PML, as is alteration in CNS T-cell immune surveillance following treatment with immunomodulatory agents such as natalizumab or brentuximab vedotin. $CD8^+$ T cells are important in maintaining HSV and VZV in their latent states and in controlling both primary and reactivated infection. In general, the host immune response is protective, although the inflammatory process that results may augment cerebral edema; however, CNS or systemic infections may also elicit an immune response cross-reactive with antigens to the central or peripheral nervous system, leading to postinfectious neurologic injury.

VIRAL MENINGITIS

Acute viral meningitis is most commonly a disease of children and young adults and is the most frequent CNS complication of viral infection. Viral meningitis accounts for an estimated 400,000 hospitalizations yearly in the United States; studies from Great Britain give an annual incidence of 2.73 per 100,000 population. Major causative agents in Western countries are enteroviruses (accounting for up to 77% of cases), HSV-2 (10 to 20% of cases), and VZV (10 to 20% of cases) (Table 42-1).[1] A minority of cases are caused by WNV or other arthropod-borne agents, HIV, HSV-1, lymphocytic choriomeningitis virus (LCMV), mumps virus, or other agents. In northern Europe, cases may be associated with tick-borne encephalitis virus and in southern Europe with Toscana virus. In Asia, Japanese encephalitis virus is a common etiologic agent for meningitis as well as encephalitis. In 35 to 50 percent of cases, no agent is identified.

The clinical presentation of viral meningitis in adults is similar to that of bacterial meningitis, although patients usually are less acutely ill (Table 42-2).[1] Onset of meningeal symptoms may be preceded by fever and other symptoms of systemic illness, but viral meningitis often is of abrupt onset with severe headache and nuchal rigidity. Although headache is most commonly the presenting symptom, it may be not be evident in infants and may be less prominent in young children and immunosuppressed individuals. Patients may exhibit photophobia, nausea, vomiting, and, in some cases, irritability and lethargy. Progression to obtundation or coma is rare without accompanying encephalitis. Some patients may have evidence of systemic viral infection such as pharyngitis or rash, but abnormalities on general physical examination are often absent. Meningeal signs are typically less severe than in bacterial meningitis and may be subtle. The neurologic examination otherwise is usually unremarkable, and the presence of focal neurologic signs should raise concern that some other process is present.

Enteroviruses

Enteroviruses are unenveloped single-stranded RNA viruses forming a genus in the family picornavirus. They account for 60 to 80 percent of cases of viral meningitis in which an agent is identified. Enteroviruses survive well in water and sewage, are transmitted by fecal–oral or hand–mouth routes, and replicate initially in the gastrointestinal tract. Enteroviruses were previously subdivided into three groups: polioviruses, echoviruses, and coxsackieviruses. Newer isolated enteroviruses have been assigned numbers (e.g., enterovirus 71 or EV71). Coxsackievirus A9 and echoviruses E7, E9, E11, E19, and E30 have accounted for 70 percent of all cultured isolates from cerebrospinal fluid (CSF) in cases of enteroviral meningitis. Polioviruses have been largely eradicated, persisting only in Nigeria, Pakistan, and Afghanistan. Other enteroviruses have a worldwide distribution, and although cases of enteroviral meningitis occur throughout the year, infection is most likely to occur during summer and early fall months when conditions of sanitation are most lax. Acute enterovirus infection is usually asymptomatic or may result in mild gastroenteritis or pharyngitis; less than 5 percent of patients will develop meningitis or encephalitis.

TABLE 42-1 ■ Major Viral Agents Associated With Human Neurologic Disease

Viruses	Genus (Family)	Animal Reservoir	Transmission	Geographic Location	Peak Season[a]	Neurologic Syndromes	Acute Diagnosis[b,c]	Treatment
Major Viruses in North America and Europe								
Coxsackieviruses Echoviruses Enterovirus 71 and other numbered enteroviruses	Enteroviruses (Picornaviridae)	No	Fecal–oral spread	Worldwide	Summer to early autumn	Meningitis (Encephalitis)[d] (Poliomyelitis) (Acute flaccid myelitis)	CSF PCR	Supportive (Pleconaril)[e]
Herpes simplex virus type 1 (HSV-1)	Herpesviruses (Herpesviridae)	No	Human contact	Worldwide	No seasonal distribution	Encephalitis	CSF PCR	Acyclovir
Herpes simplex type 2 (HSV-2)[f]	Herpesviruses (Herpesviridae)	No	Human contact	Worldwide	No seasonal distribution	Meningitis Recurrent meningitis Myelitis	CSF PCR	Acyclovir[g]
Varicella-zoster virus	Herpesviruses (Herpesviridae)	No	Respiratory or human contact	Worldwide	No seasonal distribution	Shingles Postherpetic neuralgia Meningitis Vasculitis involving brain, spinal cord, eye, peripheral nervous system (Encephalitis)	CSF PCR (acute infection) CSF IgM and IgG (reactivated infection)	Acyclovir Valacyclovir[g]
Cytomegalovirus[h]	Herpesviruses (Herpesviridae)	No	Human contact	Worldwide	No seasonal distribution	Encephalitis (infants or immune-compromised patients)	CSF PCR	Ganciclovir (Foscarnet)
Human herpesvirus 6[i]	Herpesviruses (Herpesviridae)	No	Human contact	Worldwide	No seasonal distribution	Meningitis Encephalitis	CSF PCR	Ganciclovir, Foscarnet
West Nile virus	Togaviruses (Flaviviridae)	Birds, esp. crows, jays, magpies	Mosquito sp. Organ transplantation	USA excepting Alaska and Hawaii[j]	Summer to early autumn	Meningitis Encephalitis Poliomyelitis	CSF IgM	Supportive
St. Louis encephalitis virus	Togaviruses (Flaviviridae)	Small mammals	Mosquito sp.	USA excepting Alaska and Hawaii	Summer to early autumn	Meningitis Encephalitis	CSF IgM	Supportive
Eastern equine encephalitis virus	Alphavirus (Togaviridae)	Salt marsh and other birds	Mosquito sp.	Atlantic seaboard, Gulf coast, upper Midwest	Summer to early autumn	Meningitis Encephalitis	CSF IgM (PCR)	Supportive
California/La Crosse virus[i]	(Bunyaviridae)	Small mammals	Mosquito sp.	USA, esp. Midwestern and mid-Atlantic states	Summer to early autumn	Meningitis Encephalitis	CSF IgM	Supportive
Colorado tick fever	Orbivirus (Reoviridae)	Small mammals	Tick sp.	Western USA (esp. mountain states), western Canada	Spring to mid-summer	Meningitis Encephalitis	PCR CSF IgM	Supportive

(Continued)

TABLE 42-1 ■ (Continued)

Viruses	Genus (Family)	Animal Reservoir	Transmission	Geographic Location	Peak Season[a]	Neurologic Syndromes	Acute Diagnosis[b,c]	Treatment
Lymphocytic choriomeningitis virus (LCMV)[k]	Arenavirus (Arenaviridae)	Mice (Hamsters)	Aerosol	Worldwide	Autumn to winter	Meningitis Encephalitis	PCR CSF IgM Serum and CSF IgM and IgG	Supportive
HIV1, (HIV2)	Human immunodeficiency virus (Retroviridae)	None	Intimate sexual contact; IV drug abuse	Worldwide	No seasonal distribution	Meningitis acutely. See Chapter 43	PCR Serology	ART
JC virus[h]	Polyoma virus (Polyomaviridae)	None	Unknown	Worldwide	No seasonal distribution	PML	PCR	Supportive[i]
Viruses Which Are Uncommon in North America but May Be Seen in Individuals Exposed in Endemic Areas								
Mumps virus[m]	Rubalavirus (Paramixoviridae)	None	Respiratory spread	Worldwide	January to May	Meningitis Encephalitis	CSF PCR	Supportive
Toscana virus	Phlebovirus (Bunyaviridae)	Reservoir in nature unknown	Sand fly	Italy, other Mediterranean countries	May to September	Meningitis (Encephalitis)	CSF PCR	Supportive
Japanese encephalitis virus	Flavivirus (Flaviviridae)	Pigs, wild birds (herons)	Mosquito sp.	Southeast Asia and Far East	Following wet season: varies by country	Encephalitis	CSF IgM	Supportive
Nipah virus	Henipa-virus (Paramyxo-viridae)	Pteropid fruit bats	Consumption of food contaminated with infected bat saliva or urine Human-to-human	India Bangladesh Southeast Asia Indonesia Australia	No seasonal distribution	Encephalitis	PCR CSF IgM Serum Serology	Supportive
Venezuelan equine encephalitis	Alphavirus (Togaviridae)	Birds, small mammals	Mosquito sp.	South and Central America, Extreme southern United States	No seasonal distribution	Encephalitis (Meningitis)	PCR	Supportive
Tick-borne encephalitis virus	Flavivirus (Flaviviridae)	Birds, small mammals	Tick sp. Unpasteurized milk	Europe, former Soviet Union, Asia	April to November	Meningitis Encephalitis		Supportive
Chikungunya virus	Alphavirus (Flaviviridae)	Birds, small mammals, monkeys	Mosquito sp.	Africa, Asia, Europe, and the Indian and Pacific Oceans	Summer to early autumn	Encephalitis (Rare)	PCR CSF IgM	Supportive
Dengue virus	Flavivirus (Flaviviridae)	Predominantly humans (nonhuman primates)	Mosquito sp.	Essentially worldwide but most common in tropical regions	Summer to early autumn	Encephalitis (rare) Meningitis (rare) Myelitis (rare)	CSF IgM	Supportive

Zika virus	Flavivirus (Flaviviridae)	Predominantly humans Nonhuman primates Possibly other animal species	Mosquito sp.	Africa, Pacific Islands, South America	Summer to early autumn	Encephalitis (rare) Meningitis (rare) Guillain–Barre syndrome Transplacental infection with fetal anomalies	CSF IgM (serum IgM and IgG antibodies in women suspected of being pregnant)	Supportive
Rabies virus	Lissavirus (Rhabdoviridae)	Bats, skunks, foxes, raccoons Dogs where canine rabies vaccination not utilized	Animal bite Aerosol (organ transplantation)	Worldwide	No seasonal distribution	Encephalitis (“furious” or “dumb” rabies) Ascending motor paralysis[n]	CSF PCR Nuchal biopsy	Rabies immune globulin and immunization after bite Supportive after onset of illness

ART, Antiretroviral medications.

[a] Sporadic cases of many agents may occur outside peak season.

[b] Retrospective diagnosis may be made by comparing antibody titers in acute and convalescent sera or by comparing serum:CSF ratios of antibody against those of other agents.

[c] Diagnostic methods for common agents such as HSV-1, HSV-2, enteroviruses, West Nile virus, and varicella-zoster virus are readily available through many hospital and commercial laboratories. Advice concerning less usual infections may be obtained through the Centers for Disease Control and Prevention, 1600 Clifton Rd, Atlanta, GA 30333, phone: 800-232-4636 and through their Division of Preparedness and Emerging Infections: 404-639-0385.

[d] Less frequent forms of illness are shown in parentheses.

[e] Not available in the United States.

[f] HSV-2 meningitis may occur as a single event but may also be recurrent and is the major cause of Mollaret meningitis.

[g] Mild cases of HSV-2 meningitis may not require treatment. Severe HSV-2 meningitis may require treatment with acyclovir. Treatment of recurrent HSV-2 meningitis may employ valacyclovir.

[h] Immunocompromised patients.

[i] Predominantly an infection of children.

[j] West Nile virus also present in much of Europe, the United Kingdom, Egypt, Israel, Africa, India, and Western Asia.

[k] A murine virus. Infections also reported after exposure to infected pet hamsters.

[l] Treatment in AIDS involves suppression of HIV with ARVs; treatment in patients developing PML in the setting of natalizumab therapy (and possibly other monoclonal agents) has consisted of withdrawal of the monoclonal agent and plasma exchange to reduce circulating levels of the monoclonal.

[m] Previously one of the major causes of viral meningitis in the United States. Still a major cause of meningitis in countries where vaccination is not routine. Associated with occasional outbreaks of infection in unvaccinated individuals in the United States and Europe.

[n] Incubation period may be 3 or more years. Obtaining history of exposure should take this into account.

TABLE 42-2 ■ Signs and Symptoms of Viral Meningitis

Common
Headache
Fever
Nausea, vomiting
Stiff neck (not present in all cases; may be subtle)
Less Common
Lethargy, mild confusion, irritability*
Seizures*
Systemic signs including rash, diarrhea, pharyngitis, myalgias, adenopathy (with mumps: parotitis)

*Significant impairment in consciousness, seizures, and/or focal neurologic signs suggest the likelihood of encephalitis or other severe infection (meningitis, parameningeal infection, encephalitis).

Enteroviral CNS infection typically causes meningitis rather than encephalitis, with fever, headache, and stiff neck. These symptoms commonly last for 1 to 3 weeks in older children and adults. In occasional patients, enteroviruses may cause encephalitis or rarely a paralytic disease similar to polioviruses (see below) and may cause protracted, atypical infection in immunocompromised patients.

Herpes Simplex Virus Type 2

HSV-2 is a double-stranded DNA virus that is universal in human populations. HSV-2 is usually transmitted sexually, with antiviral antibodies first appearing in adolescence or early adult life. Following acute infection, the virus persists predominantly in spinal sensory ganglia and is subject to periodic reactivation, often without cutaneous or mucosal signs of infection. HSV-2 accounts for up to 10 to 20 percent of isolates in adults with viral meningitis and is roughly twice as common among women. HSV-2 as a cause of viral meningitis should be considered, particularly in young, sexually active adults. Older data suggested that up to 36 percent of women and 11 percent of men had headache, fever, or nuchal rigidity at the time of their first attack of genital herpes. Some patients with HSV-2 meningitis following genital herpes may have focal lumbosacral symptoms including urinary retention suggesting nerve root infection, and the virus may also be associated with myelitis. HSV-2 DNA can frequently be detected in CSF by amplification using the polymerase chain reaction (PCR). Approximately 20 percent of individuals with acute HSV-2 meningitis may subsequently develop recurrent episodes of meningitis (Mollaret meningitis). Many individuals with recurrent meningitis have no history of genital herpes and lack genital lesions during attacks of meningitis.

Patients with HSV-2 meningitis usually recover without treatment. Although successful treatment with acyclovir has been described in individual cases, the efficacy of antiviral therapy in acute or recurrent HSV-2 meningitis is uncertain. In one clinical trial, suppressive treatment with valacyclovir did not prevent recurrence of HSV-2 meningitis.[2]

Varicella Zoster Virus

VZV is a herpesvirus typically associated with chicken pox during acute infection and with cutaneous zoster (shingles) during reactivated infection. Like HSV-2, VZV is thought to account for 10 to 20 percent of identified cases of viral meningitis. Meningitis may occur during either primary or reactivated infection and may do so in the absence of rash. In contrast to many other viruses, VZV meningitis may result in significant CSF hypoglycorrachia and may be accompanied by a CSF pleocytosis characterized by atypical lymphocytes. As with HSV-2 meningitis, most immunocompetent patients with VZV meningitis recover without treatment. VZV infection may also produce a wide variety of other neurologic conditions, which are discussed in greater detail below.

Less Common Causes of Viral Meningitis

The arthropod-borne agents—WNV, St. Louis encephalitis virus, California encephalitis virus, Powassan virus, Jamestown Canyon virus, and Colorado tick fever virus—are most commonly associated with encephalitis, but may also cause meningitis. WNV, St. Louis encephalitis virus, Jamestown Canyon virus, and California encephalitis virus are transmitted by mosquitoes and tend to be more common in summer and early autumn months. The tick-borne agents Powassan virus and Colorado tick fever virus can cause a rash and most frequently occur during spring and early summer months. An important diagnostic consideration in patients with suspected Colorado tick fever is the tick-borne rickettsial illness Rocky Mountain spotted fever, which also has a peak incidence in spring and summer, usually has a rash, and requires antibiotic treatment.

LCMV is an arenavirus whose natural host is mice but which can cause meningitis and, less frequently, encephalitis in humans. The virus is present in mouse urine and is acquired by the respiratory route. At one time, it was thought to account for roughly 4 percent of diagnosed cases of viral meningitis, but in recent years it has become much less common, for unknown reasons. LCMV infections are classically most common in autumn and winter. Occasional outbreaks of infection have been associated with exposure to mice in animal facilities or to pet hamsters or guinea pigs. The meningitis associated with LCMV may be accompanied by low CSF glucose levels, which may persist over weeks to months in cases with prolonged recovery. In neonates, LCMV may cause a fatal systemic and CNS infection. Outbreaks of severe infection with high mortality have also been reported in which LCMV has been transmitted by organ transplantation. Reliable antiviral therapy for LCMV infection is not available; one patient with transplant-acquired LCMV infection recovered after reduction of the patient's immunosuppressive regimen and treatment with ribavirin.

Mumps virus, once a major cause of meningitis worldwide, is now rare in developed countries but remains a significant cause of meningitis in areas where mumps immunization is not practiced. The virus has also caused occasional epidemics in Western countries in unvaccinated populations exposed to individuals who have visited areas where mumps is still prevalent.

Human Immunodeficiency Virus

CNS invasion occurs early in the course of primary HIV infection, and meningitis due directly to HIV occurs in 9 to 24 percent of patients (see Chapter 43). The meningitis usually develops near the time of seroconversion and often occurs in the setting of an acute, mononucleosis-like retroviral syndrome characterized by fever, pharyngitis, and cervical lymphadenopathy; CNS findings of disorientation, confusion, or psychosis accompany this syndrome in some patients. Primary HIV meningitis should be considered in young adults with meningitis, particularly when they have HIV risk factors or a coexistent mononucleosis-like syndrome. The symptoms of meningitis are usually not severe and resolve in most but not all cases; in some patients, HIV meningitis becomes chronic. The CSF typically reveals a mild lymphocytic pleocytosis, mildly elevated protein content, and normal glucose level. HIV meningitis may be the initial presentation of HIV infection and may also occur early enough that standard serologic tests for HIV (as well as tests for home use) have not yet become positive. Initial diagnostic testing, per CDC recommendations, ideally involves a combined HIV-1/2 antigen/antibody assay; this should be repeated in 45 days if the assay is negative but there is high suspicion of HIV. Individuals testing positive should be assayed for viral load in serum and CSF. Treatment of HIV is with antiretroviral therapy, and follow-up assay for antiviral antibodies is used to confirm the diagnosis. In approaching patients with suspected HIV meningitis, it must be kept in mind that lymphocytic meningitis in patients with HIV infection may be caused by a wide variety of other agents, many of which are treatable.

Approach to Patients With Viral Meningitis

Bacterial meningitis is the primary concern in any patient presenting with acute meningitis. If the patient is severely ill, bacterial meningitis should be suspected and presumptive antibiotic therapy should be initiated immediately, usually along with corticosteroids.[3] Similarly, acyclovir should be initiated if HSV encephalitis is a significant diagnostic concern. Antibiotics and acyclovir can be discontinued once CSF studies are negative. In general, patients presenting with viral meningitis are less severely ill, and antibiotic and acyclovir treatment may often be deferred.

The diagnosis of viral meningitis is made by lumbar puncture and CSF analysis.[3] In acute bacterial meningitis, there is often an elevated opening pressure and typically a marked neutrophilic pleocytosis, with significantly elevated protein and depressed glucose concentrations. In contrast, in viral meningitis the opening pressure is usually normal or mildly elevated, and the CSF white cell count is usually in the range of 50 to 2000/mL. Although viral meningitis typically produces a lymphocytic pleocytosis, polymorphonuclear leukocytes may constitute over 50 percent of the cells during the first 24 to 36 hours of the infection and may occasionally remain the predominant cell type for longer periods of time. Protein is usually elevated in the range of 50 to 100 mg/dL but is sometimes higher. The CSF glucose level in viral meningitis is usually greater than 50 percent of blood glucose; the absence of CSF hypoglychorrachia is an important consideration in differentiating viral from bacterial meningitis. Depression of glucose to levels approaching those of bacterial meningitis may occasionally occur in meningitis caused by HSV-2, VZV, mumps, and LCMV. In the proper setting, lymphocytic pleocytosis with low CSF glucose may also raise concern about tuberculous or fungal meningitis.

Specific diagnosis of viral agents in CSF currently involves PCR amplification of viral RNA or DNA; at present, tissue culture isolation of virus is rarely performed for diagnostic purposes (Table 42-1). PCR is rapid and has a high level of sensitivity in meningitis due to enteroviruses, HSV-2, and VZV during acute infection. PCR can identify all strains of enteroviruses but does not distinguish between individual strains. Enteroviral RNA can be identified in CSF in the first 1 or 2 days of meningitis, from throat for several days, and from stool for a few weeks. Because asymptomatic enterovirus infections are common in the summer months, enterovirus isolation from throat or stool does not make a definitive diagnosis of enterovirus meningitis. Use of an enterovirus PCR assay in the emergency department in children with aseptic meningitis has resulted in significantly less antibiotic use, shorter length of hospitalization, and lower hospital costs. Film-based multiplex assays, capable of detecting nucleic acids of multiple infectious agents provide rapid screening but should be followed up with conventional PCR. Although CSF PCR is the diagnostic study of choice in many viral meningitides, the assay may be negative early in the disease course, and diagnostic yield may be highest when CSF is obtained within 3 to 14 days of onset of meningitis. In certain instances, the detection of CSF immunoglobulins may have greater diagnostic sensitivity than PCR. This is the case in WNV neuroinvasive disease and other arbovirus infections, in which detection of virus-specific immunoglobulin M (IgM) is more sensitive than PCR. Similarly, detection of virus-specific immunoglobulin G (IgG) in CSF may prove diagnostic in infections due to protracted or reactivated VZV where PCR is negative. Identification of the causative agent in viral meningitis may be made retrospectively by detecting a rise in IgG antibody titers between acute and convalescent (obtained after 3 to 6 weeks) serum or, at times, by detecting an abnormal serum:CSF ratio of antiviral antibodies.

Other laboratory studies in viral meningitis are usually unhelpful. Peripheral white blood cell count may be normal or elevated. Computed tomography (CT) scans and magnetic resonance imaging (MRI) of the brain are typically normal. The electroencephalogram (EEG) is usually normal but may occasionally show mild background slowing. Marked asymmetries or seizure foci should not be seen unless encephalitis predominates.

Viral meningitis is sometimes referred to by the older term "aseptic meningitis." This term, however, subsumes a broad range of clinical entities characterized by a meningeal reaction but distinct from purulent bacterial meningitis. It may include not only viral meningitis but also infections by bacteria that are not readily detected in routine cultures (*Leptospira icterohaemorrhagiae*, *Borrelia burgdorferi*, *Treponema pallidum*, *Mycoplasma pneumoniae*), meningeal involvement by *Rickettsia*, *Ehrlichia*, or *Anaplasma*, and infection by parasites such as *Toxoplasma gondii*. The possibility of infection by one of these agents should be kept in mind in a patient with suspected viral meningitis, since all are amenable to antibiotic treatment. In particular, *B. burgdorferi* can be a major cause of lymphocytic meningitis in endemic areas (see Chapter 39). Aseptic meningitis may also be associated with a variety of pharmacologic agents including nonsteroidal anti-inflammatory agents, trimethoprim-sulfamethoxazole, augmentin, carbamazepine, intravenous immunoglobulin G, and the murine monoclonal antibody OKT3. Treatment of viral meningitis is supportive in most cases. Analgesics may be required for individuals with severe headaches, and antiemetics for those with considerable nausea and vomiting. Hospitalization is seldom required except when vomiting is severe enough to cause dehydration or when bacterial meningitis cannot be excluded. Acyclovir and valacyclovir have been used to shorten the duration of illness in acute meningitis due to HSV-2 and VZV. However, controlled studies do not exist, and no standardized regimen has been developed. Patients with recurrent HSV meningitis may wish to keep oral acyclovir or valacyclovir at home and take the drug at the onset of meningeal symptoms. Ongoing twice daily treatment with valacyclovir at a dose of 0.5 mg has not been shown to prevent recurrence, but higher dosages have not been formally studied. The antiviral agent pleconaril, which prevents uncoating of viral RNA, has been used in enteroviral meningitis but is not routinely available in the United States.

As a group, patients with viral meningitis generally make a complete recovery within 1 to 2 weeks. Not all patients recover this quickly, however, and symptoms such as fatigue may last for weeks or even months. CSF abnormalities may also persist for well beyond the initial period of recovery. In addition, there have been occasional reports of permanent sequelae, usually but not always in small children, including cognitive impairment, deafness, and cranial nerve palsies. Aqueductal stenosis with hydrocephalus is a rare complication of HSV-2 and mumps meningitis.

VIRAL ENCEPHALITIS

Viral encephalitis represents viral infection of cells within the brain parenchyma, and signs and symptoms reflect this involvement (Table 42-3)[4]. The cell populations in which viral replication occurs differ among the various viruses and may involve neurons, glia, or, at

TABLE 42-3 ■ Signs and Symptoms of Viral Encephalitis

Common
Impairment of consciousness: confusion, lethargy, delirium, coma
Inability to recall new information/anterograde amnesia (esp. HSV-1 encephalitis)
Headache
Fever
Stiff neck (may be subtle)
Less Common
Focal or generalized seizures
Hemiparesis, spasticity, or other signs of focal CNS dysfunction including aphasia, blindness, or ataxia
Cranial nerve palsies
Tremors

HSV, herpes simplex virus; CNS, central nervous system.

times, vascular endothelial cells. The result of the infection may be death of specific cell populations or more widespread destruction involving multiple cell types. Viruses affecting unique populations of cells include rabies, which infects neurons exclusively; poliomyelitis, which involves spinal and other motor neurons; and JCV, which causes lytic infection almost exclusively in oligodendrocytes. Viruses infecting multiple cell types, often with extensive parenchymal destruction, include HSV and agents of the arthropod-borne encephalitides. Parenchymal destruction in severe infections such as herpes simplex encephalitis may be accompanied by hemorrhage. Virtually all viral encephalitides are accompanied by some degree of meningeal inflammation and cerebral edema, the latter of which may be severe enough to cause death.

Viral encephalitis occurs worldwide, with a particularly high incidence in the tropics. Table 42-1 outlines the major viruses that cause encephalitis and lists some of their distinguishing characteristics. Each year in the United States, between 1,000 and 5,000 cases of encephalitis are reported to the Centers for Disease Control and Prevention (CDC). Identification of the etiologic agent in viral encephalitis is achieved in only about 50 percent of cases.

Herpes Simplex Virus

Herpes simplex encephalitis represents only 10 to 15 percent of cases of viral encephalitis in the United States. However, it remains the most common cause of fatal nonepidemic viral encephalitis and is the only viral encephalitis for which effective antiviral therapy has been proven in clinical trials.[4,5] HSV is ubiquitous in human populations. HSV-1 is most commonly acquired in early childhood as a gingivostomatitis which may be either symptomatic or asymptomatic. HSV-2 is more commonly sexually transmitted and is classically acquired during adolescence or adulthood. Both agents enter neuronal processes during primary infection and persist in neurons within sensory ganglia. HSV-1, which may also persist within the CNS, is responsible for the majority of cases of herpes simplex encephalitis in adults; of these cases, roughly two-thirds represent reactivated infection. Although HSV-2 has traditionally been associated with meningitis and, less frequently, myelitis, it may also be isolated from cases of herpes simplex encephalitis.

The pathogenesis of herpes simplex encephalitis is not well understood. Encephalitis has been postulated to follow the spread of virus from the trigeminal ganglia through sensory fibers to the meninges overlying the temporal lobes and orbitofrontal cortex or, alternatively, to follow reactivation of virus in the olfactory bulbs prior to spread to the brain itself. HSV infects neurons, glia, and ependyma.

Herpes simplex encephalitis occurs throughout the year without seasonal incidence, affects men and women equally, and may occur at any age. Immunosuppression does not increase the risk of encephalitis, but the course of encephalitis may be atypical in these individuals. The virus has a predilection for orbitofrontal cortex and temporal lobes, which it may involve unilaterally or bilaterally. The cingulate cortex is also involved in many patients. Occasionally herpes simplex encephalitis involves the occipital cortex or brainstem, in rare cases without temporal lobe involvement. Vascular congestion and petechial or larger hemorrhages may be present; progression of the infection results in extensive and frequently hemorrhagic destruction of brain.

Herpes simplex encephalitis presents with an almost universal triad of headache (in over 90% of cases), fever, and alteration in mental state. Changes in mental state at presentation may range from confusion, frank psychosis, or somnolence to stupor or coma. Temporal lobe involvement may be manifested by olfactory or gustatory hallucinations, déjà vu phenomena, and upper quadrant visual field defects. Bilateral temporal involvement may result in the loss of ability to store and recall new information, and involvement of the dominant hemisphere can result in aphasia. Rare patients present with symptoms and signs referable to the occipital lobes. Focal or generalized seizures may occur at any point during the acute illness or after recovery.

The CSF typically contains a lymphocytic pleocytosis of 50 or more cells/mm^3 (median, 130 cells/mm^3). In occasional patients, however, the cell count is normal. Although herpes simplex encephalitis is frequently hemorrhagic, the presence or absence of red blood cells in CSF does not differentiate HSV infection from encephalitis due to other causes. CSF protein concentration has a median value of 80 mg/dL, but ranges from normal to over 700 mg/dL; CSF glucose is usually normal. MRI with gadolinium enhancement is the initial diagnostic procedure of choice and will usually demonstrate hyperintense T2-weighted signal along with gadolinium enhancement within the temporal lobe; it may also show involvement of the insula, orbitofrontal cortex, and cingulate gyrus (Fig. 42-1). MRI abnormalities in other regions of cortex or brainstem, without temporal lobe involvement, do not exclude the diagnosis. The EEG may show temporal lobe slowing or spike-wave activity. CT with contrast and EEG are less sensitive, but used together may provide diagnostic information when MRI is not available.

A specific diagnosis of herpes simplex encephalitis is made by amplification of viral DNA from CSF using PCR. The overall diagnostic accuracy of PCR in patients with brain biopsy-proven HSV encephalitis is 98 percent. Rapid provisional diagnosis may be achieved by film array methods, but these should be confirmed with more traditional PCR. In some patients, PCR may be negative at presentation due to low copy numbers of DNA in the CSF; in these cases, repeat CSF PCR after 4 to 7 days is usually positive. The diagnostic yield of PCR falls to 21 percent in patients after 2 weeks of antiviral treatment. Determination of acute antibody titers is not of value in the acute diagnosis of HSV encephalitis; however, comparison of acute and convalescent serum titers may be useful retrospectively and, in rare cases, provides diagnostic information when PCR was negative or when CSF was not obtained initially. Retrospective serologic confirmation of herpes simplex encephalitis may also be made by determining serum:CSF ratios of HSV-specific antibodies to identify intrathecal antibody production.

Herpes simplex encephalitis is treated with intravenous acyclovir (Table 42-4), which inhibits HSV

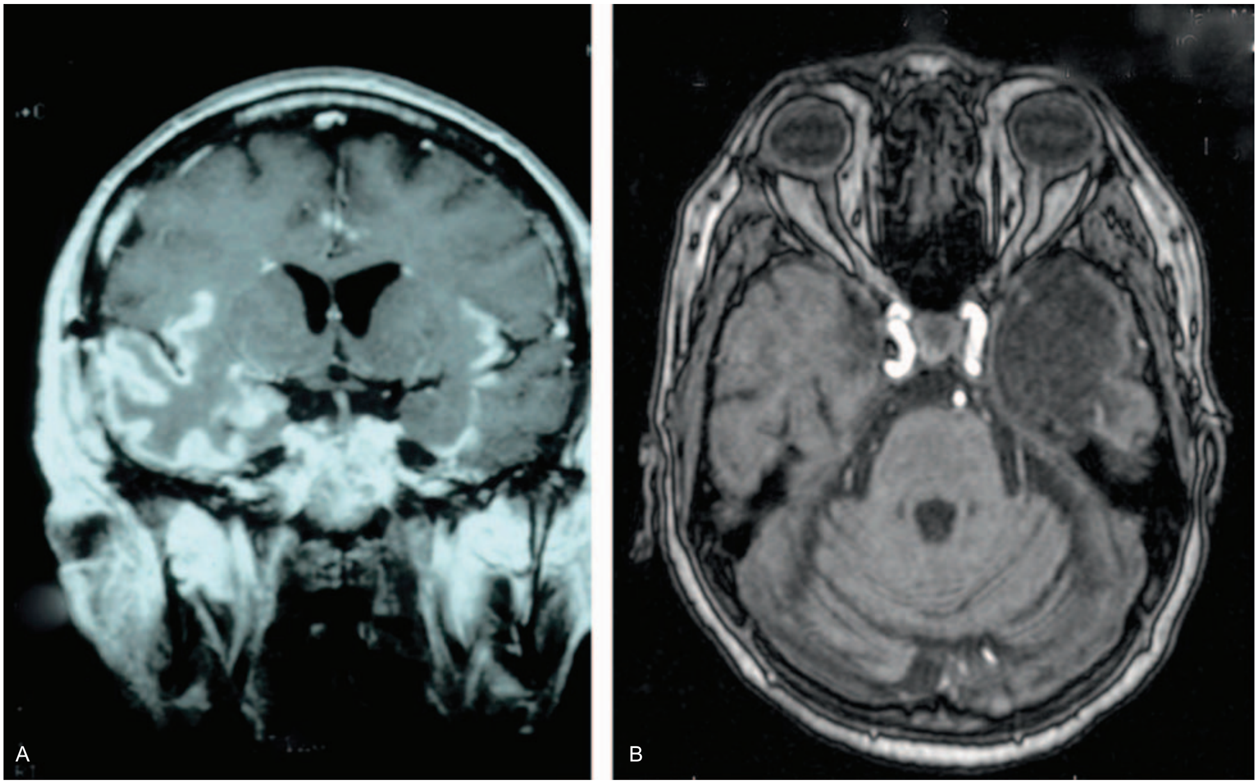

FIGURE 42-1 ■ *A*, Magnetic resonance imaging (MRI) of herpes simplex virus encephalitis. T2-weighted fluid-attenuated inversion recovery sequence showing increased signal in right temporal lobe, insula, and orbitofrontal cortex. There is also involvement of the left insula. *B*, T1-weighted MRI 6 months after infection, showing massive destruction of the left temporal lobe.

TABLE 42-4 ■ Antiviral Agents Used for CNS Infections

Antiviral	Mechanism of Action	Indication	Regimen in Adults	Major Adverse Effects
Acyclovir	Competes with deoxyguanosine triphosphate as a substrate for DNA polymerase. Causes viral DNA chain termination. Converted to active form in infected cells	HSV encephalitis Severe HSV meningitis VZV encephalitis, CNS vasculitis, or severe meningitis	10 mg/kg IV every 8 h × 21 days	Nephrotoxicity: may cause renal failure if patient not adequately hydrated Psychosis Stevens–Johnson syndrome Tissue necrosis
		Recurrent HSV-2 meningitis	800 mg 5×/day for 5–7 days given orally	
		Varicella (chicken pox) or herpes zoster (shingles)	800 mg 5×/day for 5–7 days given orally	
Valacyclovir	Same as acyclovir	HSV meningitis (esp. recurrent)	1000 mg every 8 h for 7 days	Similar to acyclovir
		Herpes zoster (shingles)	1000 mg every 8 h for 7 days	
Ganciclovir	Similar to acyclovir: inhibits viral DNA polymerization	Encephalitis due to cytomegalovirus or HHV-6	5 mg/kg every 12 h for 14–21 days	Hematologic toxicity (anemia, leukopenia, thrombocytopenia) Nephrotoxicity: may cause renal failure if patient not adequately hydrated
Foscarnet	Selective inhibition of viral DNA polymerase	Encephalitis due to cytomegalovirus or HHV-6; acyclovir resistant VZV	90 mg/kg IV every 12 h for 14–21 days	Hematologic toxicity (anemia, leukopenia, thrombocytopenia) Nephrotoxicity: may cause renal failure if patient not adequately hydrated

synthesis by competing with deoxyguanosine triphosphate as a substrate for DNA polymerase and causing DNA chain termination. The drug is converted into its pharmacologically active monophosphate form by virally encoded thymidine kinase and thus only becomes active in infected cells. Acyclovir is administered intravenously at 10 mg/kg body weight every 8 hours for 21 days. Complications of acyclovir therapy are usually mild. The major concern is nephrotoxicity due to deposition of drug crystals, which can be avoided by careful hydration. Although acyclovir resistance has been reported in other conditions, acyclovir-resistant herpes simplex encephalitis is rare.

Prior to the introduction of acyclovir, overall mortality from herpes simplex encephalitis was over 70 percent, with mortality approaching 100 percent in patients over the age of 40 years.[5] The advent of acyclovir has reduced the overall mortality to 28 percent, and instituting antiviral therapy at presentation when the diagnosis is suspected has reduced 1-year mortality to 14 percent. Patients who are alert or lethargic when treatment is initiated have an excellent likelihood of survival, but mortality in patients treated when comatose still approaches 25 percent. The likelihood of death or serious neurologic impairment is greater when the patient is elderly, initiation of acyclovir treatment is delayed, or evidence of extensive CNS involvement is present on initial neuroimaging. Even with prompt initiation of treatment, up to two-thirds of patients are left with permanent neurologic deficits including epilepsy, impaired cognition, aphasia, anterograde amnesia, or motor deficits. Neurologic improvement takes place over months, and some patients who are severely impaired immediately after treatment may have a good functional recovery over time. In roughly one-quarter of patients, apparent recovery from HSV encephalitis may be followed by apparent clinical relapse. Although late neurologic symptoms may occasionally be due to recurrent viral infection,[6] clinical worsening in most cases does not represent viral recrudescence but rather postinfectious autoimmune injury due to antibodies directed against neuronal *N*-methyl-D-aspartate or, less often, GABA_A receptors (NMDAR; $\text{GABA}_\text{A}\text{R}$).[7] Antibody-mediated encephalitis as a consequence of HSV encephalitis is discussed in greater detail below.

Varicella Zoster Virus

VZV, like HSV, is an enveloped double-stranded DNA virus that is worldwide in distribution. The virus is acquired by the respiratory route and replicates initially in tonsillar tissue to produce a viremia followed by seeding of multiple tissues including skin. Primary infection classically results in chicken pox, but individuals may also be infected acutely with little or no rash. The virus is then taken up by nerves supplying infected skin or other tissues and is transported to sensory ganglia, establishing lifelong persistence. VZV thus differs from HSV in that it produces an acute viremic illness and only then persists secondarily and spreads within neurons. Viral latency in sensory ganglia is heavily controlled by T-cell-mediated immunity, and reactivation of infection may occur with waning of immune response during old age or in states of compromised host immunity.

Cutaneous zoster (shingles), the most common manifestation of reactivated VZV infection, affects roughly 1 million adults in the United States annually.[8] The likelihood of developing zoster is higher in individuals who acquired chicken pox during infancy. Most cases of zoster occur in patients older than 50 years. Neuropathologic correlates of cutaneous zoster include focal meningeal inflammation, necrosis of associated neurons, and degeneration of motor and sensory nerve roots in the involved area. Cutaneous zoster may develop without known precipitating cause or may be triggered by systemic cancer, spinal irradiation, HIV infection or other immunosuppressed states, or spinal trauma. Many patients experience a sharp, burning discomfort in a dermatomal distribution for 2 to 5 days before onset of the rash. A localized redness with red macules then develops and progresses to vesicles in the same dermatomal pattern as the pain. Additional vesicles may appear over the next 2 to 7 days. The distribution of herpes zoster is usually unilateral and involves a single dermatome. The rash involves the trunk in 50 percent, the head in 20 percent, the arms in 15 percent, and the legs in 15 percent of cases. Over the next month, the dermatomal pain slowly disappears, leaving residual hypoalgesia or hyperalgesia. Occasional patients may present with dermatomal pain without rash, termed *zoster sine herpete*. Treatment with oral valacyclovir (1 g three times daily for 7 to 10 days) shortens the duration of rash and acute pain. Recommended treatment in immunocompromised individuals is 5 to 10 mg/kg of usually intravenous acyclovir given three times daily for 5 to 7 days.

Postherpetic neuralgia (PHN)—pain occurring in the distribution of the original rash and persisting for longer than 3 months—occurs in 9 to 14 percent of patients following shingles and increases with advancing age.[8] The pain may be relentless, episodic, or paroxysmal and may be elicited by cutaneous contact or stimulation. Postherpetic itch is also common. Two vaccines are in use to prevent VZV infection. The live attenuated Oka strain VZV vaccine (Zostavax®), introduced in 2006, has been shown to reduce the incidence of cutaneous zoster in healthy individuals by 50 percent and the incidence of PHN by 67 percent. The newer recombinant Shingrix® vaccine, introduced in 2017, reduces the incidence of both shingles and PHN by over 90 percent and is preferred in most patients. To what extent antiviral treatment of acute zoster lessens the likelihood of PHN has not been clearly demonstrated. Symptomatic treatment of PHN is often disappointing. Tricyclic antidepressants, gabapentin, pregabalin, duloxetine, controlled-release morphine sulfate, oxycodone, and lidocaine patches have moderate to high efficacy, but are sometimes completely unhelpful, as are a variety of approaches including nerve stimulation and botulinum toxin. Aspirin in cream or ointment form, topical capsaicin, and intrathecal methylprednisolone are less effective, limited by side effects, or both. For most of these medications, treatment involves escalating dosages of medication until pain relief is achieved or unacceptable side effects occur.

VZV may invade the CNS during primary or reactivated infection and, in reactivated infection, may do so in the absence of cutaneous zoster.[8] Prior to the advent of PCR testing, CNS invasion by VZV was considered unusual. It is now realized, however, that CNS involvement by VZV is much more frequent; in one series VZV was found to be the most common agent identified in viral meningitis and encephalitis (nearly 30% of isolates). Studies from France and England have identified the agent in 5 to 15 percent of encephalitis isolates. The virus is now known to cause a wide range of syndromes of neurologic injury involving not only brain and spinal cord but also cranial nerves and brainstem or peripheral ganglia. CNS invasion in reactivated VZV infection occurs following the spread of virus from trigeminal or spinal sensory ganglia; in this process, the virus may produce ophthalmic involvement or may produce Ramsay–Hunt syndrome, in which infection of the tympanic membrane and surrounding structures is accompanied by facial nerve palsy. Of greater concern and unlike HSV, VZV may infect both large and small vessels supplying the brain or spinal cord, at times followed by spread of the infection into neural parenchyma. Involvement of vessels may produce focal or multifocal ischemic injury or may cause vessel-wall necrosis with resulting arterial dissection, aneurysm formation, or hemorrhage within the subarachnoid space or brain parenchyma. An association of VZV with giant cell or temporal arteritis has been reported, but the association between these two entities is still disputed.[8]

The classic presentation of VZV vasculopathy is herpes zoster ophthalmicus, in which there is initial superficial zoster in the distribution of the ophthalmic branch of the trigeminal nerve followed days to weeks later by stroke in the territory of the carotid or middle cerebral artery. However, VZV vasculitis may occur with or without preceding cutaneous zoster or herpes zoster ophthalmicus or oticus and may involve virtually any vascular territory within the brain or spinal cord. VZV vasculitis may be significantly more severe in HIV infection or other immunosuppressed states, and immunosuppressed patients may develop a more slowly progressive CNS vasculopathy or myelitis.[8]

CSF in acute VZV CNS infection may reveal a mononuclear pleocytosis, at times with red blood cells and sometimes hypoglycorrhachia. VZV encephalitis in the setting of acute VZV infection may be diagnosed by PCR; however, the reaction rapidly becomes negative, so that a negative PCR does not exclude the diagnosis. Diagnosis of VZV vasculopathy in the setting of reactivated infection is made by the presence of elevated titers of anti-VZV IgG antibodies in CSF. Oligoclonal bands are commonly present and are reactive with VZV proteins.

Treatment of VZV encephalitis is with acyclovir, 10 mg/kg, usually intravenously, every 8 hours for a minimum of 14 days. Oral prednisone, 1 mg/kg, given daily for 5 days, may be used to treat the inflammatory component of the vasculitis; more prolonged treatment is avoided to prevent steroid-induced immunosuppression.

West Nile Virus

WNV, a single-stranded RNA flavivirus virus, is currently the most common cause of epidemic encephalitis in the United States.[4,9] The virus infects multiple species of animals and birds, in particular crows, jays, magpies, and ravens. *Culex* species mosquitoes, predominantly *C. tarsalis* and *C. pipiens*, are the primary vectors for human infection. WNV produces infection predominantly in the summer and early autumn, when mosquitoes are most active. WNV causes infections nationwide (Fig. 42-2). Of reported cases, nearly two-thirds represent neuroinvasive disease. As of November 2019, 872 cases had been reported for the year (Fig. 42-2) with 570 neuroinvasive cases and 46 deaths (Fig. 42-3). In most individuals, WNV infection is silent or produces only trivial symptoms. In 20 percent of infected patients, symptomatic West Nile fever develops, characterized by malaise,

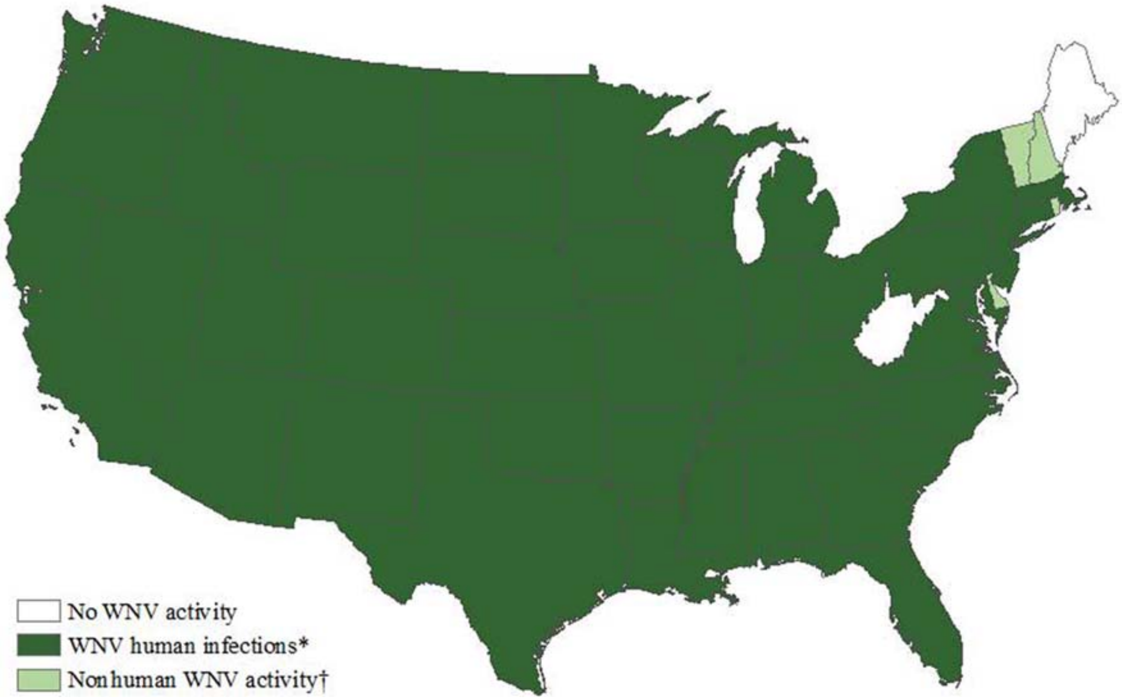

FIGURE 42-2 ■ Distribution of West Nile virus in the United States: Human and animal cases as of November, 2019. (From the US Centers for Disease Control and Prevention.)

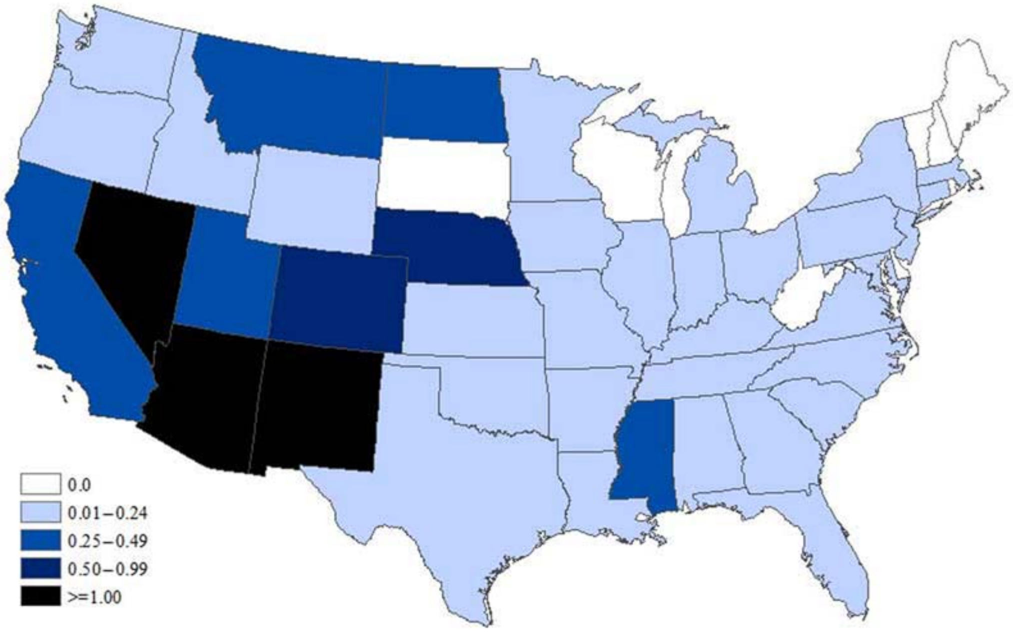

FIGURE 42-3 ■ Distribution of cases of West Nile neuroinvasive disease in the United States, 2019. (From the US Centers for Disease Control and Prevention.)

fatigue, anorexia, headache, nausea, vomiting, myalgia, fever, eye pain, and a nonspecific maculopapular rash. The illness usually lasts less than 7 days, although a minority of patients may remain symptomatic for as long as 6 weeks.

Less than 1 percent of infected patients develop neuroinvasive disease, which is more common in the elderly and is especially severe in immunosuppressed patients or transplant recipients. West Nile encephalitis typically presents with fever, headache, and altered mental state, stupor, or coma. Other signs of parenchymal involvement may include cerebellar ataxia or movement disorders including tremor, myoclonus, and parkinsonian symptoms. WNV infection may also result in a syndrome of acute flaccid paralysis similar to that seen with polio virus or Japanese encephalitis virus infection. A minority of patients develop chorioretinitis or vitritis. CSF in neuroinvasive WNV infection typically shows a mild elevation in opening pressure, lymphocytic pleocytosis, mild elevation of protein level, and normal glucose concentration. CSF white blood cell count is usually 50 to 260 cells/mm^3 but may be as high as 2,600 and may be heavily polymorphonuclear, in particular at presentation. In one series, the cell count was normal in 20 percent of patients. Occasional patients have low serum sodium levels indicative of the syndrome of inappropriate antidiuretic hormone secretion (SIADH). MRI is often normal, although a minority of patients have areas of increased signal on T2-weighted and fluid-attenuated inversion recovery (FLAIR) sequences in the substantia nigra, basal ganglia, and thalamus. Patients with WNV-induced flaccid paralysis may show increased signal in the anterior horns of the spinal cord. A single, acute, CSF specimen positive for WNV-specific IgM antibodies is diagnostic of WNV neuroinvasive disease. PCR is less reliable. Paired sera positive for WNV-specific IgM antibodies (a fourfold or greater rise in titer from the "acute" serum, obtained 0 to 7 days after symptom onset, and the "convalescent" serum, obtained 14 to 21 days after symptom onset) also provide serologic confirmation.

Treatment of WNV encephalitis is currently supportive. A multicenter controlled trial of human intravenous IgG containing high titers against WNV did not show an effect on the disease. Prognosis for recovery after WNV meningitis or encephalitis is good, although recovery may be extremely prolonged. The likelihood of complete recovery after West Nile flaccid paralysis is poor.

Other Arthropod-Borne Viruses

Several arthropod-borne viruses other than WNV may infect humans and cause neurologic disease. All but two of the agents occurring in the United States and Canada are carried by mosquitoes, with rates of infection that peak in mid-summer through early autumn.

Colorado tick fever virus and Powassan virus are carried by ticks, and infections caused by these agents tend to occur in late spring and early summer. Prior to the advent of WNV in the United States, St. Louis encephalitis was the most common arthropod-borne cause of encephalitis. Eastern equine encephalitis, although rare, remains the most deadly and outbreaks have recently occurred. No human case of Western equine encephalitis virus infection has been reported since 1994.

St. Louis encephalitis virus, like WNV, is a mosquito-borne virus that is a member of the family Flaviviridae. Cases of St. Louis encephalitis have been reported from almost every area of the United States, but the majority occur in the central Midwest and Texas. The virus is usually seen with scattered rural infections but may also cause urban epidemics. St. Louis encephalitis resembles neuroinvasive West Nile disease but rarely if ever produces a flaccid, polio-like illness. The two diseases are both more severe in the elderly and they have similar CSF findings. Diagnosis of St. Louis encephalitis is either by CSF IgM, by a rise in antibody titers, or both.

Eastern equine encephalitis virus is an agent of wading and migratory birds that is found predominantly along the Atlantic seaboard, the Mississippi valley, the Gulf of Mexico, Michigan, and Wisconsin. Although the virus does not usually produce severe infection in its natural hosts, it can cause lethal infection in horses and may cause epizootic outbreaks of infection in flocks of turkeys or in exotic or game farm birds. The virus is most apt to cause encephalitis in infants and in individuals over 55 years of age. A prodromal illness which may include fever, headache, and abdominal pain frequently occurs. Onset of encephalitis may be fulminant: nearly 70 percent of patients present in stupor or coma, and presentation only with meningeal symptoms is uncommon. Corticospinal or extrapyramidal signs are often present, and the illness may be complicated by focal or generalized seizures. Overall mortality is around 35 percent, with one-third of survivors suffering significant neurologic impairment.

In recent years, small numbers of cases of encephalitis in the United States have been associated with viruses more commonly found in tropical or other countries. The alphavirus, Chickungunya, and the flavivirus, dengue virus, although usually associated with systemic illnesses may rarely cause encephalitis. Chickungunya virus has been associated with both transverse myelitis and myositis. Zika virus, first isolated in Africa, was subsequently detected in outbreaks of infection in Africa, Asia, and the Pacific Islands. An association between Zika virus infection and Guillain–Barré syndrome was noted in French Polynesia in 2013–2014. In that same outbreak it was recognized that the virus is capable of maternal–fetal transmission. Unlike other arboviruses, Zika virus can persist in semen and produce sexually transmitted infection. In 2015–2016, a major epidemic of Zika virus infection in Brazil was followed by a sharp rise in cases of microcephaly and other CNS neurologic abnormalities in newborns as well as clusters of Guillain–Barré syndrome. In the majority (50 to 80%) of patients, Zika virus infection is asymptomatic, and in a minority of patients can cause a systemic illness with rash, low-grade fever, arthralgia, myalgia, and conjunctivitis. The major neurologic complications of Zika virus infection are Guillain–Barré syndrome and, less commonly, encephalitis or encephalomyelitis. A major concern with Zika virus—unlike other related agents—is that inapparent or mild infection in pregnant women can result in devastating fetal neurologic injury.

Two additional groups of arthropod-borne infections occur outside the United States and should be considered when evaluating patients with encephalitis coming from endemic areas (Table 42-1). Tick-borne encephalitides relate to multiple viral agents existing throughout Eurasia, with greatest prevalence in northern Europe and Asia. Japanese encephalitis virus, endemic in eastern and southeastern Asia, results in 15,000 deaths annually. Both tick-borne encephalitis and Japanese encephalitis may present with findings similar to those produced by WNV, including flaccid paralysis.

Rabies Virus

Rabies virus is an unenveloped single-stranded RNA virus that is a member of the Lyssavirus genus of the family Rhabdoviridae. Rabies virus exists worldwide. In developed countries where canine rabies vaccination is mandatory, predominant animal reservoirs include bats, skunks, foxes, and raccoons. In the United States, most—but not all—human cases result from bat bites. In less developed countries, dogs are the source of most human cases; other animals including infected monkeys, sometimes kept as pets, may account for a minority of cases.[10]

Rabies virus is typically acquired through the bite of an infected animal; rare cases have occurred following exposure to aerosolized rabies virus or after inadvertent transplantation of infected tissue. The virus may remain latent at the site of an infected bite for 6 or more years before the onset of neurologic disease. Unlike most other viruses causing encephalitis, rabies is specifically neurotropic: the virus enters peripheral nerve fibers at the site of inoculation, is carried proximally by reverse axoplasmic flow, and progressively infects the CNS through neuron-to-neuron spread (the centripetal phase of infection). The virus then spreads outward within nerves (the centrifugal phase of infection) to involve multiple tissues including salivary glands, corneas, and the heart. In animals, this centrifugal phase of infection, with shedding of salivary virus, may occur prior to clinical disease.[10]

Rabies classically begins with dysesthesias at the site of the bite, followed by progressive neurologic involvement with a clinical picture (termed "furious rabies") of agitated delirium, stimulus-sensitive laryngeal spasm with hydrophobia, prolonged inspiratory spasm, and progression to coma and death. Rabies may also present as a more classic encephalitis with stupor and coma ("dumb rabies"), or as an ascending paralysis, similar to Guillain–Barré syndrome, followed by signs of CNS involvement. Rabies should be considered in appropriate clinical settings, in particular when there is a history of animal bite or of recent or remote travel to, or residence in countries where rabies is a significant health problem. There may be no history of a bite, however. The minute punctures caused by bat bites may go unnoticed, or, alternatively, the animal bite may have occurred long enough ago to have been forgotten. MRI may show ill-defined, mild T2-hyperintensities in the brainstem and hippocampus; early in the disease these lesions may fail to enhance with gadolinium. Specific diagnosis of rabies is made by identifying rabies antigen in nuchal biopsy or by PCR from saliva or CSF.[10]

Management of rabies consists of two strategies: prevention of clinical disease by immunotherapy and immunization at the time of the bite and supportive treatment of clinical rabies. Preventive therapy involves washing the area of the bite thoroughly, infiltrating the area with rabies virus-specific immunoglobulin, and administration of diploid cell rabies vaccine. This treatment, when administered soon after the bite, is highly effective in preventing clinical rabies. Once clinical rabies develops, the patient's course may be influenced by a wide variety of CNS, autonomic, and systemic complications. Rabies is almost invariably fatal; fewer than 10 patients are known to have survived, and of these, only one made a full recovery. Of interest, a handful of patients known to have received infected corneal tissue or organs failed to develop clinical rabies. One patient surviving rabies was treated with midozalam and ketamine, but the use of these agents in other cases has been unsuccessful.

Other Viruses

Although enteroviruses are most commonly associated with viral meningitis, they may also cause encephalitis and rarely may result in paralytic disease. Enterovirus 71, a cause of hand, foot, and mouth disease and herpangina in children, may cause encephalitis with involvement of the brainstem or, less frequently, the cortex, cerebellum, or spinal ventral roots. In some patients, MRI abnormalities are detected on diffusion-weighted (DWI) or FLAIR sequences. Beginning in 2014, an upsurge of cases of paralytic illness, now known as acute flaccid myelitis, was noted in children nationwide. This illness is characterized by the acute development of flaccid limb weakness accompanied by spinal cord gray matter lesions on MRI and electrodiagnostic evidence of motor neuron injury.[11] Although a minority of patients may exhibit clinical improvement in weakness, most patients have poor recovery. Although other agents have been reported in this condition, epidemiologic evidence supports an association with enterovirus D68.[11]

The mouse arenavirus LCMV usually causes meningitis but may occasionally cause encephalitis. Infection in children and adults is rarely fatal, but clinical recovery and return of CSF to normal can be prolonged. LCMV meningoencephalitis is one of the few viral CNS infections that may cause hypoglycorrhachia. Parvovirus B19, the agent of the childhood condition erythema infectiosum (fifth disease), is an uncommon cause of encephalitis in both children and adults. Human herpesviruses type 6 (HHV-6, associated with roseola infantum) and type 7 (HHV-7) have been associated with seizures or, rarely, encephalopathy in early childhood. In one study, HHV-6 was detected in the CSF of 40 percent of patients with encephalitis of otherwise undetermined cause. Important viruses to consider in patients exposed in Southeast Asia include Japanese encephalitis virus and the bat henipavirus, Nipah virus (Thailand) (Table 42-1).

Epstein–Barr virus (EBV), the agent of infectious mononucleosis, has been associated with a wide variety of infectious and postinfectious neurologic disorders in both immunologically normal and immunocompromised patients. The association of EBV with specific disease presentations, however, is made difficult by two properties of the virus. First, EBV infects and can remain latent in B lymphocytes for many years. For this reason, PCR amplification of EBV DNA from CSF in patients with suspected CNS infection may simply indicate the presence of the virus in lymphocytes rather than proving it as a causative agent. Second, like HSV, EBV can reactivate under situations of physiologic stress, so that a rise in antibody titer in the setting of acute illness may or may not be indicative of disease causation.

Viral Encephalitis in Immunocompromised Patients

Impairment of host B- or T-cell response, whether because of congenital immunodeficiency, HIV infection, or iatrogenic immunosuppression, may result in infection with unusual agents or produce atypical infection by more common viruses. Because control of enteroviral infection depends heavily on antibody, enteroviruses have been associated with chronic meningitis and progressive encephalitis in children with X-linked hypogammaglobulinemia or X-linked hyper-IgM syndrome; these patients exhibit ongoing presence of enteroviral RNA in CSF and may show continued enterovirus excretion in stool. Chronic enteroviral meningoencephalitis has also been reported in patients treated with the anti-CD20 monoclonal agent rituximab. Impairment of T-cell immune response, as in HIV-infected or immunosuppressed patients, may lead to infection with less commonly pathogenic agents such as JCV, cytomegalovirus, adenovirus, HHV-6, or HHV-7, or may result in prolonged or atypical presentations of infections with HSV or VZV. HSV and VZV are treatable with acyclovir, as is the case in immunologically intact patients. Treatment of cytomegalovirus CNS infections has usually involved ganciclovir, foscarnet, or a combination of both agents; cidofovir has been used as a second choice (Table 42-4). Cases of encephalitis associated with HHV-6 have been treated with ganciclovir, foscarnet, or a combination of the two drugs. CNS infections in immunocompromised patients may involve common infections as well as those caused by unusual organisms. An important point to remember in dealing with CNS infections in severely immunocompromised individuals—especially those infected with HIV—is that more than one infective agent may be present.

Progressive Multifocal Leukoencephalopathy

PML is an uncommon opportunistic infection of immunocompromised patients. Its causative agent, the human polyomavirus JCV, affects over 50 percent of individuals worldwide by late adult life[12]. Acute viral infection is not known to cause symptomatic illness, but the virus establishes protracted infection of renal tubular epithelial cells and other tissues, possibly including the brain. In PML, JCV produces lytic infection of oligodendrocytes, causing areas of demyelination; astrocytes are also infected in some cases. PML was initially described as a rare disorder of patients with hematologic malignancies and in immunosuppressed patients. In untreated acquired immunodeficiency syndrome (AIDS), however, 4 percent of patients will die of PML, and PML can be the presenting illness in patients with HIV. In recent years, PML has also become increasingly frequent in patients treated with the more aggressive immunosuppressive regimens now used for collagen-vascular diseases and solid organ or hematopoietic stem cell transplantation. PML has also become a significant—although infrequent—complication of treatment with natalizumab and, to a lesser degree, other monoclonal immunosuppressive agents such as rituximab, efalizumab, alemtuzumab, brentuximab vedotin, and TNF-α inhibitors.[12] The course of PML involves the progressive development of multifocal neurologic deficits which may involve motor control, sensation, speech, vision, or cognition. Occasional patients develop cerebellar or brainstem signs, but clinical involvement of the spinal cord is virtually never present. Rarely AIDS patients have been reported to develop JCV infection of cerebellar granule or other neurons. PML is presumptively diagnosed by MRI, which typically shows multifocal white matter lesions in the cerebrum or, less often, brainstem or cerebellum (Fig. 42-4)[12]; PML lesions are often not apparent on CT. Although PML lesions usually do not enhance, gadolinium enhancement may occur in AIDS and in patients in whom PML is a consequence of treatment with natalizumab or other monoclonal agents. A definitive diagnosis of PML is made by PCR amplification of JCV DNA from the CSF. Sensitivity of PCR in early studies approached 80 to 90 percent. However, in HIV patients treated with antiretroviral therapy, PCR is positive in only around 60 percent of cases.

There is no proven treatment for PML.[12] Cytosine arabinoside has been reported to have limited efficacy in non-AIDS patients only. Cidofovir, mefloquine, and mirtazapine have not been effective in controlled trials. Some recent reports of success with immune checkpoint inhibitors need to be confirmed in larger trials. Restoration of host immune function with antiretroviral therapy in AIDS patients may lead to stabilization or improvement, as may reduction of immunosuppressive therapy in transplant recipients or other patients receiving these drugs. Treatment of PML in cases

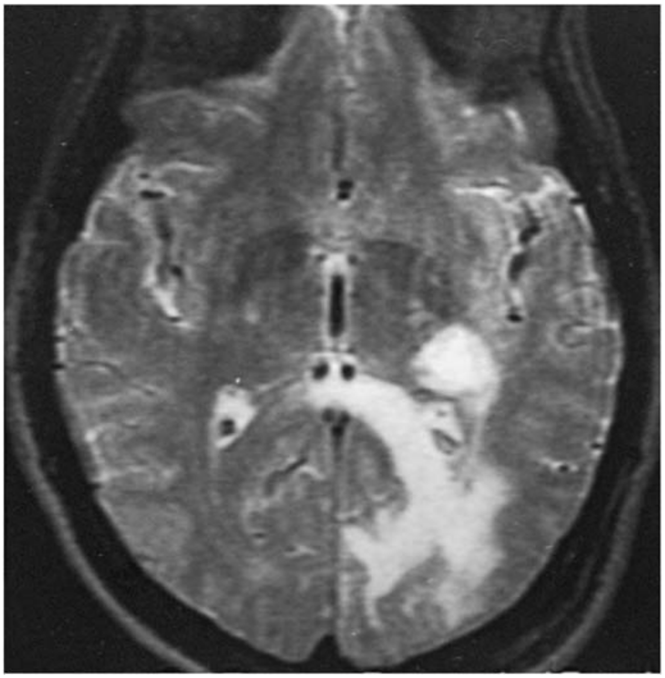

FIGURE 42-4 ■ Progressive multifocal leukoencephalopathy: axial T2-weighted MRI showing multifocal involvement of cerebral white matter.

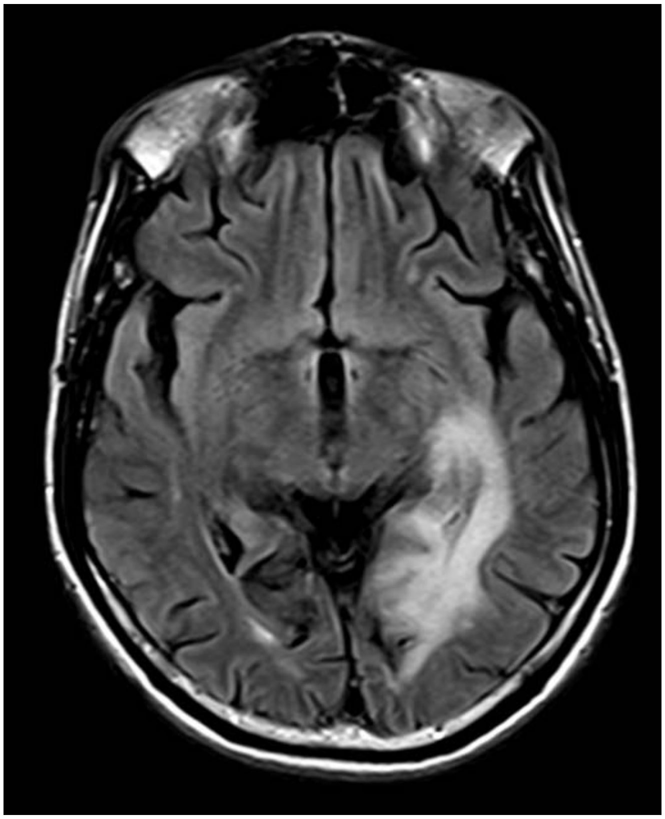

FIGURE 42-5 ■ FLAIR MRI showing PML with immune reconstitution inflammatory syndrome (IRIS) in a patient with human immunodeficiency virus (HIV) following institution of antiretroviral therapy. There is edema in and surrounding a lesion within the left posterior cerebral white matter.

associated with natalizumab or similar agents involves withdrawal of that agent and plasma exchange or immunoabsorption to remove the agent from the circulation; this approach has been used frequently with natalizumab-associated PML but much less frequently in cases of PML associated with other monoclonal agents. Improvement of immune status may cause a fulminant immune reconstitution inflammatory syndrome (Fig. 42-5).

Approach to Patients With Viral Encephalitis

Viral encephalitis should be suspected in any patient presenting with signs suggesting acute involvement of the brain parenchyma, especially in individuals with fever and alteration of consciousness. Meningeal signs may or may not be present. Signs indicating temporal lobe involvement suggest herpes simplex encephalitis, but other viral encephalitides may have a similar presentation as may occasional bacterial infections or autoimmune encephalitis from antineuronal antibodies. Patients often have an elevated peripheral white blood cell count, but signs of systemic infection may also be absent. Diagnosis relies heavily on clinical findings, MRI, and the results of CSF analysis. MRI in herpes simplex encephalitis characteristically shows abnormalities of one or both temporal lobes, at times with involvement of the orbitofrontal cortex, insula, or cingulate gyrus. Similar findings, however, may be seen in other potentially treatable conditions including neurosyphilis and autoimmune encephalitis. The CSF in viral encephalitis typically shows significant pleocytosis and an elevated protein but normal glucose concentration. The pleocytosis is commonly lymphocytic, but is neutrophilic in rare cases. A depressed CSF glucose level, while not typical, has been described in VZV, LCMV, mumps, and HSV-2 infections. CSF should be sent for PCR for HSV, and consideration should be given to ordering PCR for other agents. Film array PCR, which tests for multiple infectious agents, may provide rapid diagnosis but should be supplemented with conventional PCR. Detection of virus-specific IgM in CSF is more sensitive than PCR for the diagnosis of WNV and may be useful in other arboviral infections where PCR is negative. Similarly, elevated CSF titers of IgG may be more sensitive than PCR in encephalitis due to reactivated VZV. Lumbar puncture may need to be deferred when there is evidence on examination, CT, or MRI of increased intracranial pressure or mass lesion.

Acyclovir should be initiated presumptively where viral encephalitis is strongly suspected and should be continued until PCR has been shown to be negative for HSV (Table 42-4). Because the initial PCR in herpes simplex encephalitis may occasionally be falsely negative, acyclovir should be continued in seriously ill patients until a second CSF PCR, obtained 3 to 7 days later, is also negative. Acyclovir should also be continued if VZV is detected by CSF PCR or serology. Ganciclovir should be instituted if CMV or HHV-6 infection is diagnosed; ganciclovir may be supplemented with foscarnet (Table 42-4). Antibacterials should be initiated if bacterial meningitis, brain abscess, or parameningeal infection is suspected.

Treatment of encephalitis is otherwise supportive. Seizures may require intravenous fosphenytoin, levetiracetam, or other agents. Cerebral edema is a major concern in severe encephalitis; dexamethasone (10 mg orally or intravenously followed by 4 mg every 6 hours), mannitol, and hyperventilation have all been used in individual cases, but their efficacy is unproven. Decompressive craniectomy has resulted in patient survival with good initial outcome in a few cases of herpes simplex encephalitis complicated by fulminant cerebral edema. Cerebral salt wasting or SIADH may require treatment with hydration and sodium supplementation, or fluid restriction, respectively. Attention must be given to preventing complications of severe illness such as pneumonia, deep venous thrombosis, and decubitus ulcers. Recovery in viral encephalitis may be extremely prolonged, with the full extent of recovery not realized for many months.

PRION DISEASES

Prion diseases represent a group of rare disorders including Creutzfeldt–Jakob disease (CJD), new variant CJD (vCJD), Gerstmann–Straussler–Schenker disease, familial fatal insomnia, kuru, and variably protease-sensitive prionopathy. Prion diseases of animals include scrapie of sheep (the prototype for this group of conditions), bovine spongiform encephalopathy (BSE), wasting disease of deer and elk, and transmissible mink encephalopathy. Prion diseases are not caused by viruses but rather by a self-replicating isoform of a normal intracellular sialoglycoprotein. The normal cellular protein is termed “PrP(c)” and the self-replicating protein causing disease is referred to as “PrP(Sc).” PrP(Sc) does not contain nucleic acid, its presence does not elicit an immune response, and it is not inactivated by many agents normally used for decontamination. Interaction of PrP(Sc) with PrP(c) appears to be essential for disease. Except in familial cases, PrP(Sc) is thought to arise from a spontaneous mutation in PrP(c). Several different subtypes of CJD have been associated with homozygosity or heterozygosity of methionine or valine at codon 129 of the *PrP* gene, differences in variation in glycosylation patterns of PrP(Sc), and patterns of electrophoretic mobility of PrP(Sc) after proteinase K digestion. Prion diseases have repeatedly been shown to be transmissible through PrP(Sc)-contaminated material, including PrP(Sc)-containing human grafts of dura mater or other tissues, contaminated electrodes used for intracerebral recording, and human pituitary-derived growth hormone. In the case of vCJD, transmission has occurred predominantly through ingestion of contaminated beef, but it has also occurred through blood transfusion.

The most common human prion disease is CJD, which occurs worldwide with 1 to 2 cases per million population per year. The average age at onset is 60 years, with an equal sex distribution. Most cases are sporadic (sCJD), but 12 percent cluster in families. The condition affects the CNS only, without systemic symptoms. The onset of CJD is typically with subtle changes in cognition and personality changes that may include apathy, irritability, depression, or paranoia. Occasional patients present with ataxia, spasticity, or visual complaints. These initial symptoms are followed by progressive dementia, often involving parietal lobe symptoms and, at times, aphasia. As the disease progresses, over 85 percent of patients develop stimulus-sensitive myoclonic jerks that tend to disappear as the disease progresses to profound dementia and a vegetative state. CJD is untreatable, and its course is relentlessly progressive, resulting in death within 6 months to 2 years.

The diagnosis of CJD has traditionally been made on the basis of clinical presentation, EEG, MRI, and evaluation of CSF for the proteins 14-3-3, tau, and neuron-specific enolase. The yield of these studies, however, varies among the different subtypes of CJD. CSF cell count and protein levels are usually normal, such that significant pleocytosis suggests strongly that the diagnosis is incorrect. The EEG initially may show only mild slowing but subsequently becomes strikingly abnormal, with repetitive, periodic, stereotyped, bilaterally synchronous sharp waves that usually occur at a frequency of 1 to 2 per second and are often associated with myoclonic jerks. This periodic EEG activity may give way to generalized slowing late in the disease. MRI has become the most useful initial diagnostic test in suspected CJD and typically shows foci of increased signal in the putamen, caudate, thalamus, and gray matter of the cerebral cortex. These findings are most prominent on DWI sequences and, with less sensitivity, FLAIR sequences (Fig. 42-6); MRI changes are not reliably present in familial CJD. Detection of 14-3-3 and tau proteins as well as neuron-specific enolase in CSF provides supportive evidence for the presence of CJD in patients with clinical, EEG, or MRI markers of the disease. None of these CSF markers is specific for CJD, however, and their use in unselected patients may lead to erroneous diagnosis. Recently, a sophisticated molecular technique, the real-time quaking-induced conversion test (RT-QuIC) has come into use, based on the self-replicating (self-seeding) nature of PrPSc.[13] This test, now in its second generation, allows rapid diagnosis of CJD and other prion diseases from CSF with a specificity of 98.5 to 100 percent and a sensitivity of 92 to 95 percent.[13] Postmortem diagnosis can be made by the characteristic brain histopathology and staining with specific prion antibodies or by demonstration of prions from homogenized brain using immunodiagnostic procedures or the RT-QuIC assay.

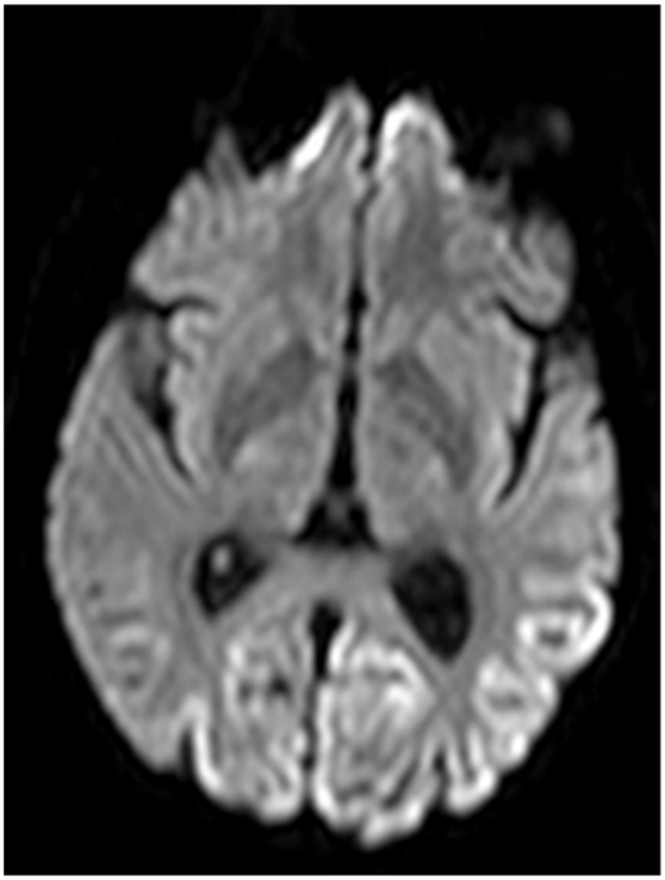

FIGURE 42-6 ■ Creutzfeldt–Jakob disease. Diffusion-weighted MRI image showing restricted diffusion within the cortical ribbon of the posterior hemispheres bilaterally.

In general, animal prion diseases such as scrapie have not been thought transmissible to humans. However, the appearance in Britain of BSE ("mad cow disease"), a prion disease, was followed by an outbreak of human cases of vCJD, which were presumably acquired by ingestion of contaminated beef. Human cases peaked in the year 2000 after extensive culling of affected cattle. Cases of vCJD have occurred primarily in younger individuals and have tended to present with psychiatric signs, with dementia and painful sensory symptoms occurring commonly. In contrast to the general population, all patients studied with vCJD have been homozygous for methionine at codon 129 of the *PrP* gene. Unlike sporadic CJD, the EEG in vCJD only rarely shows periodic activity. MRI typically demonstrates increased signal in the pulvinar on DWI and FLAIR sequences. Survival in vCJD may be more prolonged compared with sCJD. Unlike sCJD, there have been cases of vCJD transmitted by blood transfusion.

SARS-CoV-2

COVID-19 infection, caused by the SARS-CoV-2 virus, has numerous neurologic manifestations that more commonly occur in patients with more severe respiratory presentations requiring hospitalization. CNS involvement includes an incidence of ischemic stroke that is higher than with other similar severe respiratory viral illnesses, such as seasonal influenza. Mechanisms underlying ischemic stroke are likely varied and include systemic hypercoagulability and viral involvement of the heart leading to a central embolic source. An encephalopathy is also common, resembling hospital-acquired delirium. Headache is a well-described heralding feature of the illness. Brain autopsy series suggest that direct viral involvement of the brain, a SARS-CoV-2 viral encephalitis, is rare, and likely most CNS symptoms are reflective of the effects of systemic illness including a massive cytokine response in those who are severely affected.

Peripheral nervous system manifestations include myalgias and an elevated serum creatine kinase, which is common among those with moderate-to-severe respiratory involvement. Guillain–Barré syndrome, likely postinfectious in nature, has been described in small series. Loss of smell is common, even in individuals with mild disease, and in some cases does not rapidly recover with illness resolution. This anosmia is probably due to involvement of the olfactory epithelium, although MRI evidence of hyperintensity in the olfactory nerve and brain regions responsible for olfactory processing has been described.

Postinfectious autoimmune encephalitis and myelitis can occasionally occur following COVID-19 infection. Treatment is uncertain, but intravenous immunoglobulin (IVIg) and plasmapheresis have been tried alone or in combination. Long-term neurologic effects following resolution of the illness remain unknown. Some patients have described a more long-term mild cognitive syndrome that merits further investigation.

POSTINFECTIOUS COMPLICATIONS OF CENTRAL NERVOUS SYSTEM VIRAL INFECTION

The interaction of an infective agent with the host immune system usually results in containment of the agent and eradication of disease. In some instances, however, systemic or CNS viral infections may induce an immune response that reacts not only with the infecting agent but also with components of nervous tissue. Neurologic injury with antineuronal autoantibodies is seen in anti-NMDAR (or, rarely $GABA_AR$) encephalitis which may follow herpes simplex virus encephalitis. In addition, autoimmune CNS injury can occur follow systemic infection and may result in postinfectious encephalomyelitis, acute hemorrhagic leukoencephalitis, transverse myelitis, or injury to the peripheral nervous system resulting in peripheral nerve involvement including plexopathy and the Guillain–Barré syndrome (see Chapter 60). Rarely, optic neuritis may also occur as a postinfectious condition.

Autoimmune Encephalitis Following Herpes Simplex Encephalitis

In roughly 25 percent of cases, individuals surviving herpes simplex encephalitis may develop an apparent clinical relapse caused by anti-NMDAR antibodies; the illness may begin between 7 days and 2 months following infection.[7] Affected children below the age of 4 tend to develop choreoathetosis and may develop refractory seizures. Affected adults exhibit behavioral changes without choreoathetosis; seizures in adults are uncommon. The diagnosis is made by detection of anti-NMDAR antibodies in CSF or (of less sensitivity) serum. In rare cases, antibodies have been detected to a second neuronal membrane protein, the $GABA_A$ receptor.[7]

Postinfectious Encephalomyelitis

Postinfectious encephalomyelitis is defined as an acute, monophasic demyelinating illness occurring within 2 to 4 weeks of a viral or other infection (Table 42-5).[4,14] The condition bears strong similarity to two other conditions: postvaccination encephalomyelitis, which follows immunization, and the experimental autoimmune demyelinating disease, experimental allergic encephalomyelitis. Postinfectious encephalomyelitis and postvaccination encephalomyelitis have been grouped under the common term *acute disseminated encephalomyelitis* (ADEM), which is a final common pathway of autoimmune CNS injury that may be produced by a variety of infectious agents or immunizations.

Postinfectious encephalomyelitis is more common in children than in adults and is rare in the elderly. In children, the peak age of onset is 5 to 8 years. The onset of postinfectious encephalomyelitis may be preceded by fever, malaise, headache, nausea, vomiting, or combinations of these symptoms. These prodromal symptoms are followed by the abrupt—at times fulminant—onset of CNS dysfunction. Altered mental state is almost universal and may range from drowsiness to frank coma. Meningeal signs are common. Neurologic examination may reveal unilateral or bilateral corticospinal tract signs, hemiplegia, ataxia, aphasia, sensory loss, visual field defects, or cranial nerve palsies. Focal or generalized seizures occur in up to 70 percent of children under 5 years of age, 80 percent of whom may develop status epilepticus. Occasionally, postinfectious encephalomyelitis may be accompanied by optic neuritis or by involvement of the peripheral nervous system. The simultaneous occurrence of central and peripheral demyelinating events appears to be more common in adults than children. A syndrome of ataxia may be seen in patients following chicken pox or, less frequently, other viral infections.

The presence of multifocal neurologic signs should raise the level of suspicion of ADEM, as should the presence of signs referable to both the CNS and the peripheral nervous system. Excluding active nervous system infection is important. CSF typically shows a lymphocytic pleocytosis; however, roughly 30 percent of patients will have a mixed pleocytosis with neutrophilic predominance. Traditionally, the presence of oligoclonal bands was considered unusual; however, oligoclonal bands have now been detected in 20 percent of patients with ADEM. In more recent studies, oligoclonal bands were reported in nearly two-thirds of individuals presenting with illnesses initially diagnosed as ADEM, but over half of these patients are subsequently diagnosed as having multiple sclerosis.

MRI with gadolinium enhancement is the diagnostic study of choice in ADEM. T2 and FLAIR sequences classically show multiple, large, asymmetric, irregularly shaped lesions involving the subcortical white matter and the gray–white junction of both cerebral hemispheres (Fig. 42-7). The periventricular white matter may be involved, but lesions confined to the corpus callosum are unusual, in contrast to multiple sclerosis. Gadolinium enhancement is seen in 30 to 100 percent of patients and may vary with stage of the disease. Ring-enhancing lesions are sometimes present. However, the presence of ring-enhancing lesions should raise the possibility of brain abscess or other active CNS infection. Spinal cord involvement, usually with extensive edema and swelling, may occur in children or adults and has a predilection for the thoracic region. The majority of these lesions will resolve over time.

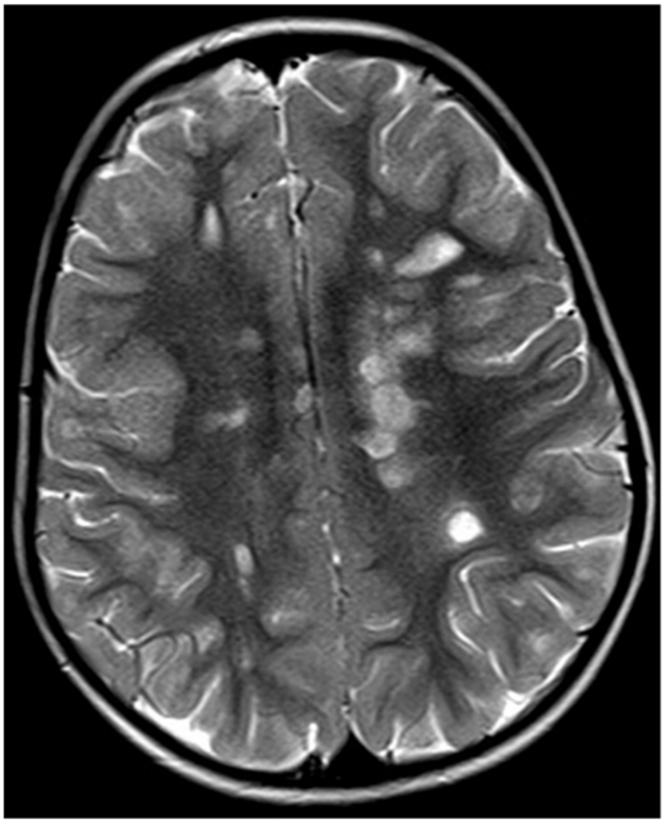

FIGURE 42-7 ■ Acute disseminated encephalomyelitis. T2-weighted MRI showing multifocal areas of increased signal in the white matter. (From Wender M: Acute disseminated encephalomyelitis (ADEM). J Neuroimmunol 231:92, 2011, with permission from Elsevier.)

Acute Hemorrhagic Leukoencephalitis

In roughly 2 percent of children (more rarely in adults), postinfectious encephalitis may present with fulminant hemorrhagic demyelination and cerebral edema, a condition termed "acute hemorrhagic leukoencephalitis," "acute necrotizing hemorrhagic leukoencephalitis," or "Weston Hurst syndrome." MRI demonstrates not only demyelination but also hemorrhage, edema, and at times evidence of ischemia on DWI MRI. In contrast to postinfectious encephalomyelitis, mortality is greater than 50 percent.

Transverse Myelitis

Postinfectious encephalomyelitis may be confined to the spinal cord, resulting in transverse myelitis (Table 42-5). Unlike postinfectious encephalomyelitis, which is more frequent in young children, transverse myelitis is more common in the second decade of life. In the majority of cases, the condition involves the thoracic level of the spinal cord.[15] Onset of symptoms is often abrupt, with rapid progression to maximal deficit; in some patients, however, progression occurs over 1 to 2 weeks. Symptoms typically include fever, back and leg pain, muscle weakness, sensory disturbances, and sphincter dysfunction. Neurologic examination may demonstrate corticospinal tract signs and level-specific sensory loss. The patient may initially exhibit flaccid weakness that progresses over weeks to spasticity. CSF usually shows a lymphocytic or polymorphonuclear pleocytosis with protein levels that may be as high as 500 mg/dL. MRI of the spinal cord often demonstrates focal areas of increased T2 signal. Acute transverse myelitis may represent the first episode of multiple sclerosis, neuromyelitis optica spectrum disorder, or antimyelin oligodendrocyte glycoprotein antibody-related encephalomyelitis. MRI may have diagnostic value in differentiating these entities from postviral transverse myelitis, and partial transverse lesions are more likely to represent these relapsing demyelinating conditions.

Approach to Patients With Postinfectious Neurologic Injury

Patients with clinical relapse following herpes simplex virus encephalitis should be retested for the virus using CSF PCR but should also be tested for anti-NMDAR antibodies in both serum and CSF. Treatment, while awaiting results, should include both acyclovir and high-dose methylprednisolone. Once the presence of viral DNA has been excluded in CSF, acyclovir can be stopped. Methylprednisolone may be supplemented by treatment using plasma exchange, IVIg, or plasma exchange followed by IVIg. The initial approach to the patient with suspected Guillain–Barré syndrome involves hospitalization and, if the patient is demonstrating respiratory failure, intubation (see Chapter 60). The major initial step in patients with suspected postinfectious encephalomyelitis is to exclude multifocal CNS infection or, less likely, vasculitis. In patients with transverse myelitis, extrinsic spinal cord compression requiring surgery must be excluded. Lumbar puncture is of diagnostic value in Guillain–Barré syndrome. In contrast, the most valuable diagnostic test in postinfectious encephalomyelitis or transverse myelitis is contrast-enhanced MRI using gradient echo or susceptibility-weighted images to detect blood products indicative of acute hemorrhagic leukoencephalitis. In Guillain–Barré syndrome, the efficacy of plasma exchange and IVIg has been demonstrated in controlled trials, as discussed in Chapter 60. In contrast, the treatment of ADEM is typically based on case reports and observational studies; some evidence exists for the use of methylprednisolone, usually given at a dose of 1 g daily for 5 days. Plasma exchange (usually five exchanges in total, performed daily or every other day) and IVIg, given as a total dose of 2 g/kg over 3 to 5 days, have also been used, either in combination with methylprednisolone or after methylprednisolone failure. A variety of other immunosuppressive agents including cyclophosphamide have been used in individual cases. Initial treatment of acute transverse myelitis typically involves high-dose intravenous methylprednisolone. Although treatment of acute hemorrhagic leukoencephalitis is frequently unsuccessful, occasional patients have survived after early treatment with combinations of methylprednisolone, IVIg, plasma exchange, or cyclophosphamide[4].

Human immunodeficiency virus type 1 (HIV-1) infection involves the central nervous system (CNS) beginning during primary viremia and continuing over the course of untreated infection.[1] Although the majority of patients with HIV infection do not present with neurologic symptoms, HIV disease has protean manifestations in the CNS determined largely by host characteristics such as immune status, treatment history, and access and adherence to antiretroviral therapy (ART).

HIV BEYOND THE IMMUNE SYSTEM

Nearly four decades after the report of five unexplained cases of *Pneumocystis carinii* pneumonia in men suffering from what would eventually become recognized as the acquired immunodeficiency syndrome (AIDS), HIV infection remains the subject of intense biochemical, molecular, clinical, and epidemiologic investigation. HIV infection is a bloodborne and sexually transmitted disease that impacts both individuals and public health and has disproportionately affected vulnerable and marginalized populations including the poor and underserved, injection drug users, commercial sex workers, and men who have sex with men. The epidemic has also changed in the last decades. What once was largely a disease of young men who have sex with men in urban centers has expanded to affect all populations; the highest route of overall transmission of HIV is currently through heterosexual contact, often in rural areas, underserved and marginalized populations, and individuals unaware of their risk of HIV acquisition.

It is estimated that there are currently 38 million people living with HIV worldwide and 1.7 million new infections annually. Around one million individuals die

Aminoff's Neurology and General Medicine, Sixth Edition.

from the disease and its sequelae each year. Although the greatest number of new infections and the worst outcomes occur in the lowest-resource settings in sub-Saharan Africa and Southeast Asia, nearly 40,000 individuals are newly infected in the United States each year.

A better understanding of the virus's characteristics, including its pathogenesis and transmission patterns, has led to both prophylactic and therapeutic interventions, but many questions about the pathogenesis of HIV infection remain unanswered. An increased focus on the effects of HIV infection beyond the immune system has emerged, including its end-organ effects on the nervous system.

HIV IN THE NERVOUS SYSTEM

HIV is a single-stranded, positive-sense retrovirus of the genus *Lentivirus*. Once transmitted to a new host, the virus uses a reverse transcriptase to transcribe viral RNA into DNA. This DNA is, in turn, integrated into the genome of the host. The stages of HIV infection are divided into the acute phase that immediately follows transmission and includes the $CD4^+$ T-cell nadir; the asymptomatic latent phase characterized by a slow decline in $CD4^+$ T cells; and the symptomatic phase of chronic AIDS. In antiretroviral-naïve patients, it takes approximately 10 years to develop AIDS, although this time may be extended indefinitely with combination ART (Fig. 43-1). Following the development of AIDS, median survival is typically between 1 and 4 years.

It is increasingly recognized that the body's reaction to HIV infection can be as damaging as the activity of the virus itself, and this is particularly true in the nervous system. The inflammatory milieu that is induced by the activity of HIV in invading cells and that triggers an immune response has important implications throughout the time course of infection. It is thought that HIV pathogenesis within the CNS is mediated primarily by inflammation induced by both systemic immune activation as well as HIV infection of macrophages, microglia, and astrocytes. It is hypothesized that an indirect toxic injury to neurons results from a cascade of chronic and persistent neuroinflammation, in part fostered by cytokines produced by infected or activated cells within the

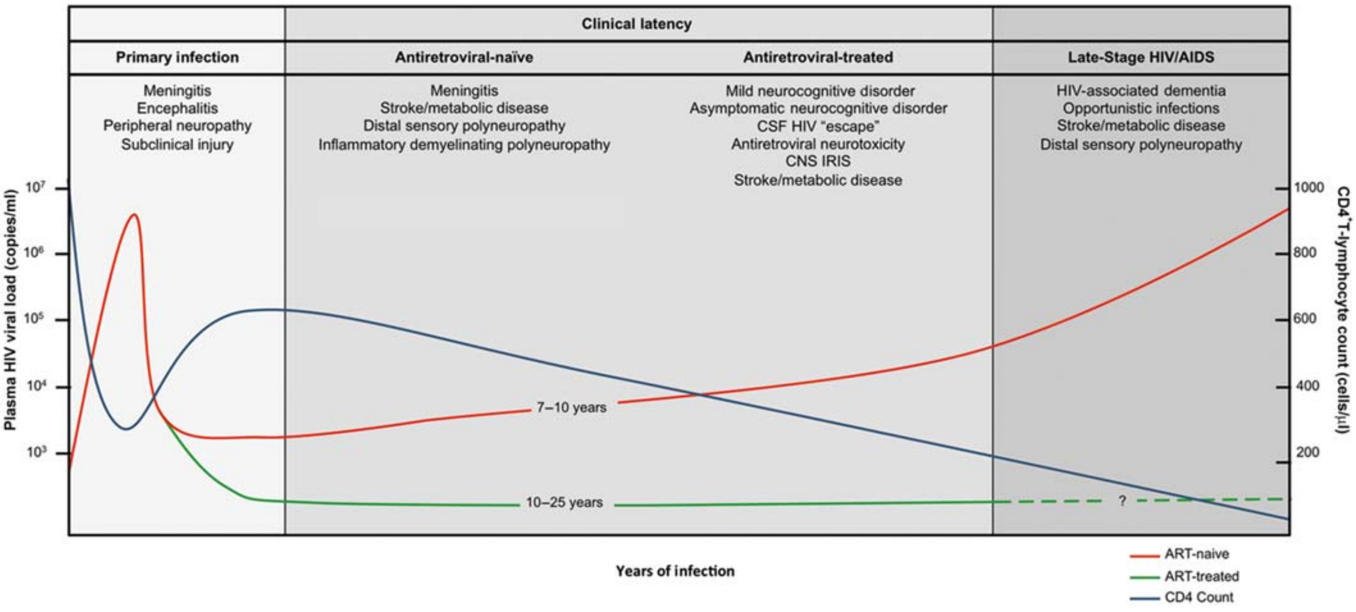

FIGURE 43-1 ■ Typical time course of HIV-1 infection and characteristic neurologic abnormalities. Primary HIV infection refers to the first year following viral transmission, which includes the acute retroviral syndrome, widespread distribution of the virus, the seeding of lymphoid organs, and the $CD4^+$ T-cell nadir. After a recovery in the $CD4^+$ T-cell count, infected individuals enter a long period of clinical latency in which they experience a slow decline in the $CD4^+$ T-cell population. If treatment is not initiated, the $CD4^+$ T-cell count falls to critically low levels and the patient develops acquired immunodeficiency syndrome (AIDS) after 7 to 10 years. This period is characterized by viral proliferation, acquisition of opportunistic infections, and end-organ damage in a variety of body systems, ultimately leading to death from one or a combination of these causes. If treatment is initiated, clinical latency persists for an undetermined period of time, but patients continue to be at risk of a variety of neurologic complications, including several unique to individuals on therapy.

brain. In the earliest stages of infection, the virus crosses the blood–brain barrier for the first time and initiates cytokine release that contributes to breakdown of that barrier. Other effects include a cerebrospinal fluid (CSF) pleocytosis, macrophage and lymphocyte activation, interference with neuronal synthesis and maintenance pathways, and ultimately neuronal injury that can be detected through biomarkers and neuroimaging. Although control of the virus through the initiation of ART can decrease the viral load and suppress the immune response, the CNS remains particularly vulnerable to further insult and may not normalize as well as systemic compartments.[2]

Recent studies of the end-organ effects of HIV beyond the immune system have led to the recognition of a biologic compartmentalization that allows for infection and injury of target tissue, independent evolution of the virus from its counterparts in the plasma, and protection of the virus from systemic therapy. The existence of these distinct biologic compartments, such as those in the breast and genital tract, facilitates viral replication, complicates viral eradication, and leads to organ-specific effects. Chronic HIV infection is associated with the establishment of a CNS reservoir of infection, as evidenced by the detection of HIV DNA in perivascular brain macrophages, microglial cells, and astrocytes, compartmentalization of HIV quasi-species in CNS tissues, and clinical cases of isolated CNS "escape" from ART.[3] Targeting treatments and strategies toward CNS reservoirs of HIV has become an important aspect of recent efforts to achieve a cure for HIV infection.

NEUROLOGIC DYSFUNCTION IN THE SETTING OF ANTIRETROVIRAL THERAPY

The introduction of ART in the mid-1990s fundamentally altered the landscape of both systemic and neurologic HIV disease. The profound immunodeficiency associated with HIV/AIDS that acted as the substrate for the "classic" neurologic manifestations of the disease itself and the opportunistic infections with which it was associated can now be significantly delayed or prevented, transforming the disease from one that was uniformly fatal into a manageable chronic illness.

In general, ART suppresses both plasma and CSF viral levels and improves neurologic outcomes in patients with HIV infection.[4] Typically, plasma HIV RNA suppression is paralleled by suppression in the CSF, and the initiation of ART also limits the extent of immune activation in the CSF, as measured by white blood cell count and immunologic markers. With systemic control of the virus and improved immune status has come a striking decline in the occurrence of neurologic opportunistic infections over the last three decades, while the attenuation of viral replication and immune activation in the CNS has resulted in a decline in the incidence of the most dramatic forms of HIV-associated neurologic disease. Nevertheless, even individuals with well-controlled HIV infection continue to experience neurologic dysfunction which, although often less pronounced than the illnesses experienced 40 years ago, has the potential to seriously impact productivity and quality of life.

HIV-Associated Neurocognitive Disorder

What was previously defined in its most severe form as the AIDS–dementia complex is now represented by a spectrum of disorders reflecting the variability in presentation, outcome, and impact of neurologic disease.

HIV-associated neurocognitive disorder (HAND) comprises a diverse set of neurocognitive diseases, ranging from clinically asymptomatic impairment to severe dementia.[5] HAND is a clinical diagnosis defined by abnormalities identified through neuropsychologic testing and is subdivided into three categories of increasing severity: asymptomatic neurocognitive impairment, mild neurocognitive disorder, and HIV-associated dementia (HAD) (Table 43-1).[5] These diagnoses require the administration of a specific neuropsychologic test battery assessing language, attention, executive functioning, memory (learning and recall), processing speed, visuospatial abilities, and motor skills. While the incidence of the most severe manifestations of HAND has decreased in the setting of widespread access to ART, mild-to-moderate HAND has persisted and has become the most prevalent primary CNS complication of HIV infection.

ASYMPTOMATIC NEUROCOGNITIVE IMPAIRMENT

The most benign and most common manifestation of HAND is asymptomatic neurocognitive impairment, which has been identified in approximately one-third of people living with HIV. It is characterized as a subclinical cognitive decline with decreased performance on neuropsychologic testing in two or more domains not attributable to comorbid conditions (e.g., mood disorders, substance abuse). It specifically requires that

TABLE 43-1 ■ Classification of HIV-Associated Neurocognitive Disorder (HAND) in Patients Being Treated With Antiretroviral Therapy

	Asymptomatic Neurocognitive Impairment (ANI)	Mild Neurocognitive Disorder (MND)	HIV-Associated Dementia (HAD)
Neuropsychologic Testing Abnormalities	One standard deviation below the age- and education-adjusted mean on two cognitive domains	One standard deviation below the age- and education-adjusted mean on two cognitive domains	Two standard deviations below the age- and education-adjusted mean on two cognitive domains, especially learning, information processing, and attention/concentration
Effect on Everyday Function	None	Mild May be noted by self or others, including impairments in mental acuity, work efficiency, maintenance of home life, and social functioning	Marked May be noted by self or others, manifesting as severe difficulty in work, independent maintenance of home life, and social functioning
Dementia	Absent	Absent	Present Other causes such as opportunistic infection, vascular dementia, severe active drug use must be absent

no negative impact on everyday functioning is present, distinguishing it from mild neurocognitive disorder.

It is unclear whether asymptomatic neurocognitive impairment predicts more severe neurologic impairment later in the course of HIV, whether it contributes to neuropathologic vulnerability, and whether initiation of ART before clinically evident neurocognitive impairment develops might prevent ongoing deterioration.

MILD NEUROCOGNITIVE DISORDER

A form of mild cognitive impairment is being recognized increasingly in individuals treated with ART, who typically have a relatively reconstituted immune system characterized by high CD4$^+$ T-cell counts and suppressed or undetectable viral loads. As the population of patients with chronic, well-controlled HIV infection continues to grow, so too does the overall prevalence of mild neurocognitive disorder, which approaches 12 percent in some studies.

The diagnosis of mild neurocognitive disorder depends on the detection of abnormalities in neuropsychologic testing in attention, processing speed, memory, and executive function domains. In contrast to those with asymptomatic neurocognitive impairment, patients typically are aware of a subtle impairment in cognitive ability and increased difficulty carrying out activities of daily living. Mild neurocognitive disorder can also affect both pyramidal and extrapyramidal motor systems, producing symptoms such as ataxia, tremor, and incoordination that may worsen over time. It can lead to behavioral symptoms that are independent of those associated with mood disorders concomitant with HIV infection.

HIV-ASSOCIATED DEMENTIA

The disorder initially described 25 years ago as the AIDS—dementia complex is now known as HAD, the most dramatic manifestation of HAND. The diagnosis remains a challenge, as there are no diagnostic studies or laboratory tests that are specific for HAD.

The diagnosis of HAD is based on progressive neurocognitive impairment and the exclusion of other conditions that can mimic these symptoms including CNS opportunistic infections and mass lesions such as tumors. HAD is still identified most commonly in patients not taking ART; the prevalence in treated patients may be as low as 2 percent. HAD most typically occurs in patients with slowed cognitive processing in the context of longstanding HIV infection and is often accompanied by motor abnormalities such as slowed movement and spastic gait along with hyperactive muscle stretch reflexes. Evaluation with computed tomography (CT) or magnetic resonance imaging (MRI) of the brain is used to exclude other AIDS-related neurologic conditions, including opportunistic infections and CNS lymphoma. With these diagnoses excluded, diffuse cerebral atrophy and subcortical or periventricular white matter changes are consistent with, although not specific for, HAD.

ETIOLOGY

Although the biologic substrate of HAND in the setting of ART is unknown, one potential mechanism involves injury occurring in the earliest stages of HIV infection. Such injury would begin before treatment is initiated and would continue along a trajectory that may or may not be mitigated by initiation of ART. After several

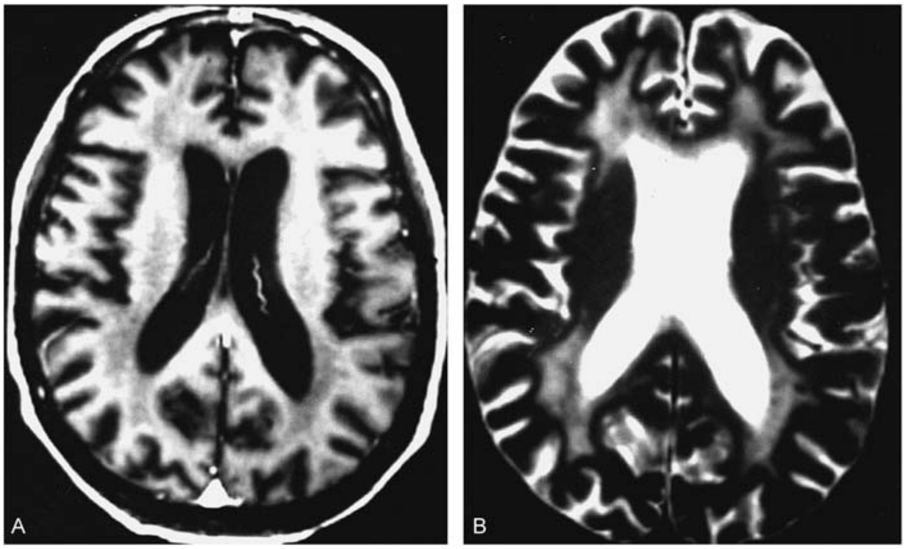

FIGURE 43-2 ■ *A*, T1-weighted magnetic resonance image (MRI) of patient with HIV-associated dementia showing marked cerebral and cortical atrophy. *B*, T2-weighted MRI of the same patient showing extensive hyperintense signal abnormalities in the white matter. (From Berger JR: AIDS and the nervous system. p. 851. In Aminoff MJ (ed): Neurology and General Medicine. 4th Ed. Churchill Livingstone Elsevier, Philadelphia, 2008, with permission.)

years, a combination of host susceptibility and disease factors may result in the development of symptomatic neurologic disease.

Another possibility is that, due to the compartment-specific nature of CNS HIV infection, neurologic injury is incurred despite the initiation and continuation of systemically suppressive treatment. Even in individuals with no overt signs or symptoms of neurocognitive impairment, the presence of HIV in the CNS may result in constant low-level inflammation and immune activation that may lead to ongoing brain injury. CSF immune activation, brain inflammation detected by magnetic resonance spectroscopy, and microglial activation persist in patients taking long-term suppressive ART.

DIAGNOSIS AND MANAGEMENT

Because HAND has no specific diagnostic markers, it is necessary to exclude CNS opportunistic infections, delirium, toxic-metabolic disorders, psychiatric disease, and other neurodegenerative conditions before making the diagnosis. Although traditional neuroimaging is useful in excluding other HIV-associated disease processes, including CNS lymphoma, infections, and inflammatory processes, there are no findings on standard imaging that are specific for HAND (Fig. 43-2). Efforts to use more advanced neuroimaging techniques to identify mild HAND have included brain mapping, high-field structural imaging, functional MRI, and magnetic resonance spectroscopy. The utility of these new modalities remains to be determined. Fig. 43-3 provides an algorithm for the identification and management of HAND.[6]

Performance on neuropsychologic tests in severe forms of HAND improves with the initiation of ART. The introduction of ART has been associated with a decreased incidence and prevalence of HAD despite increases in the prevalence of milder forms of HAND. While initiation of ART significantly improves cognitive performance and neurologic function in antiretroviral-naïve patients with HAD, this improvement is frequently incomplete. Furthermore, many patients already taking ART also have HAND.

TREATMENT

Adjunctive therapies that target the CNS have been studied in an attempt to attenuate the inflammatory events that are postulated in the pathogenesis of HAND. Adjunctive therapies other than antiretroviral agents, including memantine, selegiline, and nimodipine, have not been successful. Valproic acid and lithium have been hypothesized to decrease HIV replication and neuroinflammation through their glycogen synthase kinase-3β activity, as have serotonin reuptake inhibitors such as citalopram and paroxetine through an unknown mechanism; no clear improvement in HAND has been demonstrated with these agents. Due to its anti-inflammatory and antiviral effects, the antibiotic minocycline has also been suggested as a potential therapy, but randomized trials have been unsuccessful. Statins, which decrease progression of vascular disease in people living with HIV and have widespread

anti-inflammatory effects, are under study. Methylphenidate successfully treats fatigue and psychomotor slowing in patients with HAND, but does not alter the course of the disease. An alternate treatment strategy using antiretroviral drugs that penetrate into the CNS is discussed later.

Targeted Treatment of CNS HIV Infection

By separating the CNS from the systemic circulation, the blood–brain and blood–CSF barriers affect the ability of antiretroviral agents to access the CNS compartment. In addition, local spontaneous replication of HIV within this viral sanctuary may allow for independent mutations of HIV virions. While the response of CSF HIV RNA levels to ART parallels that in the plasma, the rate of decay in the CSF may be more gradual in some patients, suggesting a compartmentalization characterized by slower cell turnover, extended macrophage release, or attenuated drug entry.

Because of the blood–brain barrier, HIV in the CNS may be protected from the full effect of antiretroviral agents, especially those drugs that are large or hydrophilic. The CNS penetration-effectiveness (CPE) index represents an effort to estimate quantitatively the relative ability of each antiretroviral agent to penetrate the

CNS and interfere with CSF HIV replication. Each agent is assigned a CPE score based on presumed CNS exposure and efficacy of the drug in relation to others in its class (Table 43-2).

Some studies have shown that antiretroviral regimens with higher CPE scores tend to be more successful at achieving HIV RNA suppression in the CNS. While more potent HIV RNA suppression in this compartment might be expected to lead to better neurocognitive outcomes, results have been mixed, with some studies showing that regimens with higher CPE scores actually lead to poorer neurocognitive performance or only benefit those patients treated with more than the standard ART regimen of three drugs.

The inability of ART to control the potential reservoir of HIV that exists in monocytes or other myeloid lineage cells has been proposed as one possible explanation for continued neurocognitive impairment in the setting of ART. As a result, a monocyte efficacy (ME) score has been proposed as an alternative means of quantifying the ability of antiretroviral agents to affect neurologic outcomes. Preliminary work has suggested that the ME score correlates with neurocognitive performance even when the CPE score does not.

Progressive Disease Despite Systemic Response

Several new clinical syndromes have been recognized in patients taking systemically suppressive ART, often after a long period of apparently successful treatment.

CEREBROSPINAL FLUID ESCAPE SYNDROMES

CSF escape is a phenomenon of CSF/plasma discordance. In an individual with suppressed plasma HIV RNA, CSF escape occurs when the CSF HIV RNA is detectable despite plasma HIV suppression.[3] In an individual with detectable plasma HIV RNA, CSF escape occurs when the level of HIV RNA in the CSF exceeds that in the plasma. A subset of individuals with CSF escape become symptomatic. Patients with symptomatic CSF escape include a broad spectrum of individuals with ART-managed HIV, including those persistently suppressed or well-controlled for many years, as well as those with recent spikes in viral load and those beginning to achieve viral control.

The pathogenesis of symptomatic CSF escape is related to the failure of ART to suppress local CNS infection despite peripheral CD4$^+$ T-cell reconstitution. Although detectable CSF HIV RNA in the context of ART is required, it is not sufficient, since asymptomatic CSF escape has been identified as a frequent finding (up to 18%) in asymptomatic individuals undergoing lumbar puncture in the context of HIV research studies. A moderately reconstituted immune system may actually contribute to the symptomatic syndrome by eliciting a symptomatic inflammatory response and providing a substrate for ongoing discordant HIV replication within the CNS. This process may lie on the spectrum of the immune reconstitution inflammatory syndrome (IRIS), but may represent a stable state of antigen and immune response within the CNS, rather than the exaggerated response upon immune reconstitution that occurs in IRIS. Low $CD4^+$ T-cell nadir (i.e., <250 cells/mm^3) may be a risk factor for CSF "escape," suggesting that a history of advanced immunosuppression may confer increased risk of the syndrome. In addition to resistance and poor penetration, poor medication adherence might also contribute by leading to insufficient drug concentrations in the CSF and thus to the selection of resistant virus within this compartment.

The clinical features of symptomatic CSF escape include a variety of subacute to acute progressive neurologic symptoms including cognitive, sensory, and motor impairment resulting in substantial disability. The diagnosis is achieved through the recognition of plasma/CSF discordance and the exclusion of opportunistic infections including progressive multifocal leukoencephalopathy (PML). Imaging may show white matter hyperintensities on T2-weighted MRI sequences; these are often periventricular. Resistance genotyping of CSF HIV may demonstrate mutations in the CSF viral subpopulation. The CSF typically shows elevated protein levels and white blood cell counts consistent with an inflammatory response beyond that which is seen in healthy controls without HIV infection and neurologically asymptomatic subjects with HIV who are taking ART. Elevated CSF neopterin and pronounced inflammation with $CD8^+$ T-lymphocyte infiltration is seen on brain biopsy. Some patients with CSF escape demonstrate improvement when the ART regimen is optimized based upon the results of genotyping and the CPE score of the current ART regimen.

Notably, a secondary CSF escape syndrome can also occur in the setting of a documented non–HIV-related CNS infection or inflammatory condition. It is possible that each type of CSF escape is associated with a different pathophysiologic process.

$CD8^+$ T-CELL ENCEPHALITIS

Reports of a $CD8^+$ T-cell encephalitis in individuals taking ART probably reflect a disorder on a similar spectrum as CSF escape.[7] Individuals often experience memory impairment associated with extrapyramidal symptoms. This disorder has been considered a form of CNS IRIS related to HIV itself although, as in symptomatic CSF escape, many of these patients developed the syndrome while apparently immunologically stable on ART. Several reports have demonstrated perivascular inflammation and leukoencephalopathy following initiation of ART, which is consistent with previous descriptions of IRIS relating to other pathogens. There are some reports of this condition responding well to corticosteroids after other infectious processes have been excluded.

Emerging Issues in Neurologic HIV Infection

A number of new concerns regarding neurologic manifestations of HIV have arisen in the era of widespread access to ART; epidemiologic shifts in HIV disease incidence, prevalence, and course; and demographic changes in individuals living with the virus.

HIV AND HEPATITIS C COINFECTION

HIV and hepatitis C virus (HCV) coinfection occurs in up to 40 percent of individuals, due in many cases to similar routes of transmission. Injection drug users are more likely to be coinfected with both pathogens. Patients coinfected with HIV and HCV have more rapid progression of both diseases and worse overall clinical and survival outcomes.

HCV has been detected both in brain tissue and in CSF of HIV and HCV coinfected patients, and HCV core protein has been demonstrated to induce neuronal injury. Magnetic resonance spectroscopy has detected reduced cerebral *N*-acetylaspartate in these patients, further suggesting neuronal injury. HIV and HCV coinfected individuals may exhibit a higher prevalence of multiple neurologic disorders than patients living with HIV alone, including an elevated risk of seizures.

Some studies have indicated that coinfection with HIV and HCV leads to more severe cognitive effects than infection with HIV alone. Others have suggested that while the overall level of neurocognitive deficits is similar, specific impaired cognitive domains may differ.[8]

There are many confounding factors related to combined HIV and HCV disease including mood disorders, substance abuse, and socioeconomic influences. HCV management with interferon-alpha, itself known to cause cognitive abnormalities in uninfected individuals, may result in improved cognitive profiles in the coinfected population. Further work is needed to characterize the impact of modern curative hepatitis C therapies on the epidemiology of neurocognitive impairment in this population.

AGING WITH HIV INFECTION

With widespread access to ART has come a dramatic increase in life expectancy for people living with HIV infection, with some now living with the disease for over 30 years. HIV-associated cognitive deficits, particularly mild HAND, therefore have the opportunity to evolve over time and become confounded by typical age-associated neurocognitive disorders. At the same time, some individuals are beginning to acquire HIV infection at older ages, perhaps resulting in host factors that are different from those that characterized the initial epidemic. The risk of HAND appears to be higher in individuals with advanced age, although there is a need for studies that more accurately characterize its prevalence. Furthermore, differentiating HAND from neurodegenerative diseases like Alzheimer disease can be challenging.[9]

The normal process of aging involves the development of subtle deficits in neuropsychologic domains that parallel those affected by HAND, including processing speed, memory, and attention. Studies have suggested that age has an effect on cognitive impairment in patients living with HIV and that older age at seroconversion and duration of infection may increase the risk of HAD. At the same time, the trajectory of neurocognitive decline appears to be accelerated in older people living with HIV, likely due to a combination of age-related and HIV-related impairment.

Imaging studies of individuals living with HIV older than 60 years have shown disruptions in structural networks that exceed that expected with normal aging, even in the setting of access to ART. Individuals predisposed to neurodegeneration by the apolipoprotein E4 allele exhibit even worse neural network disruption. Aging patients with HIV infection display a diminished utilization of brain reserve; while patients without HAND are able to compensate for age-related declines in attention through utilization of brain reserve, individuals with HAND may be unable to do so, leading to worsening cognitive decline. These changes are possibly related to a combination of declines in dopaminergic function and glial activation in the setting of neuronal injury.

The consequences of HAND in the aging population are significant and include reduced medication adherence and increased mortality. For this reason, regular screening for neurocognitive impairment is crucial. Because of the potentially additive effects of age-related and HIV-associated neurocognitive diseases, older persons living with HIV may require additional medical and social services to optimize outcomes.

STROKE

Stroke is under-reported in people living with HIV; during the ART era, rates of hospitalization for ischemic stroke in patients with HIV have increased dramatically, whereas those in uninfected persons have declined.[10] In the context of HIV infection, ischemic stroke affects patients who are more likely female, younger, and lack traditional risk factors for cerebrovascular disease. HIV infection is an important risk factor for stroke in the developing world as well.

In the pre-ART era, most cases of stroke in people living with HIV were attributed to the intracranial opportunistic infections and tumors associated with advanced immunosuppression. In the ART era, the pathogenesis of stroke in people living with HIV is likely due to a multifactorial combination of HIV infection itself and side effects from the activity of antiretroviral agents including dyslipidemia.

HIV itself induces endothelial activation, which can lead to ischemic vascular events in the heart and brain. Cardiac disease has been increasingly recognized in people living with HIV, and cardioembolic causes of cerebral ischemia are more common than in the pre-ART era. Especially in the late stages of the disease, patients living with HIV may have diastolic dysfunction and HIV-associated dilated cardiomyopathy, which is identified as the cause of stroke in up to 20 percent of patients. While opportunistic infection-related vasculitis was commonly implicated in ischemic stroke in the pre-ART era, a small-vessel vasculopathy related to the virus itself is increasingly common. Hypercoagulability and intracranial aneurysms occur more frequently in this population than the general population and can also lead to stroke.

Although ART increases life expectancy, it also may allow patients to develop age-related atherosclerotic disease. Longer exposure to the virus itself may exacerbate stroke risk through mechanisms described earlier. In addition, the protease inhibitors used in ART regimens contribute to numerous metabolic abnormalities including lipodystrophy, dyslipidemia, and insulin resistance. While some agents are associated with adverse cardiovascular outcomes in large cohort studies, uncontrolled HIV viremia is almost certainly a greater risk factor for stroke than antiretroviral medications. Patients who interrupt therapy to reduce their overall exposure to antiretroviral drugs demonstrate increased cardiovascular-related morbidity and death.

Metabolic disorders also worsen neurologic performance outside of the context of clinically detectable stroke in patients with HIV infection. Insulin resistance and poor glucose control have been associated with poorer neurocognitive performance. Clinical or subclinical carotid artery disease is also associated with neurocognitive decline, and central obesity contributes to worse neurocognitive performance in people living with HIV.

Central Neurotoxicity of Antiretroviral Agents

The tissue-specific adverse effects of antiretroviral agents outside the nervous system include pancreatitis, lactic acidosis, ototoxicity, and lipodystrophy. In addition to controlling systemic HIV levels, a goal of therapy is to protect the brain from damage related to viral pathogenesis and to eliminate the CNS reservoir of the virus. Although ART that achieves sufficient penetration into the CSF can successfully control CNS viral replication, there has been growing concern that the therapeutic concentrations needed to achieve effective viral suppression are associated with an increased risk of neurotoxic adverse effects.

While several drugs may have neurotoxic potential, many of these medications are used rarely in the era of modern ART. The mechanism of antiretroviral toxicity outside the nervous system may relate to inhibition of mitochondrial DNA production, but it is unclear whether this occurs in the CNS. Neurotoxicity may be related not to cell death, but rather to reversible dendritic changes.

The adverse reactions associated with efavirenz are the most common and include sleep disturbances (e.g., abnormal dreams, nocturnal awakening, and insomnia), mood disorders, impaired concentration, and, in some cases, suicidal ideation.[11] These reactions typically occur in the days following initiation of treatment and are most common during the first 4 weeks; nearly half of all patients will experience some form of reaction, and the effects can persist for months or years. The incidence of these side effects may be related to drug concentration, which demonstrates significant variability between individuals, possibly related to differences in liver metabolism. Although the adverse effects of efavirenz have typically been considered mild, they can also manifest as severe depression, mania, and aggression. Neuropsychiatric effects are the primary reason for efavirenz discontinuation.

In many settings, dolutegravir has replaced efavirenz as first-line ART. A large population-based study in Botswana showed a statistically significant but not substantially increased risk of fetal neural tube defects when this agent is used in early pregnancy; it remains part of first-line therapy (with appropriate counseling) in most treatment guidelines. While this drug is generally well-tolerated in adults, there are emerging data that a subset of patients may experience dizziness or insomnia associated with its use.[12] Mood disorders, including depression and suicidality, have also been reported in a small number of patients with pre-existing comorbid psychiatric conditions. Despite these issues, discontinuation of this agent is very low and it has become a crucial component of HIV regimens worldwide.

NEUROLOGIC DYSFUNCTION IN ANTIRETROVIRAL-NAÏVE PATIENTS

The advent of ART has led to a 10-fold decrease in CNS disease. However, some patients still present with the classic complications of AIDS. This decline of neurologic complications in the developed world has not been paralleled in resource-poor settings internationally, where the diagnosis and management of neurologic disease are complicated by a lack of access to HIV diagnostic and neurologic imaging technology and co-infections with endemic pathogens including malaria and tuberculosis. Even in the era in which guidelines recommend treatment for all people living with HIV, many do not have access to ART and begin treatment late in the disease course.

Effects of Primary HIV in the Central Nervous System

The study of neurologic disease in HIV infection has traditionally focused on chronic and late-stage neurocognitive manifestations, but recent work has shown effects of HIV on the CNS much earlier in the disease course, including during primary HIV infection (defined as the first year following transmission of the virus). Primary HIV infection is characterized by a rapid and dramatic rise of HIV RNA levels in the plasma, accompanied by an increase in HIV antibody levels that are detectable within 2 weeks of transmission by fourth-generation enzyme immunosorbent assay tests. In at least two-thirds of individuals, the period of seroconversion is accompanied by the acute retroviral syndrome, characterized by vague symptoms of fatigue, malaise, fever, and anorexia. Within a few months of seroconversion, a partially effective immune response causes HIV RNA to stabilize at a reduced, chronic, individual-specific level. This plateau is a result of the increased activity of CD8$^+$ T cells in conjunction with a decreased reservoir of $CD4^+$ T cells available for infection by the virus.

In addition to the acute retroviral syndrome, a subgroup of individuals newly infected with HIV develop neurologic symptoms and signs around the time of seroconversion. HIV can be found in the CSF and brain tissue of patients during the earliest stages of infection, in the weeks to months following viral transmission. Indeed, HIV has been identified in the CSF as early as 8 days after transmission.[1] Immune activation accompanies the presence of HIV virions in the CSF during primary infection, and the elevation in CSF leukocyte count, neopterin, and inflammatory cytokines during the first months of infection suggests that CNS injury can take place even during this period. Biomarkers of neuronal injury are elevated in patients with primary HIV infection and correlate with both neuroinflammatory markers and magnetic resonance spectroscopic evidence of neuronal dysfunction.

One of the first syndromes to be linked with primary HIV infection was aseptic meningitis, characterized by a CSF lymphocytosis with or without clinical signs of meningitis. Other individuals experience varying degrees of encephalopathy in the setting of meningoencephalitis, encephalitis, or encephalomyelitis. Acute neuropathies, including facial nerve paralysis and optic neuritis, also occur frequently with seroconversion and are common in acute HIV infection. Although clinically heterogeneous, these neurologic syndromes associated with primary HIV infection share several common features, including onset 2 to 3 weeks after the symptomatic manifestations of the acute retroviral syndrome, a self-limited course, and evidence of temporally associated HIV seroconversion. The pathogenesis of these syndromes is therefore probably due to a host-mediated autoimmune response in the setting of massive systemic immune activation. Evaluation of patients with these acute neurologic syndromes should include not only HIV antibody testing but also nucleic acid testing for the presence of HIV by polymerase chain reaction (PCR) since antibody responses may be absent or indeterminate during the earliest stages of infection.

Symptomatic seroconversion, also characterized by a variety of non-neurologic symptoms, has been associated with more rapid disease progression. It appears that these early signs of neuroinflammation are related to objective neuronal injury, but it is unclear whether inflammation or injury at this early time-point predicts neurologic outcomes in later stages of the disease, and whether the early initiation of ART can ameliorate these processes before systemic immunosuppression occurs.

CNS Complications of Longstanding Untreated HIV Infection

CLASSIC HIV-ASSOCIATED DEMENTIA

The disorder now called HAD was initially described as the AIDS–dementia complex. There are no individual diagnostic studies or laboratory tests that are specific for HAD. Identification of this disorder depends on the recognition of the clinical syndrome and the exclusion of alternative diagnoses. Diagnostic criteria and approach to treatment were described earlier and in Table 43-1. Initiation of ART in these treatment-naïve patients is associated in the majority with a dramatic improvement of clinical signs and symptoms over the early weeks to months of treatment. More gradual improvement may be detectable up to 18 months later.

OPPORTUNISTIC INFECTIONS

For the first two decades following the discovery of HIV infection, opportunistic infections were among the most dramatic and dreaded complications of the disease (Table 43-3).[13] The incidence of these complications has declined with the widespread use of ART in the developed world, but HIV-associated opportunistic infections remain a significant cause of morbidity and mortality worldwide, particularly in individuals whose access or adherence to ART is limited.

Any individual with advanced HIV infection is at risk for the development of a CNS opportunistic infection, including patients with AIDS who are not on therapy, those with undiagnosed HIV (who may initially present with a CNS opportunistic infection), and those in whom ART has begun (who in turn might develop IRIS, as described earlier). More rarely, patients on ART may develop CNS opportunistic infections, due either to failure of complete viral suppression or to lack of immunologic restoration on ART.

CNS opportunistic infections should be considered in patients experiencing significant immunosuppression, typically below 200 $CD4^+$ T cells/μL, although some opportunistic disorders (e.g., tuberculosis meningitis, PML) can manifest in individuals with higher T-cell counts. Diagnosis is typically made using a combination of the clinical presentation (including host factors, symptoms, presence of other known active infections, presence or absence of prophylactic medications, and serologies) combined with CSF and imaging studies. In settings where investigations are limited, clinicians may be required to rely upon the history and physical findings alone.

A description of the time course and determination of whether focal deficits are present are important

elements for determining the identity of a CNS opportunistic infection (Fig. 43-4). Some infections, such as cryptococcal meningitis, cytomegalovirus encephalitis, and toxoplasmosis, manifest acutely over a few days. Others, such as primary CNS lymphoma and PML, follow a subacute course over weeks to months. Focal deficits typically characterize infections that involve mass lesions, such as primary CNS lymphoma or toxoplasmosis, and are also seen in PML. These localizing signs are less frequently present in other opportunistic infections causing meningitis or encephalitis.

Once a particular opportunistic disease process has been identified, ART should be initiated or modified in conjunction with appropriate antimicrobial therapy. Typically such treatment is required until immune recovery ($CD4^+$ T-cell count exceeding 200 cells/μL for 6 months) has been achieved. When this is not possible, patients may need to remain on lifelong antimicrobial suppression.

Multiple opportunistic processes co-exist in up to 15 percent of these patients.[13] The presence of a concurrent process must be considered in patients who worsen despite apparently adequate treatment for the initial infection.

Toxoplasmosis

The incidence of toxoplasmosis encephalitis in people living with HIV has declined substantially since the

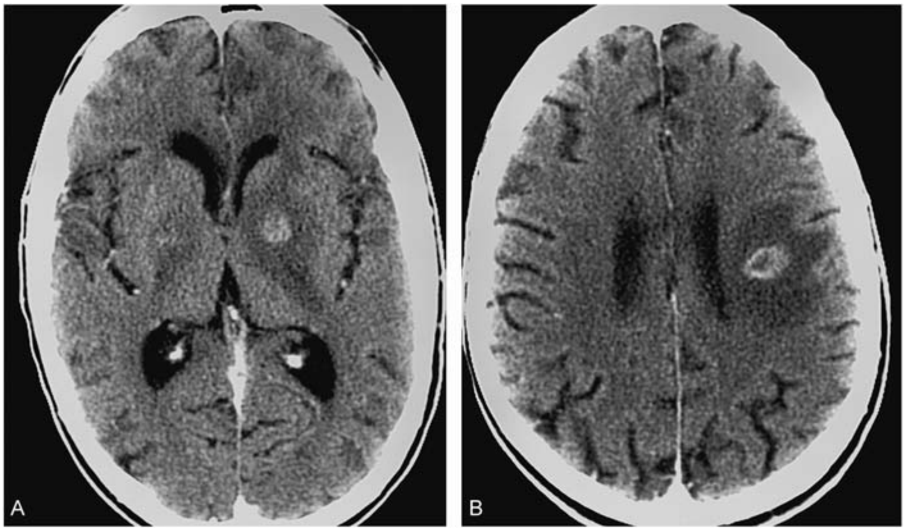

FIGURE 43-5 ■ A 33-year-old HIV-positive man presented with a seizure and right hemiparesis. *A*, Contrast-enhanced CT scan shows edema in the basal ganglia bilaterally, with abnormal central enhancement, more marked on the left than on the right. The ventricles and sulci are excessively prominent for a patient of this age, consistent with the global parenchymal volume loss of HIV dementia. *B*, A more superior image shows a ring-enhancing lesion with surrounding vasogenic edema in the left frontal lobe. The patient's anti-*Toxoplasma* titer was positive, and he responded well to a course of toxoplasmosis-specific therapy, supporting the diagnosis of toxoplasmosis. (Courtesy Nancy Fischbein, MD.)

introduction of ART, but it remains the most common neurologic opportunistic disease associated with HIV infection in many regions. The infection is related to the reactivation of latent toxoplasmic bradyzoites that survive in brain and muscle after the initial ingestion of oocysts and replication of tachyzoites. The immunodeficiency caused by HIV infection results in a loss of the ability of CD4$^+$ T cells to control this latent infection.

Patients with toxoplasmosis present with fever, headache, and focal deficits that may be accompanied by an altered mental state as described in Chapter 46. These symptoms usually present rapidly over a few days to weeks. Brain imaging demonstrates single or multiple ring-enhancing lesions, most often located in the deep gray matter, although they can be present anywhere in the brain (Fig. 43-5). A "target sign" of enhancement has been recently recognized to be a hallmark imaging finding. Serum *Toxoplasma* IgG is typically positive, but, as immunity may wane with advanced immunosuppression, treatment for toxoplasmosis is recommended even in those with negative tests when suspected clinically. CSF PCR-based detection of *Toxoplasma* DNA has a reduced sensitivity in patients with AIDS.

Traditionally, toxoplasmosis has been treated with a combination of pyrimethamine, folinic acid, and sulfadiazine. In resource-poor settings, trimethoprim-sulfamathoxazole has been shown to be equally effective, and this regimen has become increasingly used in the United States due to cost-related access issues for pyrimethamine. Patients typically experience improvement within the first week of initiating therapy, and if there is no response to therapy within 5 days, alternative diagnoses should be considered. After the 6-week induction period, maintenance therapy should continue until the patient's immune system is reconstituted with a CD4$^+$ T-cell count persistently above 200 cells/μL. Compared with other neurologic complications of HIV, there have only been sparse reports of IRIS with toxoplasmosis. In people living with HIV, the 1-year mortality associated with toxoplasmosis is as high as 60 percent, although in patients who have immune recovery due to ART and adherence to antitoxoplasmosis treatment, recovery is possible, sometimes with little or no clinical sequelae of disease.

Primary CNS Lymphoma

Primary CNS lymphoma in HIV patients is most commonly a multicentric, high-grade, B-cell tumor associated with monoclonal Epstein–Barr virus infection. Patients may experience a nonspecific syndrome of lethargy, altered cognition, headache, and focal abnormalities associated with growth of the mass lesion. Symptoms usually are present for several weeks and may be associated with constitutional symptoms such as low-grade fever, weight loss, and night sweats. In some cases, primary CNS lymphoma may present as an infiltrative lesion that resembles an encephalitis or rhombencephalitis, without focal findings or headache.

Classic lesions on MRI are multifocal, supratentorial, and often located along the ependyma. They may demonstrate heterogeneous ring enhancement with contrast, and be accompanied by marked edema and mass effect, leading them to be radiologically indistinguishable from *Toxoplasma* abscesses. More rarely, they may be hypodense on CT or hyperintense on T2-weighted MRI sequences with no enhancement and little mass effect. Patients are often given empiric anti-*Toxoplasma* therapy if radiologically compatible lesions are identified and serum *Toxoplasma* IgG is positive. If no improvement is noted within 5 days, further aggressive evaluation for alternate causes, including primary CNS lymphoma, is warranted. Identification of EBV DNA in the CSF can be a useful test in patients with HIV and suspected CNS lymphoma; although the sensitivity is low, using a cut-off value of 10,000 copies/mL can significantly improve specificity. A positive EBV PCR in CSF combined with a hypermetabolic lesion on positron emission tomography or single-photon emission computed tomography scan has been considered adequate for initiation of treatment for lymphoma. In some cases a brain biopsy is required for definitive diagnosis.

The prognosis of primary CNS lymphoma has improved dramatically in the ART era. Patients are treated with effective ART, combined with antitumor therapy employed for persons who are not living with HIV, including radiation and high-dose methotrexate. However, adverse effects of these intensive life-saving treatments may include neurologic and cognitive dysfunction that can manifest and even progress as patients survive long term into middle and advanced age.

Cryptococcal Meningitis

The inhalation of the encapsulated yeast *Cryptococcus neoformans* from soil or pigeon droppings leads to primary, latent, or disseminated disease (see Chapter 45). Although primary infection is typically pulmonary in nature, cryptococcal meningitis can result from reactivation of latent infection in immunocompromised patients. The reactivated yeast forms cerebral "soap-bubble cysts," which are accumulations in the Virchow–Robin spaces surrounding the deep penetrating vessels.

Cryptococcal meningitis often leads to communicating hydrocephalus. More than 15 percent of patients develop increased intracranial pressure, which may present with headache, vomiting, visual and hearing loss, cranial nerve palsy, altered consciousness, and even death. In some cases, hydrocephalus may be asymptomatic.

The organism may be detected in the CSF with either India ink staining or the more sensitive and specific cryptococcal antigen assays. Cryptococcal serum antigen has been demonstrated to be highly sensitive for CNS disease in people living with HIV. Neuroimaging may be normal or show hydrocephalus, leptomeningeal enhancement, gelatinous pseudocysts (particularly in the basal ganglia), or, more rarely, enhancing lesions in the parenchyma bordering the CSF spaces, especially in the posterior fossa and occipital lobes.

Management of cryptococcal meningitis, particularly when associated with increased intracranial pressure, prevents blindness, deafness, brain injury, and death. Serial daily lumbar punctures, each removing enough CSF volume to keep the pressure below 20 cmH_2O, can improve symptoms and reduce neurologic morbidity. First-line therapy for cryptococcal meningitis is intravenous amphotericin B with oral flucytosine for 2 weeks, followed by oral fluconazole for 8 weeks. Generally, ART should be deferred until at least 4 weeks of antifungal treatment have been provided to minimize the risk of CNS complications and mortality related to IRIS.[14] Prophylaxis with fluconazole should be continued at least until the patient's immune system is reconstituted.

Cytomegalovirus Encephalitis

Cytomegalovirus (CMV) is widespread—most individuals worldwide become infected by adulthood. Encephalitis caused by CMV typically occurs only in patients with advanced immunosuppression ($CD4^+$ count <50 cells/μL). Patients typically appear acutely ill, with a rapidly progressive encephalopathy that may be accompanied by seizures and typically involves bilateral subependymal structures, leading to profound amnesia. In addition, patients may experience visual symptoms including central scotoma, loss of peripheral vision, or floaters—signs of CMV retinitis which, if untreated, can lead to blindness and warrant ophthalmologic evaluation. Additionally, concomitant adrenal involvement can lead to hyponatremia.

The diagnosis of CMV encephalitis involves identifying meningeal or periventricular enhancement on MRI. CSF studies reveal a pleocytosis with neutrophils as the predominant cell type and may also show red blood cells and xanthochromia along with a high protein level. CMV PCR in the CSF is highly sensitive and specific for the diagnosis, and quantitative testing can aid in monitoring the response to therapy.

CMV encephalitis in people living with HIV should be treated with ART plus an anti-CMV agent such as ganciclovir or valganciclovir. Patients are often left with profound morbidity even when the progression of disease is halted. Retinitis can be managed with a sustained-release antiviral intraocular implant and prevented with oral gangciclovir. Other agents, such as foscarnet or cidofovir, can be considered in cases in which leukopenia or resistance is an issue. All patients should continue on prophylaxis with long-term oral therapy until they achieve a persistent $CD4^+$ T-cell count exceeding 200 cells/μL.

Progressive Multifocal Leukoencephalopathy

PML is caused by the JC virus, a common polyomavirus that reactivates in immunosuppressed individuals and occasionally in individuals with high $CD4^+$ T-cell counts. While the sequence of events leading to PML is unclear, it is likely to be related to viral mutations conferring neurovirulence and the subsequent infection of oligodendrocytes and astrocytes.

Patients with PML experience subacute to acute progressive focal neurologic deficits. Brain MRI shows one or more subcortical confluent white matter lesions corresponding to the clinical deficits. These lesions have typical qualities of demyelination, including marked hyperintensity on T2-weighted sequences and hypointensity on T1-weighted sequences, with no mass effect and absent or only trace enhancement with contrast. CSF JC virus PCR is highly specific but has a sensitivity of only 60 to 80 percent in the ART era; repeat CSF analysis may be warranted if the test is negative and clinical suspicion high. A CSF pleocytosis is typically absent and a mildly elevated protein concentration is the most common abnormal finding on routine CSF analysis. Rarely, brain biopsy is required to make the diagnosis.

Immune reconstitution induced by ART results in PML remission in the majority of people living with HIV; before the ART era, remission was rare. Immune reconstitution with ART in patients with PML increases survival from 10 to 75 percent. PML arrests or remits in approximately 50 percent of patients who are being treated with ART.

There is no effective JC virus-directed antiviral therapy despite studies of cidofovir, mefloquine, and mirtazapine. Paradoxically, neurologic IRIS has been extensively described in the context of PML through recognition that the initiation of ART results in emergence of an unexpected number of PML cases, many of which have atypical features on neuroimaging including avid contrast enhancement. These cases of PML suggest that immune reconstitution leads to an extreme, but localized, inflammatory response in a subset of patients, with JC virus serving as the inciting antigen. Corticosteroids may be beneficial in such cases although recommendations are conflicting. Emerging data on approaches using novel immunotherapy, including checkpoint inhibitors, adoptive transfer of donor-derived T-cells, and treatment with interleukin-7, offer hope that more effective treatments are on the horizon.

Tuberculous Meningitis

Nearly one-third of the global population is infected with *Mycobacterium tuberculosis*, a bacillus that is transmitted through aerosolized droplets and controlled by T-cell immunity (see Chapter 40). When this immunity wanes with HIV infection, *M. tuberculosis* disseminates to extrapulmonary sites including the CNS. Within the CNS, granulomas are formed in the subpial and subependymal layers of the brain, and these can expand into abscesses or rupture to cause meningitis. The mortality from tuberculous meningitis in patients with HIV is over 50 percent, and ART initiation does not necessarily improve outcomes.

Despite the importance of rapid treatment of tuberculosis infection, definitive diagnosis is often challenging since the tuberculin skin test and interferon-gamma release assay are particularly insensitive in patients with $CD4^+$ T-cell counts below 200 cells/μL. The CSF profile typically shows increased lymphocytes, depressed glucose, and normal or mildly elevated protein levels. In many resource-poor settings, the diagnosis of tuberculous meningitis may rely only upon CSF studies without a definitive molecular diagnosis through culture or PCR-based techniques.

Management of tuberculous meningitis begins with a standard quadruple-therapy regimen (e.g., rifampin, isoniazid, ethambutol, and pyrazinamide) for 2 months, followed by 9 to 12 months of isoniazid and rifampin maintenance therapy. In cases in which the organism is drug-resistant, second-line therapies including fluoroquinolones and injectable aminoglycosides must be used; worse outcomes occur in these individuals.

Antimycobacterial therapy should begin prior to the initiation of ART in patients with tuberculous meningitis, presumably to decrease the risk of IRIS. Drug–drug interactions between HIV and antituberculous drugs are an important consideration in these cases. The use of adjuvant corticosteroids remains controversial in tuberculous meningitis; studies have suggested that dexamethasone decreases mortality but may not improve morbidity in those patients who survive the illness.

SPINAL CORD DISEASE ASSOCIATED WITH HIV INFECTION

The most common spinal cord disorder in patients with AIDS is vacuolar myelopathy, which before the ART era was present in 30 percent of patients at autopsy and closely associated with opportunistic infections. Patients present with progressive leg weakness and spasticity along with sensory ataxia and loss of vibratory and joint position sense. Urinary frequency and urgency as well as erectile dysfunction may also occur. There is typically an absence of back pain and no involvement of the upper extremities. A lumbar puncture should be performed to exclude infectious or oncologic causes. Spinal MRI should be performed to exclude space-occupying or compressive spinal cord lesions, but is typically normal. In some cases, cord atrophy or nonenhancing T2-weighted hyperintensities may be present, correlating with histopathologic findings of vacuolation.

Management of HIV-associated myelopathy should focus on physical and occupational therapy and symptomatic management, with adjunctive treatments to manage pain, spasticity, and incontinence.

HIV-ASSOCIATED PERIPHERAL NEUROPATHIES

The peripheral nervous system is particularly affected during primary HIV infection, and peripheral neuropathies constitute the most prevalent neurologic problems in patients with AIDS. The most common of these chronic peripheral neuropathies are a distal sensory polyneuropathy and a neuropathy secondary to antiretroviral toxicity.

Distal Sensory Polyneuropathy

Distal sensory polyneuropathy occurs in up to two-thirds of people living with HIV and is most common in older patients with more advanced disease characterized by low $CD4^+$ T-cell counts and high plasma viral loads. It is particularly common in individuals with concomitant alcohol use or diabetes, and in those who have used neurotoxic first-generation antiretrovirals including stavudine and didanosine.

The distal sensory polyneuropathy may be related to loss of distal unmyelinated fibers in addition to Wallerian degeneration of myelinated fibers. Patients experience progressively worsening parasthesias and dysthesias that begin distally and then slowly spread to more proximal regions. In late disease, the thighs and hands may be affected and distal muscle wasting may occur. The diagnosis can usually be made by the history and a neurologic examination, with decreased ankle reflexes and diminished vibratory, pinprick, and temperature thresholds in the legs. Patients with a co-existing myelopathy may have a mixed picture of proximal hyper-reflexia and distal hyporeflexia. Distal sensory polyneuropathy should be considered as a diagnosis of exclusion after other neuropathic processes including diabetes, syphilis, thyroid abnormalities, and vitamin deficiencies are considered. Electromyography and nerve conduction studies demonstrate features of a predominantly axonal neuropathy but are usually not necessary to make the diagnosis.

Treatment begins with the discontinuation or dose reduction of neurotoxic antiretroviral drugs, with subsequent resolution in neuropathic symptoms usually taking between 8 and 16 weeks. Following antiretroviral discontinuation, symptoms might actually worsen for 4 to 8 weeks in a phenomenon known as the "coasting period." Symptomatic management involves treatment of neuropathic pain with gabapentin, pregabalin, lamotrigine, or tricyclic antidepressant medications, which are all generally compatible with antiretroviral medications including protease and integrase inhibitors.

Inflammatory Polyneuropathies

Inflammatory neuropathies are relatively uncommon in patients with HIV infection. Primary HIV infection may be complicated by an acute inflammatory polyneuropathy; patients experience a rapidly ascending paralysis and loss of reflexes. Unlike typical Guillain–Barré syndrome, albuminocytologic dissociation may not occur in the CSF. Chronic inflammatory demyelinating polyneuropathy progresses more slowly and often relapses.

Since inflammatory neuropathies are thought to be associated with an autoimmune component, it has been suggested that they might respond to immunomodulation with plasmapheresis or intravenous immunoglobulin. In severely immunosuppressed patients with evidence of co-existing CMV infection, therapy with ganciclovir, foscarnet, or cidofovir is recommended.

HIV infection may cause a sensory neuronopathy or rarely a systemic vasculitis. The vasculitis typically occurs in the early symptomatic stage of the disease and may lead to a mononeuropathy (single or multiple) or to cranial neuropathies. Nerve biopsy shows a necrotizing vasculitis. Other causes of mononeuropathy, such as herpes zoster, CMV infection, or lymphomatous infiltration of nerve roots, must be excluded. Multifocal neuropathies in people living with HIV may also arise from neurolymphomatosis and diffuse infiltrative lymphocytosis syndrome.

A cauda equina syndrome due to CMV infection may occur with advanced HIV infection or, less commonly, at first presentation. It is characterized by progressive paraparesis and sacral paresthesias, with ascending sensory loss, areflexia, and sphincter dysfunction. A similar presentation may occur in the upper extremities; this polyradiculitis presents with pain, weakness, and often asymmetric atrophy. The CSF typically shows a polymorphonuclear pleocytosis, and CMV may be detected by culture or DNA PCR assay. In occasional instances, cytomegalic cells may be found in the CSF. Treatment is with ganciclovir, foscarnet, or both.

MUSCLE DISORDERS AND HIV INFECTION

These are discussed in Chapter 60 and are mentioned here only briefly. Several muscle disorders may occur in people living with HIV including polymyositis and a syndrome resembling inclusion-body myopathy. A myositis resembling polymyositis also occurs as part of IRIS. Type II muscle fiber atrophy sometimes leads to proximal muscle weakness and wasting, accompanied by a normal serum CK level. Vasculitic processes and opportunistic infections can involve muscle—treatment involves antiretroviral and immunomodulatory agents or specific antimicrobial therapy. Pyomyositis manifesting as localized pain and swelling in a limb is usually associated with *Staphylococcus aureus* infection. Nemaline rod myopathy may occur with or without associated inflammation.

High-dose zidovudine treatment may cause a proximal myopathy associated with myalgias in the thighs and calves. Serum CK levels are normal or mildly elevated. Muscle biopsy reveals "ragged red" fibers consistent with mitochondrial toxicity. Discontinuation of the medication usually results in improvement but recovery is sometimes incomplete.

INFECTION WITH HUMAN T-LYMPHOCYTIC VIRUS TYPE I

Worldwide, as many as 20 million people are infected by the human T-lymphocytic virus type I (HTLV-1), a retrovirus endemic to Japan and equatorial regions of the Caribbean, South America, and Africa. In these areas, the prevalence of HTLV-1 can be as high as 2 percent. In the United States, HTLV-1 infection is most common in Native American and African American populations. Like HIV, HTLV-1 is a bloodborne virus that can be transmitted through sexual contact, breastfeeding, intrauterine infection, intravenous drug use, and exposure to contaminated blood products.

The majority of individuals harboring the HTLV-1 virus are asymptomatic carriers. Between 2 and 3 percent of patients develop adult T-cell leukemia, which in many cases is fatal. Up to 4 percent exhibit a progressive, debilitating myelopathy known as HTLV-associated myelopathy or tropical spastic paraparesis (HAM/TSP).

Although commonly used, the term HAM/TSP is problematic since HTLV-associated disorders are limited neither to myelopathy nor to tropical regions of the world. HAM/TSP is best conceptualized as a variety of neurologic syndromes caused by HTLV-1 infection.

Pathogenesis of Neurologic Disorder

The mechanism by which HTLV-1 induces HAM/TSP is uncertain, but may be related to direct glial cell toxicity, autoimmunity resulting from molecular mimicry, or the generation of myelinotoxic metabolites by a neuroinflammatory response within the CNS. Genetics may also play a role in determining the magnitude of the immune response or in affecting the rate of disease progression.

Symptoms, Signs, and Course of Infection

HAM/TSP presents as a slow, progressive spastic paraparesis accompanied by bladder dysfunction and sensory abnormalities. The most common symptoms are leg weakness and difficulty walking, sometimes associated with leg and back pain and with parasthesias. Falls are common and result in significant morbidity. Urinary symptoms include nocturia and hyperactive bladder; erectile dysfunction also occurs. Patients with HAM/TSP have high rates of co-existing depression.

HAM/TSP is associated with non-neurologic manifestations including pulmonary abnormalities (e.g., centrilobular nodules, thickened bronchovascular bundles, ground-glass opacities, bronchiectasis, intralobular septal thickening), bladder and renal infections, arthritis, and the presence of other autoimmune disorders (e.g., Sjögren syndrome, sarcoidosis). These processes probably result in part from the altered host immune response induced by HTLV-1.

Typical signs in HAM/TSP include a spastic paraparesis with reduced pain sensation, along with bilateral upper-extremity hyper-reflexia in the absence of arm weakness. Urodynamic studies demonstrate bladder dysfunction. Less commonly, patients have neuromuscular manifestations including inflammatory myopathy or demonstrate ophthalmologic findings such as uveitis, retinal vasculitis, or lymphomatous eye infiltration.

Progression from mild to severe disability can range from 2 to 10 years. Risk factors for more rapid progression include severe spasticity, diminished vibration sense, and the presence of tremor. Disease progression is more rapid in women than men, particularly in those who are premenopausal.

Proviral load, the number of integrated copies of HTLV-1 expressed as a proportion of peripheral blood mononuclear cells, has also been identified as a marker of disease progression. Whereas the viral load in an untreated patient with HIV infection increases as the disease progresses, the HTLV-1 proviral loads remains relatively stable. Symptomatic individuals have proviral loads at least 10 times greater than asymptomatic individuals and progress more rapidly, possibly due to increased activity of infected lymphocytes in the CNS. Unlike HIV infection, the proviral load is maintained through cell division rather than viral replication, resulting in a slower evolution.

Diagnostic Studies

The diagnosis of HAM/TSP requires the exclusion of other disorders that can cause a chronic, progressive spastic paraparesis including mass lesions within the spinal cord, extrinsic cord compression, multiple sclerosis, amyotrophic lateral sclerosis, vitamin deficiencies (e.g., vitamin B_{12}), syphilis, and HIV vacuolar myelopathy.

In addition to serologic testing for the presence of the virus and determination of the proviral load, the peripheral blood smear in HAM/TSP reveals atypical lymphocytes with convoluted nuclei, known as “flower cells.” Further serologic testing may show hypergammaglobulinemia, increased β_2-microglobulin, and an elevated $CD4^+$ T-cell count.

The CSF in patients with HAM/TSP demonstrates a lymphocyte-predominant pleocytosis and elevated CSF protein concentration in the setting of normal glucose levels. The magnitude of these abnormalities declines over the disease course. Oligoclonal bands, inflammatory markers, and HTLV-1-specific antibodies may also be present. A CSF proviral load greater than 10 percent and a ratio with the plasma proviral load of greater than 1:1 may distinguish HAM/TSP from asymptomatic disease.

MRI does not distinguish HAM/TSP from other demyelinating processes; spine MRI is normal most commonly. Brain MRI findings may include T2-weighted hyperintensities in the subcortical, deep, and periventricular white matter. These multifocal white matter lesions are associated with longer duration of disease and increased disability.

Treatment

Treatment options for HAM/TSP are limited due to a combination of factors including a disease burden that is highest in countries where access to care is limited and surveillance data are poor; little financial incentive for drug development for a relatively rare disorder; and difficulty in developing trials due to a limited understanding of disease pathogenesis.[15]

A wide array of interventions that lack efficacy have been tried in HAM/TSP. Corticosteroids are the most commonly prescribed drugs, and there is some evidence for efficacy in the short term.

Although associations between inflammatory cytokines and proviral load have been identified, there are few randomized, controlled trials of immunomodulatory drugs. Interferon-alpha has been tested in small series but the drug also is limited by a severe side-effect profile. The efficacy of other agents such as cyclosporine, azathioprine, and sulfasalazine remains unclear. The utility of treatment with monoclonal antibodies is uncertain. An investigational agent used for adult T-cell leukemia, mogamulizumab, may improve spasticity and CNS inflammation in some individuals with HAM/TSP. Although antiretroviral agents against HTLV-1 are effective in the laboratory, studies have failed to demonstrate a decrease in the proviral load, perhaps due to the lack of continuous replication cycles requiring reverse transcriptase in chronic HTLV-1 carriers.

Due to the lack of effective disease-modifying therapies, symptomatic management is the mainstay of treatment. Spasticity and muscle spasms can be relieved with a combination of physical therapy and muscle relaxants. Neuropathic pain is managed with gabapentin or tricyclic agents. The threshold for testing for and treating urinary tract infections should be low; urine acidification can decrease this risk. Oxybutynin can be used to relieve urinary urgency and frequency arising from bladder spasticity, and stool softeners help manage chronic constipation.

Neurologic Complications of Transplantation and Immunosuppressive Agents

ALEXANDRA D. MUCCILLI ■ ELAN GUTERMAN ■ S. ANDREW JOSEPHSON

NEUROLOGIC COMPLICATIONS COMMON TO ALL TRANSPLANTATION TYPES
- Encephalopathy
- Seizures
- Cerebrovascular Complications
- Infections
  - *Bacterial*
  - *Viral*
  - *Fungal*
  - *Parasitic*
- Immune Reconstitution Inflammatory Syndrome
- Lymphoproliferative Disorders
- Autoimmune Disorders

HEMATOPOIETIC CELL TRANSPLANTATION
- Early Complications (<1 Month)
- Intermediate Complications (From Engraftment to 6 Months)
- Late Complications (Occurring Beyond 6 Months)

SOLID ORGAN TRANSPLANTATION
- Hepatic Transplantation
- Renal Transplantation
- Cardiac Transplantation
- Pulmonary Transplantation
- Pancreatic Transplantation
- Small Bowel and Multivisceral Transplantation

COMPLICATIONS OF IMMUNOMODULATORY THERAPIES
- Calcineurin Inhibitors
- Mammalian Target of Rapamycin Inhibitors
- Corticosteroids
- OKT3 Monoclonal Antibody
- Azathioprine
- Mycophenolate Mofetil
- Disease-Modifying Therapies for Multiple Sclerosis
- Immune Checkpoint Inhibitors
- Chimeric Antigen Receptor T-cell Therapy

Advances in solid organ and hematopoietic cell transplantation (HCT) have revolutionized the treatment of many previously fatal diseases. Immunologic and procedural innovations in tandem with the development of new immunosuppressive agents have increased the number, type, and durability of these transplantations. Post-transplant complications affecting the nervous system are particularly devastating in some cases. Neurology consultants are often asked to evaluate transplant recipients who have a wide array of neurologic signs and symptoms. An organized approach and astute clinical judgment are required to ensure proper management of these patients.

NEUROLOGIC COMPLICATIONS COMMON TO ALL TRANSPLANTATION TYPES

Encephalopathy

Altered mental status is one of the most common reasons for neurologic consultation in the post-transplantation period. The degree of encephalopathy can range from mild confusion to coma. A wide array of etiologies may be responsible including infection, metabolic disturbances, seizures, cerebrovascular disorders, and medication toxicity (discussed separately below). Postoperative hepatic or renal dysfunction may contribute to prolonged metabolism of sedative-hypnotic agents. Electrolyte abnormalities should be recognized as a potential etiology; in the case of hyponatremia, clinicians should be careful to ensure slow correction (<8 mmol/L in 24-hour period) in order to avoid osmotic demyelination syndromes.

Due to their prolonged illness course, decreased oral nutrition, and occasional caloric supplementation with total parenteral nutrition, transplant recipients are susceptible to the development of Wernicke's encephalopathy from thiamine deficiency. In addition to encephalopathy, patients may also exhibit other features of the classic triad including eye movement abnormalities and ataxia. Magnetic resonance imaging (MRI) may demonstrate symmetric increased

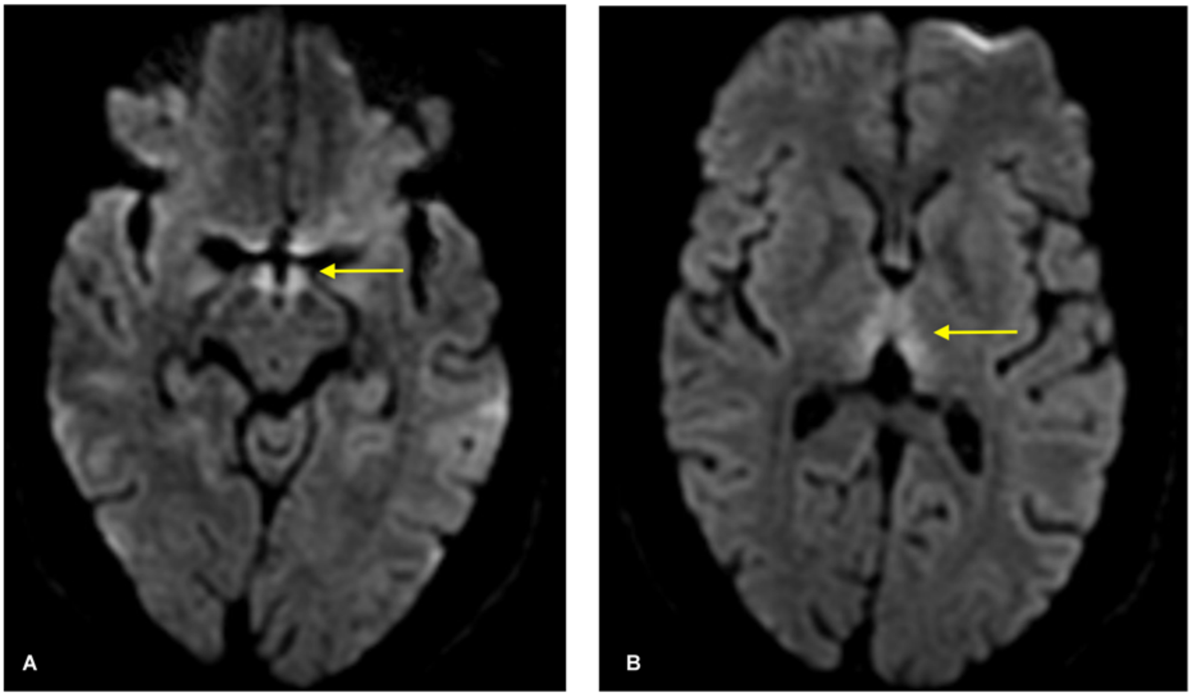

FIGURE 44-1 ■ Brain MRI findings in a patient with Wernicke encephalopathy. *A*, Axial diffusion-weighted image (DWI) demonstrating restricted diffusion in the mammillary bodies (*arrow*). *B*, Axial DWI through the thalami showing restricted diffusion of the dorsomedial thalamic nuclei bilaterally (*arrow*). Concordant T2 hyperintensities as well as gadolinium enhancement can be found in the same locations.

T2 signal intensity as well as contrast enhancement or restricted diffusion in the mammillary bodies, dorsomedial thalami, or periaqueductal area (Fig. 44-1), but cerebrospinal fluid (CSF) analysis is normal and EEG often demonstrates nonspecific diffuse slowing. Prompt supplementation with intravenous thiamine is imperative to reduce neurologic morbidity and prevent progression to Korsakoff syndrome.

Post-transplantation encephalopathy may also be caused by posterior reversible encephalopathy syndrome (PRES). While the syndrome preferentially affects the posterior cerebral regions (Fig. 44-2), variations do occur, most frequently involving the frontotemporal lobes and rarely the basal ganglia, brainstem, or thalami. Patients often present with headache, encephalopathy ranging from mild inattention to akinetic mutism or coma, seizures, or various visual syndromes. Transplant recipients are particularly vulnerable to developing PRES as they experience significant fluctuations in blood pressure, renal failure, and sepsis, all known risk factors for the development of the disorder.[1] Medications that commonly trigger PRES include the calcineurin inhibitors tacrolimus and cyclosporine, but the condition has also been described with other immunomodulatory therapies used in this population.[1] The patient's blood pressure need not be very high for occurrence of this syndrome, which appears to be related to the rate of change of blood pressure from baseline combined with a loss of cerebral autoregulation and endothelial dysfunction. Lowering of the blood pressure by any means will usually result in resolution of both the clinical syndrome and imaging abnormalities, although in some cases permanent neurologic sequelae can occur.

Seizures

Seizures are particularly common in the post-transplantation period. The most common causes of seizures are immunosuppressive agents (especially cyclosporine, tacrolimus, and OKT3), metabolic derangements, and hypoxic-ischemic injury. Infection, stroke, and tumor are less frequent causes of seizures in this population. Often, the seizure disorder is transient and requires no treatment other than reduction in the dose of offending medications, correction

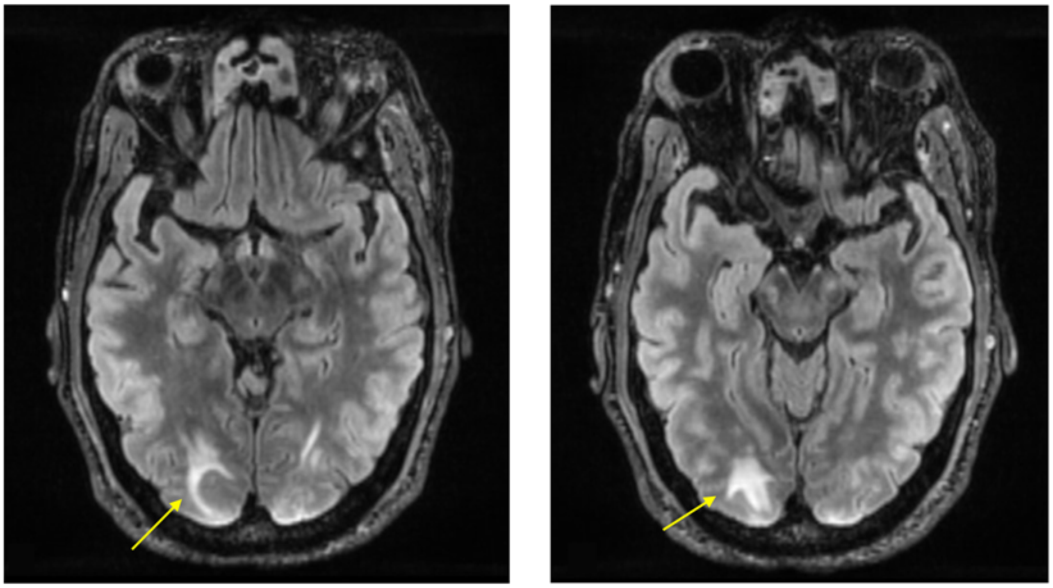

FIGURE 44-2 ■ Brain MRI of a hepatic transplant recipient with posterior reversible encephalopathy syndrome. Axial T2-weighted fluid-attenuated inversion recovery MRI demonstrating bilateral subcortical hyperintensities within the right greater than left occipital lobes (*arrows*).

of metabolic derangements, or treatment of underlying infection. Long-term therapy with antiepileptic drugs is undesirable in transplant recipients as interactions can occur with their immunosuppressive regimen; inducers of the hepatic cytochrome oxygenase P-450 system (e.g., carbamazepine, phenytoin) result in a decrease in the levels of many calcineurin inhibitors, necessitating dose adjustments. As such, if antiseizure medication is required, selection of a nonenzyme-inducing agent such as levetiracetam, lacosamide, or valproic acid is often preferable, although in liver transplantation, valproic acid should be avoided given potential hepatotoxicity.

Cerebrovascular Complications

Patients undergoing both hematopoietic cell and solid organ transplantation (SOT) are at risk of cerebrovascular events especially during the surgical and postoperative periods. Cerebral ischemia occurs as a result of arrhythmias, hypercoagulable states, underlying atherosclerosis, cardiac emboli, or prolonged hypoxic injury. Both ischemic and hemorrhagic stroke may occur in the setting of PRES and thus perioperative blood pressure management in this population is critical. Transplanted organ-specific cerebrovascular complications will be highlighted below.

Infections

Patients receiving long-term immunosuppression are at an increased risk of developing infections. Neurologic infections are particularly clinically relevant as they have the potential to cause significant morbidity and mortality in an immunocompromised host. Nearly every conceivable type of infection—bacterial, viral, fungal, and parasitic—has been reported to infect transplant recipients, but about 75 percent of cases are due to *Listeria monocytogenes*, *Cryptococcus neoformans*, or *Aspergillus fumigatus*.[2,3]

One important risk factor for infection is the immunosuppression necessary to prevent rejection of the allograft. The single most important risk factor for developing post-transplantation central nervous system (CNS) infection is the magnitude and length of immunosuppression. In addition, after transplantation, patients often have indwelling catheters, endotracheal tubes, and other portals of entry for infection. Patients' underlying diseases and their complications also contribute to the net state of immunosuppression. Certain infections themselves, especially viruses, also cause suppression of the immune system, in turn leading to increased susceptibility to additional infections.[2]

CNS infections in immunocompromised hosts may be difficult to recognize. The usual signs of infection, such as fever and meningismus, may be subtle or

	West Nile virus		

absent, as they depend on a vigorous immune response.[2] As a result, clinicians should have a high index of suspicion for infectious causes of neurologic symptoms in transplant recipients. Evidence of infection outside the nervous system may provide clues to a possible etiology. For example, skin lesions may be found to harbor *Cryptococcus* and co-existent lung infection suggests *Aspergillus*, *Nocardia*, or *Cryptococcus*.

Specific infectious pathogens complicating the post-transplantation period depend on a number of factors including the time from receipt of the graft, the specific immunosuppressive regimen, exposure and travel history, and the type of transplantation itself. Common culprit infectious organisms particular to each type of transplanted graft are discussed below. Table 44-1 lists important pathogens affecting the nervous system in recipients of both hematopoietic cell and SOT.

BACTERIAL

Although transplant recipients are at risk of the typical causes of bacterial meningitis including *Streptococcus pneumonia* and *Neisseria meningitidis*, they are particularly susceptible to less common organisms including *L. monocytogenes*.[3,4] The most common neurologic manifestation of *L. monocytogenes* is acute meningoencephalitis with a predilection for the brainstem and cerebellum. Unfortunately, the organism is often difficult to isolate and may present with a lymphocytic pleocytosis, unlike most bacterial meningitides that feature a neutrophilic predominance. Clinicians should maintain a high index of suspicion for *Listeria* infections and consider empiric treatment with ampicillin. Immunosuppressed patients are also at risk of infection with *Nocardia* spp., particularly in the first year after transplantation when immunosuppression is highest in order to prevent graft rejection. This gram-positive bacteria most commonly results in pulmonary infection but dissemination to the brain in the form of single or multiple cerebral abscesses may occur.[3] Prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) reduces the risk of nocardiosis but is not commonly employed for this purpose. With CNS involvement, treatment with prolonged IV TMP-SMX and imipenem is recommended with clinical and radiologic monitoring for treatment response.

VIRAL

Several different viral infections may occur in recipients of transplants. In cases of cytomegalovirus (CMV) and Epstein–Barr virus (EBV), these infections themselves may predispose patients to infections with additional opportunistic organisms including *Listeria*, *Aspergillus*, and *Nocardia*.[2,3] CMV results in a spectrum of neurologic complications including retinitis, ventriculoencephalitis, and polyradiculitis with a predilection for the caudal spine. Diagnosis is made with CSF PCR and treatment typically includes a combination of ganciclovir and foscarnet. Infection with EBV may similarly result in an encephalitic or myeltic picture, but also predisposes this patient population to post-transplant lymphoproliferative disorder (PTLD). Treatment of EBV involves ganciclovir for infectious presentations and immunosuppression with B-cell depleting therapies for EBV-associated lymphoproliferative disorders.

Varicella-zoster virus can involve both the central and peripheral nervous systems. Due to widespread use of antiviral prophylaxis in the pretransplantation period, complications related to reactivation of varicella-zoster virus now emerge later than in the past. The most common complication is cutaneous zoster, but transverse myelitis, vasculitis, and polyneuritis also occur.[3] Often when a dermatomal rash is absent, the etiology of the neurologic syndrome is uncertain and confirmation of VZV is necessary using CSF VZV IgM and IgG along with PCR testing. Treatment with IV acyclovir is recommended in this immunocompromised population.

Progressive multifocal leukoencephalopathy (PML), a severe demyelinating disorder of the CNS resulting from reactivation of polyomavirus JC virus (JCV), may develop in recipients of both hematopoietic cell and SOT. Patients present with subacute neurologic deficits that reflect the area of white matter injury, typically sparing the optic nerves and spinal cord. MRI demonstrates multifocal, often asymmetric, white matter lesions involving the subcortical U fibers but without mass effect or evidence of enhancement (Fig. 44-3). Diagnosis is confirmed by positive JCV in the CSF but, given its poor sensitivity, brain biopsy is sometimes necessary and remains the gold standard. Unfortunately, there is no proven effective treatment for PML, though reducing immunosuppression is recommended and emerging therapies including checkpoint inhibitors are being explored.[3] A reduction in immunosuppression may occasionally lead to the development of immune reconstitution inflammatory syndrome (IRIS) with clinical worsening of PML as well as new enhancement on MRI, often necessitating steroids.

FUNGAL

CNS cryptococcal disease often presents with headache, altered mental status, or cranial neuropathies, resulting from meningitis with obstructive or nonobstructive hydrocephalus. Involvement of the parenchyma in the form of cryptococcomas, often located in the basal ganglia or midbrain, is a more rare presentation. Clinicians should be careful to accurately measure opening pressure as patients will often have increased intracranial pressure necessitating serial lumbar punctures and occasionally more permanent CSF drainage in order to prevent optic nerve damage. CSF studies typically demonstrate a mononuclear

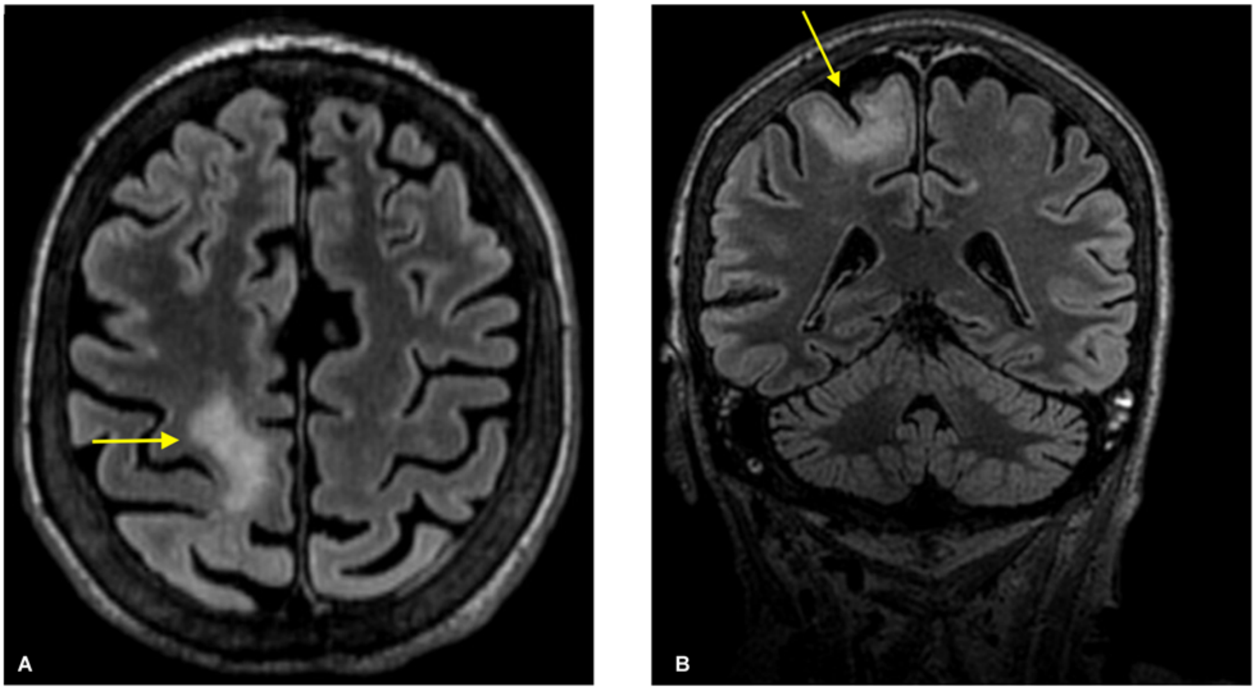

FIGURE 44-3 ■ Brain MRI in a patient with progressive multifocal leukoencephalopathy. *A*, Axial fluid-attenuated inversion recovery (FLAIR) and *B*, coronal FLAIR cuts demonstrating a T2 hyperintensity predominantly involving the right precentral gyrus and right superior frontal gyrus extending into the posterior frontal lobe white matter (*arrows*). There is no associated mass effect as is often the case in PML and there was no restricted diffusion or contrast enhancement on other sequences.

pleocytosis, elevated protein, and low glucose. Confirmation of the diagnosis is made with detection of cryptococcal antigen using latex agglutination or ELISA or India ink staining for detection of encapsulated yeast organisms.[2,5] In addition to *Cryptococcus*, clinicians should consider endemic fungi when individuals present with chronic meningitis and a history of travel to certain geographic areas—*Blastomyces dermatitis* (midwestern United States and Canadian provinces bordering the Great Lakes), *Histoplasma capsulatum* (Ohio River valley and the lower Mississippi River region), and *Coccidioides* spp. (California and southwestern United States).[5]

Infection with *Aspergillus* spp. may result in CNS manifestations and occurs in the setting of disseminated infection or from local extension from the paranasal sinuses. Patients typically present with progressive focal neurologic symptoms or seizures secondary to underlying abscess formation but may also develop acute deficits from cerebral ischemia or hemorrhage related to mycotic aneurysm development. Although candidemia is not uncommon in immunosuppressed patients, involvement of the nervous system is rare.[5]

PARASITIC

Although often overlooked, parasitic infection can also lead to significant neurologic morbidity and mortality in transplant recipients. Infection may occur via transmission from an infected graft, be acquired de novo by the immunosuppressed host, or occur due to reactivation in the setting of impaired cellular immunity.[3,6] *Toxoplasma gondii* reactivation represents the most common parasite with neurologic complications in this population. The incidence of neurologic complications of *T. gondii* is offset by the use of TMP-SMX prophylaxis in the post-transplantation period. Patients typically present with headache with or without focal neurologic symptoms but *T. gondi* reactivation can also cause extra-CNS complications, most commonly chorioretinitis and pneumonitis. Imaging demonstrates tropism for the basal ganglia and thalamus, revealing multiple ring-enhancing lesions with perilesional edema in the deep gray matter. A presumptive diagnosis is often made in patients seropositive for anti-*Toxoplasma* IgG antibodies in the presence of a typical clinical syndrome and imaging. Empiric therapy with sulfadiazine and pyrimethamine is preferred, though various alternative regimens exist.[3]

Immune Reconstitution Inflammatory Syndrome

Although well-recognized in HIV patients receiving highly active antiretroviral therapy, IRIS may also occur in recipients of hematopoietic cell and SOTs in the context of immunosuppression withdrawal. The condition features an intense inflammatory response that occurs as immune function is restored in the presence of an underlying opportunistic infection (typically *Cryptococcus*, tuberculosis, or PML).[7] When transplanted patients develop symptoms of CNS infection, immunosuppressive medications are often decreased to allow for a more robust immune response, leading to an increased risk of IRIS. Clinical presentation typically consists of paradoxical worsening of symptoms of a known infection or unmasking of a previously unrecognized infection in this clinical setting. As symptoms may mimic those of the original infection, the diagnosis of CNS IRIS is often difficult to make, especially since treatment failure, antimicrobial resistance, and additional neurologic infections are other important diagnostic considerations.[7] Management of IRIS involves prompt treatment of underlying infection and consideration of adjunctive corticosteroids to reduce the severe inflammatory response, although no related randomized controlled studies exist.

Lymphoproliferative Disorders

The chronic use of immunosuppressive agents to prevent allograft rejection increases the long-term risk of malignancy. Lymphoproliferative syndromes may occur in recipients of both hematopoietic cell and SOTs, often in the first year. The term PTLD is used to describe a wide spectrum of disorders characterized by abnormal proliferation of B cells (less commonly T cells) ranging from "benign" diffuse polyclonal lymphoid hyperplasia to malignant monoclonal lymphoma. CNS involvement occurs in up to 15 percent with PTLD and is the most common type of malignancy involving the brain in transplant recipients.[6,8] B-cell malignancies in transplanted patients are strongly associated with EBV infection unlike primary CNS lymphoma in immunocompetent patients. These B-cell lymphomas arise in deep areas of the brain with a propensity for the perivascular spaces. CNS lymphoma is distinguished radiographically from PML on brain MRI by its significant mass effect, restricted diffusion secondary to hypercellularity, and enhancement. Therapy for PTLD consists primarily of reduction of immunosuppression and a combination of conventional cytotoxic chemotherapy, radiotherapy, and often B-cell depleting agents. Unfortunately, the mortality rate remains high with CNS involvement leading to a poorer prognosis.[6,8]

Autoimmune Disorders

Several autoimmune disorders have been described in the late post-transplantation period, most of which are antibody-associated organ-specific conditions such as autoimmune thyroiditis or myasthenia gravis. These secondary autoimmune disorders may occur as a result of an underlying propensity for autoimmunity but also due to immune dysregulation in the setting of immunosuppression.

HEMATOPOIETIC CELL TRANSPLANTATION

The indications for HCT currently involve a broad range of pathologies including various hematologic malignancies, autoimmune diseases, inborn errors of metabolism, and congenital immune deficiencies. In an effort to restore bone marrow function, HCT involves the infusion of multipotent hematopoietic stem cells after a host is treated with chemotherapy with or without irradiation.

Three principal factors underlie a given patient's risk of post-HCT complications: conditioning regimen, graft type, and source of stem cells. The conditioning regimen describes the chemotherapeutic and radiation treatments delivered immediately prior to transplant. These conditioning regiments are classified as either full-intensity myeloablative or nonmyeloablative. Nonmyeloablative reduced intensity conditioning is associated with a lower risk of infection and relies on a graft-versus-tumor effect to compensate for the inherent increased risk of malignancy relapse. Graft types include autologous HCT, which requires the extraction of stem cells from the host and their reinfusion after myeloablative therapy, and allogeneic transplants that involve the infusion of cells from an HLA-compatible donor who can be syngeneic (monozygotic twins), related, or unrelated with a close degree of HLA matching. In the current therapeutic era, stem cells are most commonly harvested from peripheral blood and bone marrow, though umbilical cord blood-derived cells are also sometimes used.

Despite advances in technique, HCT continues to result in a number of neurologic complications, significantly contributing to morbidity and mortality. Recipients of an allogenic graft, notably one with marked HLA disparity, have higher rates of these side effects.[9] Neurologic complications common to transplant recipients are relevant in this population, but HCT carries its own unique risk profile. Specific issues emerge at different time-points from transplantation and can be organized accordingly: early (i.e., within the first month), intermediate (i.e., 1 to 6 months), and late (i.e., occurring beyond 6 months).[9]

Early Complications (<1 Month)

Neurologic complications during the stem cell harvesting period are infrequent, although some patients undergoing autologous HCT may experience exacerbation of underlying autoimmune diseases. During the conditioning phase, patients receive various alkylating agents with or without small doses of total-body irradiation and are prone to neurologic complications including encephalopathy, seizures, opportunistic infections, and stroke. They may also experience side effects from prophylactic antibiotic regimens as well as the medications used to prevent graft-versus-host disease (GVHD).

Patients undergoing HCT are usually more severely immunosuppressed at the time of transplant than those undergoing SOT due to both the underlying hematologic malignancy and the specific myeloablative conditioning regimen used. The granulocytopenic state continues for approximately 1 month until the new marrow begins to function. Typical clinical indicators of a neurologic infection may be absent during this period due to the host's impaired immune response, and as such physicians should be vigilant for any neurologic symptoms.

In the pre-engraftment period, patients are particularly vulnerable to bacterial infections, notably enteric gram-negative organisms including *Klebsiella* spp. and *Escherichia coli* as well as gram-positive cocci introduced via indwelling vascular catheters. More rare causes of atypical bacterial infections such as *Listeria* and *Nocardia* may also occur, although infrequently due to antibiotic prophylaxis. Neutropenic patients are also at risk for various viral infections including herpesviridae and polyomaviridae. Clinicians must recognize symptoms of post-transplant acute limbic encephalitis, a syndrome of anterograde amnesia, syndrome of inappropriate antidiuretic hormone secretion, mild CSF pleocytosis, hippocampal MRI hyperintensities, and EEG abnormalities with or without clinical seizures. While various infectious and autoimmune etiologies exist for this constellation of features, HHV-6 is the most well-recognized culprit in the acute post-transplant period and results from reactivation of previous host infection. Treatment relies on appropriate antiepileptic drug therapy as well as antiviral medications such as ganciclovir and foscarnet.

During the pre-engraftment period, patients are also at risk of invasive fungal infections. *Aspergillus* spp. are the most common, and the clinical presentation may be quite variable including headaches, seizures, focal neurologic symptoms, and altered mental status. Typical neuroimaging features include multiple ring-enhancing lesions associated with restricted diffusion on MRI, often with surrounding hemorrhage.[5] Abscesses involving the corpus callosum and brainstem are particularly suggestive of aspergillosis. Due to its angioinvasive nature, ischemic infarcts, mycotic aneurysms, and vasculitis may also be present. Since infection of the CNS often results from invasive rhinosinusitis, imaging commonly demonstrates intracerebral extension from the paranasal sinuses with dural enhancement.

Since the diagnostic yield of blood cultures is low and brain biopsy of deep or eloquent regions remains difficult, clinicians should consider serum and CSF markers of fungal infection (e.g., galactomannan antigen and β-D-glucan) in support of a suspected diagnosis of CNS aspergillosis. Voriconazole is the current first-line treatment for invasive aspergillosis, although for patients with severe disease, combination therapy with echinocandin for the first 2 weeks may be recommended.

Fluconazole prophylaxis has no activity against *Aspergillus* spp. and only reduces the risk of invasive candidiasis, which is the most common systemic fungal infection in HCT recipients. CNS involvement with disseminated candidemia, remains rare.[5] When it does occur, *Candida* spp. typically result in a meningitic picture. Multiple cerebral abscesses may occur in immunocompromised hosts. The treatment of choice for this organism is liposomal amphotericin B, with or without flucytosine, followed by step-down therapy with oral fluconazole.

Patients in the pre-engraftment period are often thrombocytopenic, and hemorrhagic complications may therefore occur. Subdural hematoma is the most frequent CNS hemorrhagic disorder in this setting, although intraparenchymal and subarachnoid hemorrhage have also been described.[9] Ischemic stroke may also complicate the early HCT period and has been linked to infusion of stem cells with dimethyl sulfoxide cryopreservative. Stroke can also occur in the setting of various CNS infections, notably with bacterial basilar meningitis, VZV-vasculopathy or the angioinvasive fungal organisms such as *Aspergillus* spp. and *Mucormycosis*.

Intermediate Complications (From Engraftment to 6 Months)

As patients enter the second month post-HCT, there is progressive recovery of cell-mediated immunity, and therefore the risk of bacterial infection decreases dramatically. Viruses and infections with opportunistic organisms predominate during this period. The most common viral infections and their typical neurologic presentations are detailed in Table 44-1. In this intermediate phase, consultants will frequently encounter transplant recipients with neurologic manifestations of herpesviruses including EBV, CMV, and VZV. Patients are at risk of CNS infection with *T. gondii*, particularly 2 to 4 months post-transplantation, with reactivation of latent parasitic infection being the most common mechanism.

Apart from increased susceptibility to infection in the first 100 days post-transplantation, recipients of an allogenic graft may also develop symptoms of acute GVHD. This complication results from an attack on host tissue by immunologically competent lymphocytes. Although most frequently associated with bone marrow transplantation, the condition can occur occasionally after liver transplantation and, in severely immunosuppressed patients, following lymphocyte-containing blood transfusions.[6] Patients receive a cocktail of immunosuppressive agents to mitigate this risk of post-transplantation immunologic reconstitution. Acute GVHD is characterized by rash, diarrhea, and liver dysfunction, typically with no associated neurologic complications. Symptoms of chronic GVHD may develop in the intermediate period and neurologic complications are often a late finding as discussed below.[9,10]

Late Complications (Occurring Beyond 6 Months)

Features of chronic GVHD occur after the 100-day mark, although this time designation is arbitrary and symptoms may occur before this period. In comparison to acute GVHD, several neuromuscular and CNS complications occur in chronic GVHD patients. Distinctive manifestations implicating the peripheral nervous system mainly involve myositis, whereas disorders of the peripheral nerve and neuromuscular junction occur less frequently and are usually accompanied by other organ involvement.[6,10] CNS manifestations are not typically associated with chronic GVHD and alternative diagnoses should always be considered.[10] The management of these neurologic complications involves treatment with immunosuppressive agents including corticosteroids with the long-term goal of a steroid-sparing regimen.

Recipients of a HCT usually require less long-term immunosuppressive therapy than those undergoing other types of transplantation, and sometimes immunosuppression may be discontinued after successful engraftment if no GVHD is present. Perhaps as a consequence, the prevalence of PTLD with CNS involvement is lower in this population.

Despite less intensive immunosuppression, HCT recipients remain at risk for infection. Most lingering infections are caused by viruses and include progressive chorioretinitis from CMV and EBV-related B-cell lymphoproliferative disease.[2,3] Opportunistic infections that develop more than 6 months after HCT tend to occur in patients with chronic allograft rejection. Such patients are maintained on higher than usual doses of long-term immunosuppressive agents such as corticosteroids and have received additional antirejection therapy, usually with OKT3, antithymocyte globulin, or antilymphoblast globulin. This cohort is at the greatest risk of developing opportunistic CNS infections, most commonly *Cryptococcus*, *Listeria*, and *Nocardia* spp.

Cerebrovascular complications are also a relatively frequent late problem after HCT with nonbacterial thrombotic endocarditis (NBTE) or infective endocarditis as common etiologies. The mechanism by which NBTE occurs in HCT recipients is unknown, although there is an association with disseminated intravascular coagulation and other acquired hypercoagulable states. Despite prolonged thrombocytopenia and abnormalities in coagulation, intracerebral hemorrhage is relatively rare in the late post-HCT period.

SOLID ORGAN TRANSPLANTATION

SOT involves the transfer of an entire organ from a tissue-matched deceased donor or a single kidney, partial liver, or intestinal tissue from a related or unrelated matched living donor. Neurologic complications are common in SOT recipients and most frequently consist of those described earlier including encephalopathy, seizure, infection, and cerebrovascular events.

Few neurologic complications occur exclusively in SOT recipients. Infectious complications related to donor organ-associated infections, however, are noteworthy. Donors undergo an extensive infectious work-up prior to SOT and consequently most donor-derived infectious disease transmission events are not unexpected. Unfortunately, despite donor screening, unforeseen transmission events occasionally occur either due to insensitivity of diagnostic testing or as a result of rare or emerging pathogens for which screening does not routinely occur. Some of the more notable cases of donor-associated infections transmitted include West Nile virus, rabies, lymphocytic choriomeningitis virus, and *Balamuthia mandrillaris*.

Hepatic Transplantation

Hepatic transplantation is used to treat acute liver failure (e.g., due to viral or drug-induced hepatitis), advanced cirrhosis due to cholestatic diseases (e.g., primary biliary cirrhosis and sclerosing cholangitis), hepatocellular disorders (e.g., alcoholic or viral hepatitis), hepatic malignancies (both primary and metastatic disease), and metabolic disorders (e.g., α_1-antitrypsin deficiency, Wilson disease, familial amyloid polyneuropathy, or acute intermittent porphyria). Although liver transplantation can improve and sometimes cure patients with end-stage hepatic disease, neurologic complications are more common than in any other type of SOT.

Due to organ shortages, patients frequently wait a considerable time for liver transplantation. As a result, by the time of transplantation they are often critically ill, with many having some degree of preoperative metabolic encephalopathy due to chronic liver failure. Patients with acute liver failure also frequently present with altered mental status in the setting of hyperammonemia, with MRI demonstrating symmetric T2-hyperintensities and restricted diffusion most commonly within the insular and cingulate cortex but

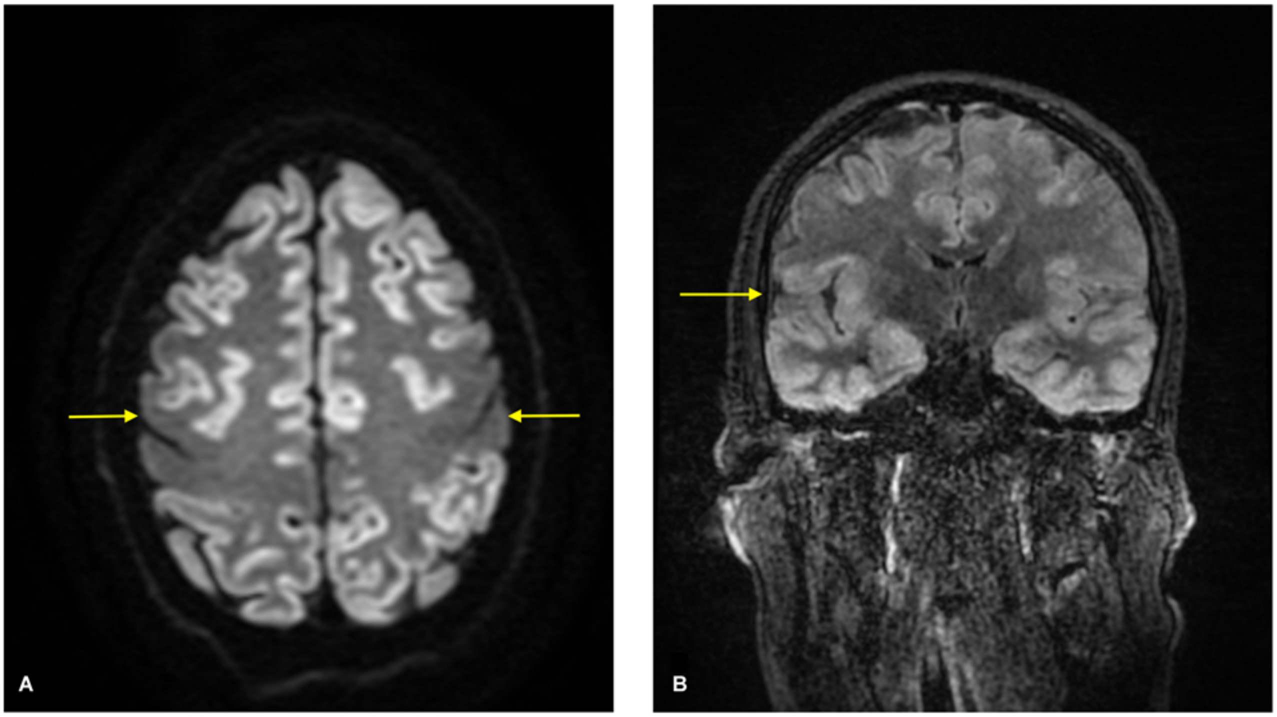

FIGURE 44-4 ■ Brain MRI in a patient with a hyperammonemic encephalopathy. *A*, Axial diffusion-weighted image demonstrating prominent cortical restricted diffusion with relative sparing of the perirolandic cortex (*arrows*). *B*, Coronal T2 fluid-attenuated inversion recovery concordant hyperintensities with prominent involvement of the insula (*arrow*).

with more diffuse cortical involvement in severe cases, typically with relative sparing of the perirolandic and occipital regions (Fig. 44-4).

Encephalopathy following hepatic transplantation is frequently multifactorial and clinicians should be mindful that seizures may occur in the perioperative period and be contributory. Seizures may be related to immunosuppressive medications, hypoglycemia, electrolyte abnormalities, or PRES.

Altered mental status may also arise secondary to cerebral edema and intracranial hypertension, which occur to some degree in almost all patients with severe hepatic encephalopathy. Medical management of increased intracranial pressure commonly necessitates hyperosmolar therapy, sedation, neuromuscular blockade, and sometimes hypothermia, though the evidence for the latter is less robust. Transplantation and restoration of normal liver function is the key to reducing intracranial pressure definitively.

Patients with chronic liver disease are at particularly high risk of osmotic demyelination resulting in a clinical syndrome classically referable to the pons (central pontine myelinolysis) but which can involve other structures including the basal ganglia, white matter, or thalamus. The clinical manifestations of these two entities are further discussed in Chapter 17. During the perioperative liver transplantation period, patients often experience large fluid shifts and resultant abrupt changes in serum sodium concentrations that may lead to this disorder. In the cirrhotic population, osmotic demyelination may occur in the absence of the marked sodium fluctuations and physicians should therefore be meticulous in their management of electrolytes and volume status. No specific treatment exists for this disorder and supportive care is the current standard.

Because of substantial blood loss intraoperatively during the transplantation procedure, patients often require significant replacements of packed red blood cells and electrolytes. Due to prolonged periods of hypotension, patients may rarely experience hypoxic-ischemic damage to the brain or watershed infarctions. Intraoperative cerebral infarctions may also be caused by air embolism or artery-to-artery embolism.

Peripheral nerve injuries may also occur during the transplantation procedure. Damage to the brachial plexus may be caused by axillary dissection performed for the placement of femoral–axillary venous bypasses. Likewise, lymphatic vessels can be damaged during the venous–venous bypass procedure resulting in a lymphocele that leads to secondary injury to the femoral nerve. Right phrenic nerve injury can occur during the transplant and results in hemidiaphragmatic weakness. Other neuropathies may occur from catheterization injuries, nerve compression, and surgical retraction.

The side effects of immunosuppression after liver transplantation are similar to those occurring in other types of transplantations. Calcineurin inhibitors are most commonly used and neurologic complications are more common and severe in this population. Additionally, the frequency of PTLD with CNS involvement in recipients of a hepatic graft is second only to cardiac and combined heart–lung transplantations.

Renal Transplantation

Since the first successful human kidney transplantation in 1954, the procedure has developed into the treatment of choice for patients with end-stage renal disease. The kidney is the most frequently transplanted solid organ worldwide, and there is now nearly a 100 percent 1-year survival rate. The indications for renal transplantation are numerous and include glomerulonephritis, polycystic kidney disease, systemic lupus erythematosus, amyloidosis, and diabetic and hypertension-related renal disease. Neurologic complications are associated with increased morbidity and mortality.

The toxic effects of pretransplantation uremia may cause subclinical neurologic impairment and leave the nervous system vulnerable to subsequent injury following transplantation. In addition, renal transplant candidates often suffer from many underlying vascular diseases, notably diabetes and hypertension, which themselves are associated with accelerated atherosclerosis and an elevated risk of cerebrovascular complications. The most common neurologic complications post-transplantation in this patient population are cerebrovascular, occurring in approximately 10 percent of all recipients of renal grafts.[11] Similar to cirrhotic patients, those with chronic kidney disease are susceptible to osmotic demyelination, and careful attention to and correction of hyponatremia is crucial.

The renal transplantation procedure itself is relatively benign. Neurologic complications, other than those caused by anesthesia or intraoperative hypotension, consist mainly of peripheral nerve injuries. Acute femoral neuropathy complicates a minority of kidney transplantations, with most patients presenting with hip flexion and knee extension weakness along with paresthesias over the anteromedial thigh and medial calf immediately following surgery, or in the early postoperative period. This acute femoral neuropathy likely results from a “steal” phenomenon with secondary nerve ischemia during anastomosis of the iliac artery and the graft renal artery, and prolonged anastomosis increases its risk. Injury to the lateral femoral cutaneous nerve due to compression caused by retractors may also complicate the transplant. The clinical outcomes for both of these mononeuropathies remain favorable, with symptoms often resolving in weeks to months. In a few patients, the caudal spinal cord is supplied by branches of the internal iliac arteries rather than by intercostal arteries; in these patients, spinal cord ischemia may result when the iliac artery is used to supply blood to the allograft.

Acute rejection of the renal allograft can produce an encephalopathy presenting as a nonfocal exam with headache, altered mental state, and seizures. Systemic manifestations may include fever, weight gain, renal failure, and swelling and tenderness of the graft. This syndrome has been described only in renal transplantation, and the mechanism is unclear; soluble neuroactive immune factors such as cytokines released during the rejection process may play a role. Of note, a similar syndrome occurs as a side effect of OKT3.

Cardiac Transplantation

Cardiac transplantation is used to treat medically intractable dilated, hypertrophic, restrictive, and ischemic cardiomyopathies, as well as some cases of rheumatic heart disease. These conditions predispose patients to embolic ischemic events, brain hypoperfusion, and hypoxia. During surgery, patients are often placed on cardiopulmonary bypass for several hours and may be subjected to long periods of hypotension and hypoxia, resulting in watershed-distribution infarcts. Additionally, cardiac transplant recipients often have a number of vascular risk factors, making them susceptible to ischemic stroke in the perioperative period. These patients are also prone to paradoxical embolic disease and air emboli during the surgery itself. These ischemic insults may present with either focal neurologic deficits or as a nonfocal encephalopathy, the latter especially when an embolic shower is the underlying etiology. Seizures may complicate any of these cerebrovascular events and often contribute to altered mental status.

Peripheral nerve injuries are another relatively common complication of the transplantation procedure. The most frequently encountered lesions are brachial plexus injuries caused by retraction of the chest wall. The phrenic nerve also may be damaged by retraction, during the dissection of nearby structures, or from the practice of packing the heart in an ice-cold slush for myocardial protection during the transplantation.[6]

Although the pattern and timetable of CNS infections are similar to those in other types of transplantations, the side effects of immunosuppression are more common and severe in cardiac transplant recipients because higher doses of immunosuppressive agents are often involved. *Toxoplasma* infections account for a higher percentage of CNS infections than in other transplantations as the parasite may reside in the donor myocardium itself.[2,3,6] To reduce the risk of *T. gondii* infection, many cardiac transplant programs suggest lifelong prophylactic treatment with trimethoprim-sulfamethoxazole.

Pulmonary Transplantation

Lung transplantations are used to treat a variety of end-stage pulmonary diseases including emphysema, other severe chronic obstructive pulmonary diseases, cystic fibrosis, α_1-antitrypsin deficiency, and idiopathic pulmonary fibrosis. Although the first successful lung transplantation was performed over 30 years ago, recipients of pulmonary grafts continue to have the highest mortality rate among all SOTs and neurologic complications portend a poorer prognosis.[12] Lung and combined lung–heart transplants require the largest doses of short- and long-term immunosuppressive agents of any SOT, therefore putting this population at a higher risk for infectious and lymphoproliferative disorders involving the CNS. The most common neurologic complications in lung transplant recipients are perioperative stroke, seizures, and a multifactorial encephalopathy often related to chronic hypoxia.[12]

Peripheral nervous system involvement can also complicate lung transplantation. Of these, phrenic nerve injury during the transplantation surgery and critical illness neuropathy/myopathy are the most common. These complications frequently lead to prolonged hospitalizations.

Pancreatic Transplantation

Pancreatic transplantations are occasionally performed in patients with type 1 diabetes mellitus with extensive end-organ damage. Most pancreas transplantations are performed in conjunction with renal transplantations, either simultaneously or in patients who already have a functioning renal transplant. The principal objectives of this procedure are to render diabetic patients independent of insulin while reducing secondary complications and improving quality of life. Whole-pancreas transplants allow patients to become euglycemic within hours of surgery, and the procedure has a greater than 90 percent graft survival rate at 1 year.

Given the advanced nature of patients' diabetes, neurologic complications are common even prior to surgery and frequently include peripheral neuropathy, autonomic changes, and macrovascular complications such as cerebrovascular disease. Several studies have suggested that transplantation might not only halt progression of polyneuropathy but also lead to improvement of clinical symptoms and nerve conduction studies. Neurologic complications directly related to the transplantation procedure are generally rare. Global cerebral ischemia is the most frequently observed serious postoperative neurologic side effect which may be a consequence of the surgery itself combined with advanced atherosclerosis and autonomic neuropathy secondary to end-stage diabetes and renal dysfunction.

Small Bowel and Multivisceral Transplantation

The most common condition leading to small bowel transplantation is a short bowel syndrome following intestinal resection in the setting of Crohn disease, trauma, mesenteric thrombosis, or malignancy. This patient population may suffer from a number of baseline neurologic complications secondary to metabolic derangements including various water- and fat-soluble vitamin deficiencies as well as hypocalcemia and hypomagnesemia. Neurologic complications of small bowel transplantation are similar to other types of SOT. A more aggressive immunosuppression regimen is required in this cohort due to the underlying enhanced immunogenicity of the gut leading to increased risk of infections, typically fungal, in the early post-transplantation period.

COMPLICATIONS OF IMMUNOMODULATORY THERAPIES

A variety of immunosuppressive agents are used in the setting of HCT, SOT, and in the treatment of autoimmune neurologic disorders. The medications themselves as well as the resulting immunosuppressive effect may result in neurologic complications. The major neurologic complications of these therapies include direct neurotoxicity, infections, and the development of new malignancies (Table 44-2).[6,13]

Calcineurin Inhibitors

Cyclosporine and tacrolimus, both calcineurin inhibitors, are the most commonly used immunosuppressive agents in the setting of SOT, both for maintenance of immunosuppression and in the treatment of acute organ rejection.[6] These agents bind to calcineurin and selectively inhibit both helper and cytotoxic T cells by blocking antigen-induced T-cell activation.[13] Renal and hepatic toxicity along with hypertension are the most serious systemic complications of these medications, although neurologic side effects occur in up to half of patients. While neurologic complications are slightly more common with tacrolimus, both therapies result in almost identical side effect profiles.[6] Higher blood levels of calcineurin inhibitors are generally associated with side effects, but there is no simple correlation between serum levels and the development of any specific neurologic complication, and symptoms may occur even with normal levels. Enzyme-inducing anticonvulsants, such as phenytoin and carabamazepine, decrease blood levels of tacrolimus and cyclosporine by inducing hepatic metabolism and may increase the risk of graft rejection as a result. Several other medications interfere with the metabolism of these drugs and may lead to higher serum concentrations.

Tremor is the most common neurologic complication of calcineurin inhibitors. It is usually mild and develops within days of initiation in up to half of patients.[13] Headache represents another common neurologic side effect, occurring in approximately one-third of patients who receive parenteral tacrolimus; oral administration is less commonly associated with headaches.

Most of the serious neurologic toxicity of calcineurin inhibitors results from their tendency to produce hypertension. The hypertension that complicates these medications is due in part to renal toxicity and, to a larger extent, stimulation of the sympathetic nervous system. The encephalopathy that results is better correlated with the rate of change in blood pressure from the patient's baseline level than with an absolute value.[13] Calcineurin inhibitor-related neurotoxicity may be thought of as a forme fruste of hypertensive encephalopathy or PRES, the clinical spectrum and radiologic findings of which were described earlier.

In addition to their vascular effects, calcineurin inhibitors are also epileptogenic. Recipients may experience focal or generalized seizures, both of which are usually, but not always, associated with high serum drug levels.[13] Precipitating factors include hypertension, hypomagnesemia, aluminum overload, and the concomitant administration of high-dose corticosteroids. Seizures may also occur in the setting of PRES.

Peripheral nervous system complications are far less common in the setting of calcineurin inhibitors. Sensory disturbances consisting of paresthesias or dysesthesias of the distal extremities are more common than weakness. Patients may present with acute or subacute demyelinating neuropathies mimicking Guillain–Barré syndrome or chronic inflammatory demyelinating polyneuropathy (CIDP), but axonal neuropathies also occur.[13] Additionally, a calcineurin inhibitor-induced length-dependent painful neuropathy syndrome may develop in some patients with normal nerve conduction studies. Necrotizing myopathies have also been described in the setting of these medications. The treatment for all the direct neurotoxic side effects of calcineurin inhibitors is either to decrease the dose or to eliminate the drug entirely, if possible. All of these complications typically resolve with cessation of the offending agent.

Mammalian Target of Rapamycin Inhibitors

Sirolimus and everolimus are drugs that act by inhibiting the mammalian target of rapamycin (mTOR)

TABLE 44-2 ■ Noninfectious Neurologic Complications Associated With Commonly Used Immunosuppressive Medications

Immunosuppressant	Neurologic Adverse Effect
Calcineurin Inhibitors

and ultimately blocking the response of T- and B-cell activation by cytokines. Although these agents are sometimes used in a primary immunosuppressive regimen, they are commonly preferred as a milder alternative when one of the calcineurin inhibitors is not tolerated.[13] These medications each have similar side effects and cause increases in serum cholesterol and triglycerides. Myelosuppression is also common as are dermatologic complications. Although mTOR inhibitors have relatively few neurologic side effects, a PRES-like syndrome which resolves on discontinuation of the drug has been reported on rare occasion.[13]

Corticosteroids

Corticosteroids were the first immunosuppressive agents used in transplantation and continue to be used for long-term immunosuppression and for the treatment of acute graft rejection. Corticosteroids affect both cellular and humoral immunity and expose patients to a greater risk of opportunistic infection than do the newer immunosuppressive agents that are relatively T-cell specific. The most common neurologic side effects of corticosteroids are myopathy, steroid psychosis, and problems resulting from corticosteroid withdrawal.

The exact frequency of corticosteroid myopathy is unknown, but many patients taking moderate-dose corticosteroids develop some signs of myopathy 2 to 3 weeks after the start of therapy. The syndrome is characterized by proximal muscle weakness that is most severe in the hip girdle muscles. Muscle enzymes including creatine kinase are typically not elevated and electrodiagnostic testing may be normal. Muscle biopsy classically demonstrates selective atrophy of type IIA fibers. Treatment is to discontinue the corticosteroids if possible or to change to a nonfluorinated corticosteroid such as hydrocortisone. The myopathy usually resolves completely after corticosteroid therapy is stopped, but this may take months.

Another more rare diagnostic consideration in a patient taking chronic corticosteroids and presenting with weakness is spinal cord or cauda equina compression from epidural lipomatosis. This syndrome usually does not occur in patients taking less than the equivalent of 30 mg/day of prednisone. Clinical manifestations can include back pain, myelopathy, and radiculopathy. The usual treatment is surgical decompression, although simply discontinuing corticosteroid therapy occasionally leads to improved symptoms.

Psychiatric complications occur frequently in patients taking corticosteroids. The phrase *steroid psychosis* refers to several psychiatric syndromes that are associated with corticosteroids including anxiety, insomnia, irritability, difficulties with concentration and memory, and mood changes. More severe acute psychiatric syndromes are rare but include schizophrenia-like disorders and an agitated delirium. The treatment of steroid psychosis involves stopping the medication, reducing the dose, and switching to dexamethasone, the corticosteroid least likely to cause steroid psychosis. Affective syndromes may respond to lithium, whereas schizophrenia-like syndromes are treatable with psychotropic medications.

Withdrawal from corticosteroids also may cause neurologic complications, including myalgias and arthralgias ("steroid pseudorheumatism"). Also observed is a nonspecific syndrome consisting of headache, lethargy, and nausea, with or without a low-grade fever.

OKT3 Monoclonal Antibody

OKT3 (Muromonab-CD3) is a monoclonal antibody directed against $CD3^+$ lymphocytes.[13] Its major neurologic side effect is a chemical meningitis, which occurs in about 5 percent of patients during the first 3 days of exposure. CSF analysis demonstrates a lymphocytic pleocytosis with normal glucose and normal or slightly elevated protein concentration. The syndrome is self-limited and benign. Lumbar puncture and culture of the CSF should be performed to exclude bacterial or fungal meningitis. The meningeal inflammation is probably part of a cytokine release syndrome (CRS) or an allergic process similar to that which occurs with nonsteroidal anti-inflammatory drugs or intravenous immunoglobulin.

A more severe syndrome with variable degrees of altered mental status, including seizures, may occur rarely. It is associated with neuroimaging evidence of cerebral edema, but it is also self-limited and benign, even sometimes if the OKT3 is continued. OKT3 use also predisposes patients to develop PTLD, a side effect that appears to be dose related. Due to these adverse events, newer monoclonal antibodies have replaced this agent in many transplant programs.

Azathioprine

Azathioprine is an antimetabolite that suppresses both cell-mediated and humoral immunity. Although currently used less frequently in the transplant setting now that more specific immunosuppressants are available, the drug is still occasionally used for long-term immunosuppression. Very rare neurologic side effects occur including mylagias and seizures, but the nervous system may be affected secondary to opportunistic infection or liver failure caused by the medication.[13]

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) decreases the immune response by inhibiting purine synthesis in lymphocytes. Similar to azathioprine, it has no severe adverse neurologic side effects but can sometimes cause headache and myalgias.[13] Since MMF has few systemic side effects it is often a favored immunosuppressive agent.

Disease-Modifying Therapies for Multiple Sclerosis

The therapeutic landscape in multiple sclerosis (MS) has evolved significantly over the last decade with the advent of new more potent and effective agents. Though the enhanced therapeutic arsenal offers MS patients improved disease control, these new disease-modifying therapies (DMTs) come with an increased risk of adverse effects. Opportunistic infections remain amongst the most serious of these side effects and their prompt recognition is critical to successful management. PML, although uncommon, results in significant morbidity and mortality and has been reported with several DMTs, most notably with natalizumab where the probability of developing PML ranges from 1/100 to 1/10,000. The risk-assessment algorithm is based on three principal risk factors: anti-JCV antibody titer, duration of natalizumab therapy, and prior exposure to immunosuppression. Apart from natalizumab, PML has been described in association with fingolimod, dimethylfumarate, and alemtuzumab as well as with teriflunomide and ocrelizumab after transition from natalizumab. Of note, prompt discontinuation of DMT can be associated with significant rebound of MS disease activity with the potential for accrual of new deficits. Several other opportunistic infections and neurologic complications may occur in the setting of DMT use, as outlined in Table 44-3.

TABLE 44-3 ■ Noninfectious Neurologic Complications Associated With Disease-Modifying Therapies for Multiple Sclerosis

Medication	Neurologic Adverse Effect
Alemtuzumab	Headache Cytokine release syndrome Intracerebral hemorrhage Ischemic stroke Cervical artery dissection Peripheral nervous system and central nervous system autoimmune disorders
Cladribine	Headache Peripheral neuropathy
Fingolimod	Posterior reversible encephalopathy syndrome Intracerebral plasmacytic lymphoproliferative disorder
Interferons	Headache Transient worsening of prior multiple sclerosis symptoms Polyneuropathy
Natalizumab	Headache Central nervous system lymphoma
Ocrelizumab	Headache
Teriflunomide	Headache Peripheral neuropathy

Immune Checkpoint Inhibitors

Immune checkpoint inhibitors (ICIs) are a novel class of therapeutic agents that have revolutionized the treatment of previously incurable malignancies. These monoclonal antibodies have been engineered to target one of two T-cell proteins, programmed cell death receptor-1 (PD-1) and cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), and exploit the immune system's natural response to foreign targets. Under normal conditions, these checkpoints guard against autoimmunity by downregulating the immune system and suppressing T-cell activity; ICIs provide an iatrogenic blockade of these intrinsic regulators of immune homeostasis, redirecting the attack against foreign cancer cells.

Although antibodies inhibiting PD-1 and CTLA-4 have resulted in a significant survival advantage, they are associated with a variety of immune-related adverse events (irAEs), of which neurologic irAEs are among the most devastating.[14] A diverse spectrum of neurologic complications involving both the central and peripheral nervous system have been described and can occur after only a few cycles of treatment. Peripheral nervous system toxicity is more common and includes disorders involving nerve roots, peripheral nerves, neuromuscular junction, and muscle, although CNS involvement including cases of encephalitis, transverse myelitis, and cerebellitis has also been documented.

Given the novelty of ICIs, the spectrum of irAEs complicating their use continues to expand. To date, no specific clinical or biologic markers exist to predict which patients will develop side effects. There is some speculation that the presence of irAEs in a given patient might be associated with an increased efficacy of neoplasm response. Given the autoimmune nature of these complications, a genetic component is strongly suspected, and large genome-wide association studies are underway to further evaluate this question. As is the case in other autoimmune diseases, the role of the gut microbiome and other environmental factors may also be relevant.

Though neurotoxicity is uncommon, likely occurring in less than 3 percent of patients on ICIs, prompt recognition and management of irAEs is critical as observational data suggest more favorable patient outcomes with early treatment. Treatment of irAEs typically involves discontinuation of ICI, high-dose corticosteroids, and consideration of additional immunosuppressive agents including intravenous immunoglobulin or plasmapheresis.[14] In cases of significant neurologic disability, more chronic immunosuppression is sometimes necessary and consideration of a monoclonal antibody or an antimetabolite agent such as azathioprine or MMF is warranted.[14]

Chimeric Antigen Receptor T-cell Therapy

Advances in cancer immunotherapy have also led to the development of reprogrammed autologous T cells engineered to express a given chimeric antigen receptor (CAR) designated for a specific tumor target antigen. These CAR-T cells are multiplied in vitro and reinfused into patients where they reorient the host's immune response toward malignant cells, resulting in pronounced cytotoxic effects. CAR-T therapy may lead to significant side effects, including most commonly, a systemic inflammatory response caused by cytokine release from infused CAR-T cells and other host immune cells. Symptoms range from mild fever to multiorgan failure. Grading CRS is imperative in determining appropriate management and depends on four principal factors: presence of fever, hypotension, hypoxia, and evidence of organ toxicity.[15] Neurotoxicity, sometimes termed immune effector cell-associated neurotoxicity syndrome (ICANS), is now considered a distinct entity and consists of a spectrum of manifestations including altered mental status, cortical signs, seizures and increased intracranial pressure.[15] ICANS may occur in conjunction with CRS or shortly thereafter, and symptoms may progress over hours to days.

Management of patients with ICANS involves supportive care with close observation in an intensive care unit in conjunction with investigations which might include MRI and CSF studies. EEG is indicated to rule out alternative etiologies as well as continued electrographic seizures. Management of high-grade toxicity with corticosteroids and anti-interleukin-6 therapy such as tocilizumab is likely helpful.

  Surgical Treatment

Recognition of fungal infections of the central nervous system (CNS) is increasing in frequency due to the growing population of immunocompromised patients and improvements in diagnostic techniques. Published information on the diagnosis and treatment of these diverse infections ranges from extensive to nonexistent. Therefore, a comprehensive survey of the literature coupled with clinical experience informs the diagnosis, pathophysiology, and management of these potentially life-threatening infections. Major recent references are cited here, and earlier comprehensive references can be found in previous editions of this book.

PATHOGENS

Fungi that cause CNS infection can be divided into two general groups. The first group consists of primary pathogens including *Cryptococcus neoformans/gattii*, *Coccidioides immitis/posadasii*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, *Histoplasma capsulatum*, *Talaromyces marneffei*, *Pseudallescheria boydii* (*Scedosporium apiospermum*), and the dematiaceous molds. CNS involvement by these fungi can occur in patients with apparently intact immune systems and, at even higher rates, in immunosuppressed patients. The second group consists of secondary opportunists that cause CNS infection almost exclusively in patients with defective host defenses; this group includes *Candida* species, *Aspergillus* species, and mucormycosis caused by fungi in the order Mucorales. Finally, some fungi for which only a few case reports of CNS involvement exist are mostly common in the environment and include *Alternaria*, *Rhodotorula*, *Aureobasidium*, *Arthrographis*, *Acremonium*, *Clavispora*, *Blastoschizomyces*, *Trichosporon*, *Sepedonium*, *Bipolaris*, *Schizophyllum*, *Paecilomyces*, *Pneumocystis*, and *Ustilago*. Such cases generally have some unique feature in the medical history, such as direct trauma or CNS penetration, that explains the presence of the fungus in the CNS. Two prime examples are the fungal meningitis outbreaks of 2002 with *Exophiala* (Wangiella) *dermatitidis* and of 2012 with *Exserohilum rostratum*; both were associated with injection of compounded, preservative-free corticosteroids.

Some of the key characteristics of the more common CNS fungal infections are listed in Table 45-1.

HOST FACTORS

Geographic factors are important for certain CNS fungal infections. Several groups of fungi are not geographically restricted and have worldwide distribution including *Candida albicans* and other *Candida* species, *Aspergillus* species, and *C. neoformans/ C. gattii*. However, other mycoses such as histoplasmosis, blastomycosis, coccidioidomycosis, talaromycosis (penicillinosis), and paracoccidioidomycosis are largely confined to certain geographic areas, although these lines are blurred with modern travel. It is therefore essential that clinicians evaluating patients with possible fungal infections acquire an accurate travel history.

The CNS is an immunologically sequestered site, with anatomic barriers that exclude not only invading microorganisms but also some components of the immune system. Host defenses normally are highly effective in excluding fungi from the CNS, but certain conditions can lead to failure of these protective functions. Some of these conditions are obvious, such as trauma or the presence of indwelling catheters that allow direct inoculation of fungi into the CNS, immaturity of the blood–brain barrier in neonates, and a high-grade fungemia. In most cases, the fungus enters via the respiratory tract and seeds the CNS hematogenously, but other extracranial origins of CNS infection have been identified such as abscesses, mycotic aneurysms, and meningitis, which can arise from septic emboli associated with endocarditis. Rhinocerebral mucormycosis involves both vascular invasion and direct neural sheath extension into the CNS.

The most important risk factor for the development of CNS fungal infections is suppression of the host immune system, whether due to an underlying disease or to immunosuppressive drugs. Both the etiology of these CNS infections and their responses to therapy depend on the type of immune suppression. For instance, administration of immunosuppressive drugs such as systemic corticosteroids is a leading risk factor for development of CNS fungal infections with *C. neoformans/gattii* and *Aspergillus* species. Neutropenia due to cancer chemotherapy is associated with CNS infections caused by *Aspergillus* and *Candida* species, and treatment with the iron chelator deferoxamine predisposes to rhinocerebral mucormycosis. Several specific underlying diseases

TABLE 45-1 ■ Features of Common Fungal Infections of the Central Nervous System

				Major Pathologic Manifestations		
Pathogen	**Risk Factors**	**CSF Cultures Positive**	**CSF Serologies**	**Meningitis**	**Infarct**	**Abscess or Mass**
Aspergillus spp.	Neutropenia, corticosteroids	Rare	None	+	++++	++
Blastomyces dermatitidis	None known	Rare	Ab	+	–	++
Candida spp.	Neutropenia, corticosteroids, CSF shunts, polymorphonuclear leukocyte defects, prematurity	50%	None	++	–	+++
Coccidioides immitis	AIDS, corticosteroids	25–45%	Ab	++++	+	+
Cryptococcus neoformans	AIDS, corticosteroids	75–85%	An	++++	+	++
Dematiaceous fungi	None	Rare	None	+	–	++++
Histoplasma capsulatum	AIDS, corticosteroids	50%	Ab/An	+++	+	+
Paracoccidioides brasiliensis	None	Rare	None	++	–	+
Scedosporium species	Corticosteroids, aspiration	Rare	None	++	–	++
Sporothrix schenckii	Alcohol, AIDS?	Rare	Ab	++	–	–
Zygomycetes (Mucorales)	Diabetes, deferoxamine, intravenous drug use	Rare	None	+	++++	+++

Ab, antibody test; An, antigen test; AIDS, acquired immunodeficiency syndrome; CSF, cerebrospinal fluid.

are associated with an increased incidence of CNS fungal infections. For instance, the most important of these associations is the link between the acquired immunodeficiency syndrome (AIDS) and cryptococcal meningitis. Prior to the advent of antiretroviral therapy (ART), rates reported from several cities ranged between 24 and 66 per 1,000 AIDS patients in the United States, but this incidence has been reduced with effective ART. Cryptococcal meningitis continues to occur early, in some patients who have either not received or have stopped antiretroviral drugs, or later, as viral resistance develops to ART. In 2009, the US Centers for Disease Control estimated that worldwide there were 1 million cases per year of cryptococcosis, with over 600,000 deaths, which made it the most deadly invasive fungal infection in the world. With widespread ART availability, the yearly incidence has now been estimated at 270,000, with 180,000 deaths. Cryptococcal meningitis accounts for approximately 8 percent of all invasive mycoses among transplant recipients. There have also been several reports of patients infected with human immunodeficiency virus (HIV) who have contracted CNS infections with *Aspergillus* species and the use of high-dose ibrutinib for cancer therapy has been associated with *Aspergillus* and cryptococcal CNS infections.[1,2] Mold infections have been manifested predominantly as cerebral mass lesions, although cerebral infarctions, meningitis, and spinal cord involvement have also been observed. Patients with advanced HIV infection may also present with disseminated and CNS histoplasmosis, talaromycosis, coccidioidomycosis, blastomycosis, or sporotrichosis.

Patients who undergo organ transplantation and receive concomitant immunosuppression are at a significant risk of CNS fungal infection. The most common fungal pathogens in this setting are *C. neoformans*/*C. gattii*, *Aspergillus* species, and *Candida* species. Infection with *C. neoformans* in organ transplant recipients is usually manifested as a chronic or subacute meningitis occurring 6 months or more after organ transplantation. Infections with *Aspergillus* and *Candida* species usually occur within the first 2 months after organ transplantation, and CNS involvement is usually manifested by brain abscesses. CNS aspergillosis may be underdiagnosed in organ transplant recipients; in one series of 44 brains from liver transplant recipients examined at autopsy, 9 cases of cerebral aspergillosis were identified, of which only 2 were diagnosed before death.

Other high-risk underlying diseases or conditions associated with CNS fungal infection include malignancies, diabetes mellitus, and prematurity. Poorly controlled diabetic patients with or without ketoacidosis are at increased risk of rhinocerebral mucormycosis. Premature infants are at risk of disseminated infections and specifically of meningoencephalitis with *Candida* species, which has substantial implications for survival and for neurodevelopment issues with CNS involvement.

Infections that arise from direct inoculation of fungi into the CNS are usually seen after head trauma or neurosurgical procedures or as complications of implanted cerebrospinal fluid (CSF) shunts. In patients who have open head injuries, fungi that are ubiquitous in the environment may contaminate the wounds, leading to meningitis and focal fungal brain abscesses. With CSF leaks, the initial infection may be bacterial, but during the use of prolonged broad-spectrum antibacterial drugs, superinfection with *Candida* can occur.

CNS fungal infections can be associated occasionally with the presence of a CSF-diverting shunt. The most common fungus associated with CSF shunt infections is *C. albicans*. It appears that infection occurs as a result of either contamination of the shunt apparatus during insertion or subsequent manipulation, or through hematogenous spread. Among the published cases of CSF shunt infections with *C. albicans*, an association exists with recent antibacterial therapy and colonization with *Candida* species at other body sites. Other fungi that have caused CNS infection in the setting of a CSF shunt include *C. neoformans*, *Trichosporon beigelii*, *Candida glabrata*, and *Candida tropicalis*. There is some controversy concerning the origin of cryptococcal shunt infections. In many of the patients with CSF shunts who were subsequently found to have *C. neoformans* infection, the shunts were originally placed for either idiopathic hydrocephalus or chronic culture-negative meningitis; these patients probably had chronic CNS cryptococcal infection before their shunts were inserted.

There are rare reports of fungal infection associated with neurosurgical procedures; among these, *Aspergillus* and *Candida* species account for most cases. In some of these patients, infection was attributed to direct extension of the fungus from the paranasal sinuses, and in others it was thought that fungi were introduced with devices inserted during the operative procedure. Many of these patients have additional predisposing conditions such as prior treatment with antibacterial agents or high-dose corticosteroids. The dramatic outbreak of over 500 patients with meningitis, arachnoiditis, and epidural abscesses due to *E. rostratum* contamination of injectable corticosteroids around the spine emphasizes how fungi can aggressively establish disease. They travel through tissue after direct inoculation and are helped by immunosuppression, such as with corticosteroids.

Immune Reconstitution Inflammatory Syndrome

While some host immunity is critical for the eradication of CNS infections, immunologic recovery can also be detrimental and contribute toward worsening disease expression. This entity of overstimulation of the immune system has been called *immune reconstitution syndrome* or *immune reconstitution inflammatory syndrome* (IRIS) and has been described vividly during ART, in transplant recipients with immunosuppressive drug manipulations, and even in apparently normal hosts with cryptococcal meningitis. For example, upon initiation of ART during management of HIV-related cryptococcal meningitis, HIV RNA levels decline rapidly and there is repopulation of the host with memory and naïve $CD4^+$ lymphocytes; within 4 to 6 weeks, an immunologic shift occurs from a Th2 to a Th1 immune response. IRIS may be manifested by headaches, fever, CSF lymphocytosis, increased intracranial pressure, and evidence of increased inflammation on neuroimaging without evidence of viable yeasts in the CSF. In IRIS the cryptococcal CSF polymerase chain reaction (PCR) is generally negative, but it remains positive if viable CSF yeasts are present, indicating infection relapse or persistent infection before return of culture results.[3] The pathologic finding in tissue is that of granuloma formation. Patients who initiated ART within 2 weeks of treatment for *C. neoformans* CNS infection are significantly more likely to develop IRIS and have a worse outcome than those who initiated ART at a later time. This observation has led to controversy about when precisely to start ART during the management of cryptococcal meningitis—present guidelines give a generous range of between 2 and 10 weeks for ART initiation after the start of antifungal therapy and most clinicians start ART at 4 to 5 weeks.

Similarly, in solid organ transplant recipients with cryptococcosis, IRIS was observed in 5 percent of patients within 1 to 2 months after initiation of antifungal therapy and was more common in those receiving potent immunosuppressive regimens and those with graft loss. IRIS occurs in patients in whom there is a rapid shift in immune reactivity. Since the appearance of IRIS in fungal CNS infections is commonly misconstrued as a treatment failure or relapse of infection that leads to unwarranted or inappropriate changes in specific therapy, its clinical recognition is extremely important. IRIS should be considered when treatment appears to have controlled the fungal disease by culture or biomarker data but new signs of inflammation develop symptomatically or on imaging studies.

Recognition of IRIS is important to the clinical management of CNS fungal infections because overabundance of inflammation can lead to clinical worsening. Thus, corticosteroid therapy for IRIS may be considered to reduce inflammation and cerebral edema.

CRYPTOCOCCUS NEOFORMANS AND GATTII

The encapsulated yeast *C. neoformans* is the most common cause of fungal meningitis worldwide. The first report of cryptococcal infection in humans was provided by Busse and Buschke in 1894 in a patient with bone infection and probable disseminated disease. The first case of meningeal cryptococcal infection was reported 10 years later, in 1905, and cryptococcosis emerged as a significant CNS infection during the twentieth century. The number of infections with *C. neoformans* rose dramatically in the United States and certain African countries following the onset of the AIDS epidemic. It peaked at approximately a million cases per year, but even with the advent of widespread ART it is estimated that there are approximately 270,000 cases per year, with over 180,000 deaths.[4]

This ubiquitous encapsulated saprophytic yeast occupies a wide environmental niche. It is found worldwide in bird excreta, soil, animals, and even humans. A large outbreak of *C. gattii* infections in the Pacific Northwest was associated with trees. It is likely that most infections occur after inhalation of small yeasts or basidiospores, leading to a primary pneumonia or a primary lung–lymph node complex in which the yeasts remain dormant for long periods in the host, until the host defenses become weakened. The reason that this yeast has a particular tendency to spread to the CNS remains imprecisely explained. It is likely that *Cryptococcus* travels by three mechanisms across the blood–brain or blood–CSF barrier: (1) transcytosis; (2) paracellular; and (3) the Trojan Horse method. Ligands on *C. neoformans* such as the hyaluronic acid antigen (CPS1) have been associated with the CD44 receptor on brain endothelial cells, perhaps allowing for transcytosis through the blood–brain barrier. Another cryptococcal mechanism for transcytosis is to use the secreted yeast metalloprotease encoded by the *MPR1* gene. On the paracellular front, the *UREl* gene and its encoded protein help control trafficking of the yeast directly through the blood–brain barrier. Finally, multiple experiments have shown *Cryptococcus* to travel across the blood–brain barrier within mononuclear cells (Trojan Horse effect). It is anticipated that not only are there multiple mechanisms for CNS targeting but that many cryptococcal genes are involved in the efficient movement of *Cryptococcus* into the brain.

CNS infection usually manifests as a meningitis or meningoencephalitis, although mass lesions or torulomas may be seen. There are four serotypes (A to D) based on the type of capsular polysaccharide, which are then divided into several species: *C. neoformans* var. *grubii* or *neoformans* (serotypes A and D), and *C. gattii* (serotypes B and C). Furthermore, *C. neoformans* has been divided into multiple genotypes or subspecies of VNI, VNII, VNB (I and II), VNIII, and VNIV; *C. gattii* has been divided into five cryptic species (VGI–V). All serotypes can cause meningitis, but there is some geographic variation in their distribution for disease; for example, most patients with cryptococcal meningitis in the United States and Europe have been infected with either the serotype A or D strains. Infections with *C. gattii* are found more commonly in southern California, Southeast Asia, and Australia; this distribution reflects the natural distribution of certain *Eucalyptus* trees that are likely one of the environmental yeast repositories. A recent outbreak of *C. gattii* infections on Vancouver Island showed that there are other trees, such as firs and oaks, that can contain this fungus, perhaps related to ecologic evolution in the setting of global climate change. Despite earlier reports that many patients with cryptococcal meningitis had no known immune deficiency, recent experience suggests that a much higher proportion of patients have some identifiable form of immunosuppression. About 10 percent of patients with cryptococcal meningitis have no known underlying disease but a series of host-altered genes linked with an increased genetic susceptibility to cryptococcosis have been identified.[5] However, most cases occur in those with known defective cell-mediated immunity due to corticosteroid treatment, reticuloendothelial malignancy, organ transplantation, sarcoidosis, collagen vascular diseases, or AIDS. Use of new anticancer agents such as ibrutinib (kinase inhibitor) can be associated with rapid development of cryptococcal and *Aspergillus* brain infections. Lymphocyte functions are abnormal in most patients with disseminated cryptococcosis. Patients with HIV infection have severe lymphocytopenia with CD4 counts below 100/μL. Most patients with AIDS and cryptococcal meningitis present with a particularly high burden of CSF yeasts. India ink examinations of the CSF are positive in over 80 percent of patients, and extraordinarily high titers of cryptococcal polysaccharide antigen in CSF and serum are common, with quantitative viable CSF yeast counts that can exceed 10^6 colony-forming units (CFU)/mL of CSF. The response of some of these patients to infection includes a paucity of CSF leukocytes; approximately two-thirds of patients with AIDS and cryptococcal meningitis have fewer than 20 leukocytes/mm^3 in their CSF on presentation. This combination of a high burden of yeasts and a quantitative deficiency in the inflammatory response indicates an impaired immune system and can lead to a poor prognosis despite administration of fungicidal therapy.

Patients with cryptococcal meningitis may present with a wide spectrum of CNS findings, ranging from symptoms of headaches with or without fever to subacute dementia developing over months. The latex agglutination test and enzyme-linked immunosorbent assay are both sensitive ($>90\%$) and specific ($>90\%$) if proper controls are used. An inexpensive and simple lateral flow assay (LFA) has been developed and it compares favorably to the other antigen tests.

The recent addition of the BioFire PCR Film Assay uses multiplex PCR for major CNS pathogens and includes *C. neoformans.* Two aspects to this test need to be discussed. First, false negatives occur with low burden of yeasts, so pelleting CSF before PCR testing may be necessary. Second, a positive PCR test supports the fact that viable yeasts are present and might be used in deciding between relapse of infection and IRIS. Although cases occasionally are difficult to diagnose, with the proper use of CSF culture, India ink studies, polysaccharide antigen, and PCR tests, the only limiting factor in the diagnosis of CNS cryptococcosis is usually failure to perform a lumbar puncture because the diagnosis is not considered.

COCCIDIOIDES IMMITIS AND *POSADASII*

C. immitis and *C. posadasii* are dimorphic fungi with a natural habitat in semiarid soil, which explains their geographic distribution in the southwestern United States and in parts of Mexico and South America. Because many tourists travel through these areas and may become infected, clinicians outside the organism's natural habitat occasionally encounter coccidioidomycosis. Inhalation of the arthrospores leads to a primary pulmonary infection. Most patients remain asymptomatic, and fewer than 0.2 percent of primary infections disseminate outside the lung. Occasionally, the fungus reaches the meninges, either by hematogenous spread or direct extension from osteomyelitis of the skull or vertebrae; seeding of the CNS usually occurs a few months after the primary infection.

Symptoms of chronic meningitis are most common. There are cases in which brain involvement occurs without meningitis, but this presentation is unusual. Spinal arachnoiditis with obstructive hydrocephalus and cerebral vasculitis with infarcts and abscesses also have been reported. It appears that patients with coccidioidomycosis involving the facial skin are at higher risk of meningitis than those with skin involvement at more distant body sites.

Diagnosis may be confirmed by culture of the fungus from the CSF, but in endemic areas it is diagnosed in many patients on the basis of a CSF pleocytosis (which demonstrates eosinophilia in up to 70% of cases) and the presence of complement-fixing antibodies (CFAs) in the CSF. CFA titers are positive in approximately 70 percent of patients at initial diagnosis, and in almost all patients as meningitis progresses. A new *Coccidioides* antigen test of CSF can also frequently detect CNS involvement.[6,7]

It is likely that genetic susceptibility plays an important role as a risk factor for meningitis. For instance, meningitis appears to develop at greater rates in Blacks, Filipinos, and possibly other ethnic groups such as Hispanics compared to Whites.

Most patients who contract CNS infection with *Coccidioides* have no apparent underlying disease, but immunosuppressed patients are at greater risk of CNS involvement after primary infection. Corticosteroid treatment has been associated with more severe manifestations of primary infection, as well as with reactivation of latent disease and dissemination to the CNS. There have also been many reported cases of CNS infection with *Coccidioides* in patients with AIDS and in transplant recipients. The natural history of coccidioidal meningitis is such that patients whose only detected extrapulmonary site of infection is the CNS live significantly longer than those with more diffuse disease. White blood cell count in the CSF decreases during the course of both treated and untreated infection, and therefore cannot be used to gauge response to therapy. Unfortunately, lifelong triazole therapy for meningitis is required because of the extremely high rate of relapse after initial induction antifungal therapy.

HISTOPLASMA CAPSULATUM

H. capsulatum is a dimorphic fungus endemic in certain areas of the Ohio and central Mississippi River Valley in the United States as well as in Latin America. It can be found in bird and bat guano, and in soil contaminated with this guano. Outbreaks of the disease have been attributed to disturbance of contaminated soil, allowing the conidia to become airborne and inhaled. Asymptomatic infection in endemic areas is very common; skin test data indicate that up to 69 percent of the population show evidence of prior infection in certain endemic areas. Most infected individuals have minimal symptoms, and dissemination occurs only rarely. When dissemination does occur, between 10 and 25 percent of patients develop CNS involvement. Although granulomas and other brain parenchymal lesions have been described, most patients with CNS lesions present with meningitis.

Although *Histoplasma* meningitis can occur in apparently normal hosts, it occurs in immunocompromised populations at a higher rate. Patients with AIDS, solid organ transplant recipients, and those receiving biologics such as anti-TNF therapy are at high risk of development of disseminated disease, usually due to reactivation of latent infection. Because CSF cultures may be positive in only 10 to 30 percent of cases even when large volumes (10 to 20 ml) of CSF are incubated for weeks, it is important to use CSF serologies. There are occasional serologic cross-reactions with other fungi, which can cause diagnostic confusion. However, the *Histoplasma* CSF polysaccharide antigen has been found to be positive in 40 percent of patients with *Histoplasma* meningitis and is a reasonable first screening test for this fungus in the CNS.

BLASTOMYCES DERMATITIDIS

B. dermatitidis and recently discovered *Blastomyces helicus* are dimorphic fungi endemic in Africa and in certain parts of the lower Mississippi River Valley, North Central states, and mid-Atlantic states in the continental United States. It is presumed that spores are inhaled from a source in the soil, but its natural location in the environment has been identified only occasionally. Most individuals have subclinical disease, and dissemination occurs rarely. Disseminated blastomycosis is characterized by granulomatous and suppurating lesions of the lung, bone, and skin. In some series, blastomycosis has been reported to involve the brain in 6 to 33 percent of disseminated cases. Although patients with CNS blastomycosis usually present with evidence of infection at other sites, occasionally meningitis is the initial presentation and there is no evidence of extraneural disease. CSF cultures are rarely positive, and a chronic neutrophilic pleocytosis is a common finding in blastomycotic meningitis. In cases of subacute and chronic meningitis, screening the CSF by *Blastomyces* antigen testing may be helpful, although the sensitivity and specificity of such testing are not well characterized.

CNS involvement occasionally presents with a mass lesion (blastomycoma) within the brain parenchyma.

Immunocompromised patients are at increased risk of disseminated infection with *B. dermatitidis*. A review of 24 cases of infection with *B. dermatitidis* in a heterogeneous population of immunocompromised patients showed 6 cases of disseminated disease, including 4 with CNS involvement.

PARACOCCIDIOIDES BRASILIENSIS

P. brasiliensis is a dimorphic fungus endemic to subtropical areas of Mexico and Central and South America. The lung is the primary location for initial infection; a few patients present with widely disseminated disease that can involve the CNS. Small case series report dissemination in 9 to 27 percent of patients, and the infection reportedly involves the CNS in approximately 13 percent of cases with disseminated disease.

Meningitis is an unusual manifestation of CNS infection with *P. brasiliensis*, with brain parenchymal involvement more common; patients frequently present with seizures. CNS infection occurs in normal hosts and in those who are immunosuppressed. The host response against this microorganism remains poorly understood but an immunosuppressed individual probably has an increased chance of CNS involvement.

SPOROTHRIX SCHENCKII

S. schenckii and its other species are worldwide saprophytes of vegetation, notably sphagnum moss. Sporothricosis presents as a chronic infection of the skin and the subcutaneous lymphatic system, developing after a primary inoculation such as a rose-thorn puncture or cat scratch. Pulmonary disease from inhalation of spores is uncommon. Dissemination beyond the skin, lung, and joints is rare; only approximately a dozen cases of *Sporothrix* meningitis have been reported in the literature, and most do not have overt extraneural disease at presentation. Diagnosis of this infection with its low fungal burden in the CNS can be extremely difficult using traditional culture methods. To reduce diagnostic delays of up to 6 to 7 months, a test for *Sporothrix* antibodies in the CSF should be performed; it may be the only clue to the diagnosis.

Although meningitis with *S. schenckii* is so uncommon that risk factors cannot be defined accurately, certain patients may be predisposed to dissemination from a local infection including patients with myelodysplastic syndromes, ethanol abusers, or patients taking corticosteroids. Disseminated and CNS sporotrichosis has also been described in patients with AIDS.

TALAROMYCES MARNEFFEI

Talaromyces (Penicillium) marneffei is a dimorphic fungus that is found in the geographic range of bamboo rats, and has become a common cause of opportunistic infection in HIV-infected patients in certain parts of Southeast Asia and China. Pathophysiologically, the infection appears similar to histoplasmosis but it has a unique predisposition for producing skin lesions, and blood cultures are usually positive. In one series, 3 of 20 CSF samples were positive for this fungus during disseminated disease. Importantly, around 10 percent of patients with disseminated talaromycosis may also have a concomitant cryptococcal meningitis.

CANDIDA SPECIES

Candida species form part of the normal human microbial flora and rarely cause invasive disease unless host defenses are impaired. The yeast can gain access to the blood stream and then the CNS via contaminated intravenous catheters or through illicit intravenous drug use. Neonates, neutropenic patients, and those recovering from major surgery are particularly susceptible to invasive candidiasis, including CNS involvement. However, neutropenic patients rarely have CNS involvement despite a high incidence of bacteremia and fungemia. The placement of foreign bodies in the CNS, such as drug wafer implants and shunts, can also provide an entry for *Candida* infections. Based on autopsy studies, *Candida* species are the most common fungi to invade the CNS in the setting of malignancy, and their ability to transverse the immature blood–brain barrier efficiently is a dreaded complication of fungemia in neonates with both mortality and associated neurodevelopmental morbidity. *Candida* may cause meningitis, ventriculitis, or brain parenchymal lesions such as abscesses or granulomas. *C. albicans* is the species implicated in most CNS *Candida* infections, but other species such as *C. tropicalis*, *Candida lusitaniae*, and *Candida parapsilosis* will occasionally produce CNS disease.

In the normal host, *Candida* rarely causes deep-seated infections. Factors that can encourage spread of *Candida* from mucosal surfaces to deeper tissues, such as the subarachnoid space, include prematurity, broad-spectrum antibacterial therapy, hyperalimentation, malignancy, indwelling catheters, treatment with corticosteroids, neutropenia, abdominal surgery, diabetes mellitus, burns, and intravenous drug use. *Candida* invades brain tissue more commonly than the subarachnoid space.

Candida meningitis has been reported in both congenital and acquired immunodeficiency syndromes, emphasizing the importance of the host response. For example, patients with chronic granulomatous disease of childhood and myeloperoxidase deficiency may present with *Candida* meningitis. Several cases of *Candida* meningitis have been reported in patients with the global immune defects caused by severe combined immune deficiency and the specific innate immunity defects of chronic mucocutaneous candidiasis. Furthermore, specific gene nucleotide polymorphisms in innate immune genes such as *CARD9* are described as risk factors for *Candida* meningitis. Therefore, a specific underlying immune deficiency should be considered in any case of spontaneously occurring *Candida* meningitis, especially in children. Patients with AIDS frequently have mucocutaneous forms of candidiasis such as thrush and esophagitis, but involvement of the CNS has been reported rarely in these patients. *Candida* meningitis has been described as a superinfection of the CNS in patients recovering from bacterial meningitis. *Candida* infection can involve the brain and subarachnoid space by direct extension through trauma, ventriculostomy placement, ventricular shunts, or after other neurosurgical procedures, particularly in the presence of antibacterial use. *Candida* uncommonly can also invade from the adjacent paranasal sinuses or bone. Intracranial extension of the infection may occur through an arteritis and can even lead to subarachnoid hemorrhage.

The CSF in *Candida* meningitis can show a predominance of either mononuclear or neutrophilic cells. Only half of routine CSF cultures yield the fungus, despite the fact that *Candida* organisms are easy to grow in the laboratory; a large CSF volume is needed to optimize culture because of low fungal burden, and better methods of CSF detection need to be validated to detect *Candida* products such as arabinitol or antigens such as β-D-glucan or mannan. The clinical significance of a positive culture for *Candida* from CSF obtained through an indwelling device such as a ventriculostomy tube may not be clear as the fungus is a frequent contaminant; if a positive culture is found and CSF parameters are normal, another CSF specimen should be obtained from a separate lumbar puncture. In the absence of symptoms or an abnormal CSF profile, and with a negative follow-up culture, further treatment is probably unnecessary but the device should be removed and, when necessary, replaced.

ASPERGILLUS SPECIES

Aspergillus species are ubiquitous in the environment and can be found in the air of most buildings, including hospitals. Both neutrophils and macrophages provide important host defense mechanisms directed against the spores and hyphae of *Aspergillus*. CNS infection with *Aspergillus* species can develop by direct extension from the paranasal sinuses, by direct inoculation after head trauma, following surgery, or by hematogenous spread in immunocompromised hosts, particularly those with prolonged neutropenia. This fungus accounts for approximately 5 percent of CNS fungal infections. A clinically important characteristic of *Aspergillus* infections is their angioinvasive attack on arteries, causing thromboses and cerebral infarction or mycotic aneurysm. Less commonly, meningitis and meningoencephalitis can occur, and rhinocerebral disease similar to mucormycosis has been described.

Most intracranial infections with *Aspergillus* occur in neutropenic patients. The risk of disseminated aspergillosis with subsequent brain parenchymal involvement or meningitis increases with the duration of neutropenia. Individuals receiving high doses of ibrutinib for CNS lymphomas are at high risk for CNS aspergillosis. Most infections manifest as brain parenchymal lesions, but spinal cord lesions may also develop. Occasionally, *Aspergillus* infection involves the vertebrae and eventually the subarachnoid space. Patients with chronic granulomatous disease of childhood with its lack of an oxidative burst by phagocytes are particularly susceptible to this type of infection. The pulmonary alveolar macrophage may be most important in initial control of this ubiquitous fungus in the lungs, but polymorphonuclear leukocytes are probably crucial in defense against CNS invasion.

Diagnosis can be delayed because of insensitivity of cultures, and both a CSF PCR and galactomannan antigen tests on CSF are helpful in diagnosing CNS involvement.

MUCORMYCOSIS

Fungi of the order Mucorales are widespread in the environment and infection is usually due to inhalation of spores. The genus *Rhizopus* is responsible for most human infections. CNS infection in immunocompromised hosts can occur by direct extension from the paranasal sinuses, through hematogenous spread such as with illicit intravenous drug use, or by spread along nerve roots. Mucormycosis commonly is associated with angioinvasion of arteries with thrombosis and resulting tissue infarction. Presentation involving invasion of the subarachnoid space occurs occasionally, but disease limited to the meninges is unusual. In a large review of 929 cases with mucormycosis, 283 patients had CNS infection, of which 69 percent were rhinocerebral, 16 percent were localized cerebral infection, and 15 percent had hematogenous dissemination from other organs.

Patients with diabetes mellitus (with or without ketoacidosis) or malignancy, and those receiving immunosuppressive drugs or prolonged voriconazole therapy are at risk for this invasive mold infection. There have been reports of disseminated mucormycosis, including brain involvement, in patients on dialysis receiving the iron chelator, deferoxamine; this agent may interfere with the antifungal activity of transferrin, thus allowing for dissemination of the mold. A different iron chelator, deferasirox, cannot be used as a siderophore by the fungus and actually has been evaluated as a treatment of mucormycosis as it competes for essential iron supplies with the fungus.

SCEDOSPORIUM SPECIES

Scedosporium species have a worldwide distribution in soil and contaminated water. These fungi are being renamed and have been known as *P. boydii*, *Monosporium apiospermum*, or *S. apiospermum* when in the asexual state. Although rare, CNS infection with these molds can result in brain abscesses or chronic neutrophilic meningitis. Classically, CNS infection is associated with aspiration of contaminated water during trauma, or near-drowning in fresh water. Presumably, the fungus penetrates through the cribiform plate during water immersion or establishes a pulmonary focus with later dissemination to the CNS, producing meningitis or brain abscesses. Other risk factors for infection include corticosteroid use and diabetes.

PHAEOHYPHOMYCOSIS

The dematiaceous fungi are a group of common environmental molds that have brown pigment in their walls; diverse genera are linked by their ability to produce melanin. This group of fungi has occasionally caused CNS infection, and for certain species it appears that there is some neurotropism. For instance, *Cladosporium trichoides*, also known as *Xylohypha bantiana* and finally renamed as *Cladophialophora bantianum*, is the most common isolate of this class of fungi found in CNS infections, which usually manifest as a brain abscess, although meningitis has been described. Meningitis and brain abscesses caused by other species of these "black molds" are also occasionally reported, such as with *Rhinocladiella mackenzei* in the Middle East.

CNS infections with these organisms have been caused by contaminated corticosteroid injections around the spine. In 2002, *E. dermatitidis* produced four cases of meningitis from contaminated corticosteroids injected epidurally for pain management. Patients presented with headaches, altered mental states, and focal neurologic findings approximately 1 to 3 months after the injections. A larger outbreak of *E. rostratum* infections in 2012 and 2013 involved over 500 cases; clinical presentations ranged from meningitis with or without stroke to parameningeal infections (e.g., epidural abscess, arachnoiditis with cauda equina syndrome, and vertebral osteomyelitis).[8]

Many patients diagnosed with brain abscesses due to one of these dematiaceous fungi have no apparent underlying immune defect, but immunosuppressed patients may be at special risk. The portal of entry for these fungi is not known in most cases, but because of a predilection for abscess formation in the frontal and parietal lobes, at least some of these infections may result from direct extension through the sinuses.

HYALOHYPHOMYCOSIS

Nonpigmented, hyaline filamentous molds cause occasional infections of the CNS. For instance, meningitis and cerebritis have been reported with *Acremonium* and *Paecilomyces* species. In severely neutropenic patients, the soil saprophytes, *Fusarium* species, can produce CNS lesions. Because of similar histopathologic features, *Fusarium* infection can be confused with aspergillosis unless cultures are performed or histopathologic tissue specimens have PCR and sequencing performed on them. In the growing immunosuppressed population, *Trichosporon* infection, which usually involves only superficial skin or hair shafts, can disseminate to the brain; CNS infections with *T. beigelii* or *T. ashaii* and *Blastoschizomyces capitatus* (*Saprochaete capitatum*) have been reported to cause CNS diseases.

DIAGNOSIS

The specific diagnosis of CNS fungal disease can be very challenging, even in the setting of known disseminated fungal infections. Factors that lead to this difficulty include the unusual and varied clinical presentations of patients with CNS fungal infections, difficulty in culturing organisms from the CNS due to a low burden of fungus, and the lack of sensitive serologic tests for many fungi.

Even in cases of cerebral mass lesions due to fungi, patients may present with nonfocal neurologic symptoms and signs. For instance, many patients present only with altered sensorium or seizures, despite having extensive CNS infection on neuroimaging. Fungal meningitis usually leads to chronic signs and symptoms including a combination of fever, headache, lethargy, confusion, nausea, vomiting, stiff neck, and neurologic deficits. However, the characteristic markers of CNS infection, fever and headache, both may be absent, and patients may present initially only with a subacute dementia. Cases of cryptococcal, coccidioidal, and *Histoplasma* meningitis may be indolent, with symptoms persisting for months to years if untreated; in consequence, the timing of symptoms is not always an accurate guide to diagnosis. In contrast, occasional cases of cryptococcal meningitis present acutely after only several days of symptoms, especially in severely immunocompromised patients and particularly those receiving ibrutinib or high doses of corticosteroids, or with advanced HIV infection.

Fungal infection is a primary consideration in the differential diagnosis of patients with chronic meningitis, defined as those with meningitis-related CNS abnormalities that either progress or fail to improve during at least 4 weeks of observation. The differential diagnosis of chronic meningitis includes both infectious and noninfectious causes (Table 45-2) but fungal infection should be high in the differential diagnosis. It may also be particularly difficult to distinguish infection due to fungi from that caused by certain other subacute or chronic CNS pathogens such as mycobacteria.

TABLE 45-2 ■ Differential Diagnosis of Chronic Meningitis

Infectious Causes	Noninfectious Causes
Fungal infections	Chronic benign lymphocytic meningitis
Mycobacterial infections	Subarachnoid hemorrhage
Parameningeal infections	Systemic lupus erythematosus
Syphilis	Granulomatous arteritis
Lyme disease	Carcinomatous meningitis
Brucellosis	Sarcoidosis
Toxoplasmosis	Behçet disease
Nocardiosis	
Actinomycosis	
Leptospirosis	
Helminthic meningitis	
Viral meningitis	

The CSF findings in fungal meningitis are well described. In most instances a mononuclear pleocytosis is present, with leukocyte counts ranging between 20 and 500 cells/mm^3. In some cases of fungal meningitis there is a predominance of polymorphonuclear cells. Eosinophilic pleocytosis of the CSF has been described in approximately 70 percent of cases of coccidioidal meningitis and, rarely, in cases of cryptococcal meningitis. Very low CSF leukocyte counts ($<10/\text{mm}^3$) may occur when patients are severely immunosuppressed; a normal CSF profile has even been observed in some cases. CSF protein levels usually are elevated, but if very high protein concentrations (≥ 1.0 g/dL) are present, a subarachnoid block should be considered. CSF glucose concentrations may vary from normal to low. The causes of hypoglycorrhachia are listed in Table 45-3. The finding of a low glucose concentration in the CSF favors an infectious disorder and may have prognostic significance in that persistent hypoglycorrhachia after treatment for cryptococcal meningitis without HIV infection raises concern for risk of relapse. Elevated CSF pressures of 250 mm CSF or higher may have prognostic and therapeutic implications, particularly in cryptococcal meningitis.

It is unusual to see fungi on direct stains prepared from CSF, except in the case of cryptococcal meningitis. The India ink test is not commonly used now that a rapid, cheap, and accurate antigen test is available. India ink preparations of CSF are positive in only 50 percent of all patients with cryptococcal meningitis, and in 80 percent or more of those who have underlying HIV infection. The number of fungi present in CSF in cases of fungal meningitis is highly variable. In some cases of cryptococcal meningitis, there are at least 10^6 CFU/mL of CSF, whereas the dimorphic fungi often have less than 1 CFU/mL of CSF. Approximately 75 percent of all patients with cryptococcal meningitis yield positive CSF cultures; patients with HIV infection have positive cultures in more than 90 percent of cases. Unfortunately, in meningitis cases due to fungi other than cryptococci, CSF cultures are often negative, and

TABLE 45-3 ■ Differential Diagnosis of Low Cerebrospinal Fluid Glucose Concentration

Acute bacterial meningitis

Viral meningitis (rare)
Hypoglycemia
Rheumatoid meningitis
Lupus myelopathy
Amebic meningitis

they are rarely positive in patients with cerebral mass lesions. For example, only one-third to one-half of patients with coccidioidal meningitis yield CSF cultures that are positive. Patients with blastomycotic meningitis rarely yield positive CSF cultures, and in proven *Histoplasma* meningitis it is difficult to find the organisms in the subarachnoid space, even at necropsy. Because the burden of organisms in CSF is so often low, relatively large volumes of CSF (10 to 20 ml) should be obtained and sent for culture in suspected cases.

The laboratory should centrifuge specimens and culture the sediment on appropriate fungal media. *Candida* organisms usually can be identified within a few days; in occasional patients, hypertonic media may be helpful for growing the yeast. In neonates, CSF cultures are important as blood cultures may be negative and CSF parameters may be normal in culture-positive *Candida* meningitis. *Cryptococcus* should be identified within 3 to 10 days in most cases, but the classic dimorphic fungi (e.g., *Histoplasma* or *Coccidioides*) may require longer incubations. The lysis-centrifugation method for isolating *H. capsulatum* from blood and CSF has improved detection compared with routine methods. Blood cultures may also be helpful for identifying the fungus that is causing meningitis in a particular host; *Candida* species, *Talaromyces*, or *Cryptococcus* are the fungi most likely to be present on blood cultures. CSF cultures can also be negative simply because the samples were not taken from the localized site of active infection. For example, because fungi commonly cause a basilar meningitis, cisternal or ventricular fluid may occasionally yield organisms when fluid from the lumbar space is sterile.

Serologic tests are important for the diagnosis of many fungal infections in the CNS. For example, the latex agglutination test, ELISA, and LFA[9] for detection of cryptococcal polysaccharide antigen are the best serologic tests for this pathogen and can be used with rapidity on blood, serum, or CSF. The tests can be positive even when culture is negative. When samples are heated to eliminate rheumatoid factor and proper controls for nonspecific agglutination and interfering substances are used, the antigen tests are more than 90 percent sensitive and specific for cryptococcal infection. If surface condensation from agar plates is added to the assay, false-positive results may occur, which can also be seen with disseminated *T. beigelii* infections and paravertebral bacterial infections. If a positive antigen test occurs in a patient whose clinical presentation is not consistent with cryptococcal meningitis, the laboratory should repeat the test, and if it is still positive, a repeat lumbar puncture is indicated. False-negative results may be due to very low burdens of pathogens, a prozone phenomenon due to antigen excess, or the performance characteristics of various different proprietary antigen detection kits. The value of using cryptococcal antigen titers as a general prognostic guide is well established; however, following serial titers are less valuable for guiding specific therapeutic decisions.

With the availability of an accurate and cheap LFA, in areas of high incidence of cryptococcal disease, screening for serum cryptococcal antigen can be undertaken in new cases of documented HIV infection with low CD4 counts.[10] Positive serum cryptococcal antigen titers will initiate a lumbar puncture to rule out CNS disease. If culture and antigen are negative in CSF and serum titer is low (≤1:256), preemptive fluconazole treatment may be started until ART improves immunity.

Detection of the *Histoplasma* polysaccharide antigen in urine and serum is a valuable adjunctive test in the diagnosis of disseminated disease. It is also useful in monitoring therapy and for the early detection of relapsing infection in HIV-positive patients. False-positive results may occur in patients with meningitis due to other fungi. Tests detecting CSF antibodies against *Histoplasma* antigens are also useful, and are positive in approximately 75 percent of patients with CNS infection. Although sensitive, these antibody tests are not highly specific, and positive results may also be found in patients with other fungal infections or with bacterial meningitis. The best way to diagnose CNS *Histoplasma* infections when cultures are negative is to perform both antigen and antibody testing on the CSF. Empiric treatment for *Histoplasma* infection should be started in patients with chronic meningitis of uncertain etiology when the antigen or antibody assays are positive in the CSF.

In coccidioidomycosis, elevated serum CFA titers above 1:32 to 1:64 are the hallmark of disseminated disease. Some patients with isolated meningitis without extraneural infection may also have low serum CFA titers. In patients with coccidioidal meningitis, CFA titers are present in the CSF in 70 percent of patients initially and in almost 100 percent as the infection progresses. A coccidioidal antigen test is now available and may be helpful. CFA is absent from unconcentrated CSF in the presence of high-serum titers due to extraneural disease, unless there is a parameningeal lesion next to the dura. The CFA titers appear to parallel the course of meningeal disease and have been used to guide treatment; titers should decline with successful therapy.

The ability to detect specific antibodies in CSF has been used in the diagnosis of meningitis caused by *S. schenckii*. Waiting for culture data can lead to delays of up to 7 months from the onset of symptoms, and therefore latex agglutination and enzyme immunoassay tests have been used successfully to detect CSF antibodies confirming the diagnosis of *Sporothrix* meningitis. When a titer cut-off of 1:8 or higher is used, there is no cross-reaction with other fungal, bacterial, or viral pathogens.

There is intense interest in developing serologic tests for other fungal infections, especially those due to *Candida* and *Aspergillus*. Detection of unique antigens (β-D-glucan and mannan) or metabolic products (arabinitol and mannitol) from these fungi in CSF has not yet been extensively validated in the clinical setting of meningitis. However, β-D-glucan is frequently detected in CSF with many fungal CNS infections and may be a good screen.[11] Furthermore, the galactomannan and β-D-glucan detection tests for *Aspergillus* in the CSF are likely to be useful in diagnosing and managing this rare and difficult-to-detect infection.[12,13]

Two other approaches for diagnosis of fungal meningitis are detection of host products and the use of molecular amplification. Although not specific for fungi, CSF lactic acid concentrations usually are elevated in fungal meningitis and, in some cases, specific fungal T-cell responses can be detected. It is likely that as further experience accumulates with PCR-based diagnostics for meningitis, fungal sequences will be included in new diagnostic approaches. For example, *C. neoformans* is part of the BioFire Film Array CNS panel that uses PCR. As previously noted with cryptococcal PCR, a false negativity may occur with a low burden of yeasts in the CSF, and CSF may thus need to be centrifuged prior to testing. The approach may be helpful in distinguishing IRIS from relapse since a positive PCR likely means that there are viable yeasts in CSF. For difficult-to-diagnose fungal infections, whole-genome sequencing of CSF may eventually become useful to detect and identify fungal DNA in the CSF.

Imaging studies can be helpful in the diagnosis and staging of CNS fungal infections. Localization of mass lesions or areas of leptomeningeal inflammation by computed tomography (CT) or magnetic resonance imaging (MRI) can guide the neurosurgeon to areas for biopsy. MRI with contrast enhancement is more sensitive than contrast CT scans. In cases of fungal meningitis, CT and MRI may be unremarkable or show leptomeningeal enhancement, hydrocephalus, infarction (as with mucormycosis), or edema. During treatment, there may be slow resolution of CNS lesions on imaging studies despite effective treatment, and clinicians must take this into account. When meningitis is refractory to conventional diagnostic approaches, meningeal biopsy for histologic study and culture can be considered, although false negatives can occur.

TREATMENT

Experience in the treatment of fungal CNS infections is varied. For example, treatment for cryptococcal meningitis has been studied extensively, whereas many fungal CNS infections are so rare that only a few cases have been described. An important adjunct to antifungal therapy is the reversal, if possible, of any immunocompromising conditions. This may include decreasing doses of corticosteroids or the use of immunomodulators to improve host immunity. However, CNS infections require very close monitoring when host immunity is changed.

Specific Fungal Infections in the Central Nervous System

CRYPTOCOCCAL MENINGITIS

Before the availability of amphotericin B, cryptococcal meningitis was uniformly fatal, although occasionally an untreated patient survived for several years. Early treatment trials showed that immunosuppressed patients with cryptococcal meningitis had higher treatment failure rates than immunocompetent patients. Patients with AIDS were found to have low response rates to initial therapy and high relapse rates once therapy was stopped. Because of this important dichotomy in the patient populations with cryptococcal meningitis, the treatments for patients with and without HIV infection are discussed separately. The 2010 Cryptococcal Guidelines of the Infectious Diseases Society of America (IDSA) separated risk groups into those with AIDS, transplant recipients, and non-AIDS, nontransplant patients.

Nonimmunosuppressed Patients

Amphotericin B used alone at daily doses of 0.4 to 0.8 mg/kg per day for 10 weeks provides effective therapy for patients without HIV infection who develop cryptococcal meningitis. The addition of flucytosine to this regimen has been studied in an effort to decrease both the duration of therapy and the total dose of amphotericin B. Following early trial data, experience with amphotericin B plus flucytosine as primary therapy in cryptococcal meningitis has accumulated. This combination usually sterilizes the CSF within 2 weeks and cures many patients within 4 to 6 weeks, with manageable amphotericin B toxicity. Patients with good prognostic features and no known immunosuppressive conditions have been successfully managed with as little as 4 weeks of combined therapy. The regimen nevertheless requires the administration of an intravenous medication for prolonged periods, and some treatment failures (15 to 30%) do occur.

Treatment regimens using oral antifungal agents for cryptococcal meningitis would obviously be attractive, and therefore both itraconazole and fluconazole have been tried. There are no large trials comparing azole antifungals with amphotericin B in patients without HIV infection. Personal experience and data extrapolated from trials in patients with AIDS suggest that high-dose fluconazole can be used successfully as monotherapy for patients with cryptococcal meningitis, but is not as effective as the combination of amphotericin B plus flucytosine because of reduced fungicidal activity. Therefore, most experts do not recommend use of fluconazole (1200 mg/day) alone for induction therapy of cryptococcal meningitis. Itraconazole has also been used successfully in treating cryptococcal meningitis, but because there is more experience with fluconazole, many physicians consider this the preferred azole. A compromise can be reached in an effort to reduce the amount of time on intravenous therapy by using an induction phase of amphotericin B plus flucytosine followed by prolonged consolidation and maintenance (suppressive) phases with oral fluconazole.

This combined drug regimen is highly recommended in treatment guidelines published by the Infectious Diseases Society of America, and consists of amphotericin B at a dose of 0.7 to 1.0 mg/kg per day plus flucytosine at a dose of 100 mg/kg per day to keep serum levels below 100 μg/mL for 2 weeks, after which the patient is switched to fluconazole at a dose of 400 to 800 mg/day, assuming normal renal function, for a minimum of 10 weeks. There has been a substantial clinical switch to using AmBisome 3 to 4 mg/kg per day rather than conventional amphotericin B so there is less toxicity and thus less interruption of therapy, which may be important for success. A lumbar puncture should also be considered after 2 weeks; if the CSF PCR or culture still yields *C. neoformans*, treatment with amphotericin B (AmBisome) and flucytosine should be reinstituted for another 2-week course of induction therapy. If the CSF is sterile after induction amphotericin B plus flucytosine therapy, fluconazole can be started. The total duration of fluconazole therapy should be tailored to the individual patient, but at least 10 weeks of treatment should be administered. Because most relapses of cryptococcal meningitis occur within 6 months to 1 year after stopping therapy, generally a maintenance or suppressive dose of fluconazole 200 to 400 mg/day is given for 6 months to 1 year in patients who do not have HIV infection. Additional and higher doses of fluconazole may be required in patients with brain parenchymal lesions, persistent symptoms, concomitant immunosuppressive therapy, or underlying immunosuppressing diseases. Patients with torulomas may require longer induction therapy.

The need for intraventricular or intrathecal amphotericin B in cryptococcal meningitis remains controversial. Some investigators have used intraventricular amphotericin B with success in cases with a poor prognosis. However, this route of administration is rarely necessary and may have complications. In high-risk patients, it may be better to switch to lipid-based amphotericin B regimens and use doses up to 5 or 6 mg/kg per day, or possibly higher, rather than risk the side effects of direct injection of amphotericin B into CSF. These lipid formulations are highly recommended in transplant recipients and generally for all patients to avoid drug interruption.

Once therapy has been started, the frequency of lumbar punctures should be determined by clinical response. As mentioned earlier, a lumbar puncture performed after the second week of therapy should show that the CSF is sterile, particularly if the combination of amphotericin B and flucytosine was used. Once therapy is completed, further lumbar punctures should be considered depending on the patient's signs and symptoms. Persistently elevated polysaccharide antigen titers or positive India ink examinations indicate failure of therapy only when the CSF culture is positive or the patient demonstrates neurologic deterioration. There is probably little value in following serial cryptococcal polysaccharide antigen titers acutely to make therapeutic decisions.

Immunosuppressed Patients

The management of cryptococcal meningitis in patients with AIDS presents a major therapeutic challenge. Response to initial therapy in ART-treated cases has improved, and the relapse rate, which was once very high, has been reduced by maintenance or suppressive fluconazole treatment and ART. Recurrence of symptomatic cryptococcal meningitis in patients with AIDS is typically due to the same strain that caused the original infection and it is thought that the prostate or brain parenchyma can serve as sites for persistent residual infection despite sterilization of the CSF.

There is a substantial amount of clinical data to support recommendations for the treatment of AIDS-associated cryptococcal meningitis published by the Infectious Diseases Society of America. Induction therapy includes amphotericin B 0.7 to 1.0 mg/kg per day with flucytosine 100 mg/kg per day for 2 weeks. The combination regimen is favored because of more rapid CSF sterilization, potentially fewer relapses, and better outcomes.[14] In patients who have significant renal dysfunction, liposomal amphotericin B 3 to 4 mg/kg per day or amphotericin B lipid complex 5 mg/kg per day can be substituted for conventional amphotericin B. The induction period usually lasts for 2 weeks but can vary depending on clinical response. Patients are then switched to fluconazole (400 to 800 mg/day) for 10 weeks. Fluconazole alone has been evaluated for primary therapy of cryptococcal meningitis, but clinical experience suggests that it takes longer to sterilize the CSF than amphotericin B and requires higher doses. If given orally for induction, fluconazole should be given with flucytosine. Triazoles may be more effective when the burden of yeasts in CSF is lower. It is anticipated that 80 to 90 percent of patients will respond well to this initial combination course of therapy.

In resource-limited areas the availability, safety, and cost of polyene therapy for 2 weeks can be problematic. In such circumstances, a combination of amphotericin B plus flucytosine for 1 week has been shown to be effective.[15] The use of one dose of AmBisome (10 mg/kg) on a fluconazole base is also successful.[16] Thus, depending on healthcare resources, induction therapy may vary, but these abbreviated short-course polyene strategies should not be used at present in resource-available healthcare systems. An unresolved issue is that in Africa flucytosine is not available consistently.

The third stage of the treatment plan is the continued use of fluconazole at a dose of 200 mg/day for prevention of relapses. The high rate of relapse in these patients led to the initial institution of lifelong fluconazole suppressive therapy for all patients with AIDS who respond to initial treatment for cryptococcal meningitis. However, the immune restoration associated with ART has prompted reinvestigation of lifelong suppression; patients who have been treated with ART and have a sustained immunologic response may be able to safely discontinue maintenance therapy. Appropriate candidates for stopping maintenance therapy are patients who have had at least 1 year of therapy with fluconazole, along with a CD4 count above 100 cells/μL (or more than 10% CD4 cells). These patients should be monitored closely, and fluconazole maintenance reinstituted if the CD4 count falls below 100 cells/μL or below 10 percent CD4 cells or if there is reappearance of serum cryptococcal antigen titers that were previously negative. In one prospective trial, 42 patients who had responded to antifungal therapy for cryptococcal meningitis were randomized to either continue or discontinue maintenance therapy for cryptococcal meningitis once the CD4 count had increased to above 100 cells/μL and the HIV viral load had been below 50 copies/mL for 3 months on ART; over a median follow-up of 48 weeks, no relapses occurred in either group. It is important to note that ART should not be started during the first 2 weeks of induction therapy for cryptococcal meningitis because of higher mortality.[17] ART is generally delayed for 5 to 6 weeks after the start of cryptococcal therapy.

Complications

Increased intracranial pressure is a well-described problem in patients being treated for cryptococcal meningitis. Symptoms in such patients usually begin shortly after initiating antifungal therapy and include systemic hypertension, increasing headaches, impaired consciousness, visual impairment, cranial nerve palsies, and death. These symptoms can occur suddenly, and head imaging usually shows no evidence of hydrocephalus or mass lesions. The opening pressure at lumbar puncture can be extremely high (≥250 mm of CSF). The pathophysiologic cause of increased intracranial pressure in this setting is uncertain but may well be CSF outflow obstruction. Most patients with AIDS-associated cryptococcal meningitis present with increased intracranial pressure, and up to 70 percent of this patient population will have opening pressures exceeding 200 mm of CSF on the initial lumbar puncture. In these patients, symptoms generally respond rapidly to removal of large volumes of CSF, which can be accomplished with CSF drainage.[18] Treatment guidelines published by the Infectious Diseases Society of America recommend that sufficient CSF be removed to achieve a closing pressure either below 200 mm of CSF or 50 percent of the opening pressure. Some patients require serial lumbar punctures for relief of severe symptoms and physical findings; for those patients requiring very frequent lumbar punctures, placement of a ventricular shunt should be considered. Despite theoretical concerns regarding placement of catheters into infected spinal fluid, experience shows no increased difficulties in clearing the infection if effective antifungal therapy has already been started. Placement of a lumbar drain is an option, but the relatively frequent complication of bacterial superinfection precludes long-term use. The use of corticosteroids or acetazolamide to decrease raised intracranial pressures in the setting of AIDS-associated cryptococcal meningitis does not appear to be beneficial except when corticosteroids are used in the setting of IRIS. Indeed, the routine use of corticosteroids is not beneficial in cryptococcal meningitis,[19] unlike for tuberculous meningitis.

Visual loss in cryptococcal meningitis may not respond to maneuvers aimed at decreasing intracranial pressure. Blindness is usually not due to endophthalmitis, is often bilateral, and may be permanent. Many treatments have been tried with inconsistent results in an effort to restore vision including repeated lumbar punctures, treatment with corticosteroids, fenestration of the optic nerve sheath, and release of perioptic nerve arachnoidal adhesions.

The management of IRIS in cyptococcal meningitis is not precise. First, the diagnosis is clinical but is considered when CSF cultures and PCR are negative and the antigen is stable or decreasing on therapy despite persistent or increasing evidence of inflammation by CSF analysis or neuroimaging. Treatment is not well studied but, importantly, clinical response does occur to corticosteroids,[20] but dose and duration remain empiric.

There are several major prognostic factors that determine the outcome of patients with cryptococcal meningitis. Control of the underlying disease is the most important factor. The burden of yeasts in the CSF, indicated by positive India ink examinations, high polysaccharide antigen titers, and elevated intracranial pressure, is also predictive. High numbers of yeasts worsen the prognosis, and patients may then need more aggressive individual clinical management. The impact of the host response is also important; patients with a poor CSF inflammatory response, such as those with less than 20 leukocytes/mm^3 on CSF examination, do not respond as well to therapy, and studies suggest that immunomodulators may be of help. Interferon-gamma levels in the CSF may help determine clearance of infection, and treatment with recombinant interferon-gamma with antifungal agents tends to reduce CSF yeast counts faster than antifungal agents alone. However, immune modulators are not standard therapy because of IRIS and lack of immune stimulation precision. Finally, symptoms at presentation, such as a decreased sensorium, suggest advanced disease and also a poor prognosis.

CANDIDA *MENINGITIS*

While there are reports of spontaneous cures of meningitis due to *Candida* species, clinical experience suggests that treatment is indicated for all patients. Even with treatment, mortality rates for *Candida* meningitis range between 10 and 20 percent. There is no consensus on the best regimen, but the combination of amphotericin B and flucytosine has synergistic activity against *Candida* in vitro and has resulted in a high-cure rate. There is substantial experience with amphotericin B alone, which also can successfully treat *Candida* meningitis. Fluconazole with its high CSF penetration can be used in certain cases, although it usually does not sterilize CSF as fast as amphotericin B—containing regimens. Liposomal amphotericin B has been used after failure of conventional amphotericin B and has been combined successfully with flucytosine. In patients with ventriculoperitoneal shunts or ventriculostomies, it is recommended that any prosthetic material or device be replaced during systemic antifungal therapy. Although mortality has improved with treatment, neurodevelopmental disabilities may persist in neonates. Echinocandins have poor CNS penetration and therefore have not been favored in treatment of *Candida* meningitis.

COCCIDIOIDAL MENINGITIS

In contrast to meningitis due to other fungi, the primary mode of treatment for coccidioidal meningitis with amphotericin B is not systemic but intraventricular. In these infections, systemic amphotericin B in a total dose of 0.5 to 1.0 g is given mainly to treat undetected foci outside the CNS and lipid formulations probably could be substituted with higher-dose exposure. Control of the CNS infection is then achieved by intraventricular administration of amphotericin B. Intrathecal therapy is begun with small doses of 0.01 mg/day and increased gradually, as tolerated, up to 0.5 mg/day. The drug can be administered into the lumbar, cisternal, or ventricular space; the latter is preferred. Arachnoiditis, neurotoxicity, and secondary bacterial infections of the CSF can complicate therapy. Recommendations for length of therapy are variable, and because of the poor prognosis for complete cure some patients have been treated indefinitely. The CSF leukocyte count has been used to follow progress and to judge the need for further therapy. Lowering of the CSF antibody titers after treatment is a good prognostic sign. If the patient worsens during treatment, the possibility of hydrocephalus or a superimposed bacterial infection should be considered.

There has been some clinical benefit from treatment with oral azoles. Miconazole and ketoconazole have been tried, but response has been only fair, and therefore these agents are not recommended. More experience has focused on using fluconazole and itraconazole as therapy for coccidioidal meningitis. In one study of 47 patients with coccidioidal meningitis treated with fluconazole 400 mg/day, a positive response to therapy occurred in 37 patients unrelated to the presence of hydrocephalus or HIV infection. Toxicity is minimal in patients treated for long periods. It is therefore reasonable to consider fluconazole as a first-line agent in patients with coccidioidal meningitis; its ease of administration and lack of toxicity compared with intrathecal amphotericin B are important considerations. The optimal dose of fluconazole is not certain and some authorities believe that at least 800 mg/day of fluconazole should be used as initial treatment. The use of induction therapy with intrathecal amphotericin B followed by long-term azole therapy has also been proposed as a possible treatment option in some cases. It is unclear what role voriconazole or posaconazole will have in treatment of refractory disease. Current treatment strategies consider coccidioidal meningitis to be suppressed rather than cured, thus requiring lifelong therapy. Observational studies suggest that with current treatments, over 70 percent of patients will relapse on discontinuation of treatment.

OTHER FUNGAL INFECTIONS

Meningitis due to *Histoplasma*, *Sporothrix*, or *Blastomyces* usually responds to prolonged courses of amphotericin B or lipid formulations of amphotericin B. The role of azole drugs in these infections is not clearly defined, but they are generally used only after aggressive induction treatment, most commonly with a lipid amphotericin B formulation. *Scedosporium* CNS infections may respond to initial therapy with the extended-spectrum triazoles such as voriconazole. Cotrimoxazole has been used successfully in *Paracoccidioides* meningitis. In one study *Talaromyces* infections appeared to respond better to amphotericin B than itraconazole treatment, although CNS disease was not a focus of the study.

Infections of the CNS with *Aspergillus* species generally have been fatal despite therapy. However, there are a few cases of successful therapy with high-dose amphotericin B, and extended-spectrum new triazoles such as voriconazole have improved outcome in CNS aspergillosis. Patients with CNS aspergillosis may be considered for combination therapy with voriconazole or posaconazole plus an echinocandin and possibly also the addition of lipid amphotericin B. It also may be helpful to debulk a large abscess surgically.

Mucormycosis of the CNS should be treated initially with high doses (5 mg/kg daily) of lipid formulations of amphotericin B and, if possible, surgical debridement of infarcted tissue. Surgical debulking of fungal masses is even more important in the phaeohyphomycoses, which then may be treated with a combination of a polyene, an azole, an echinocandin, and possibly flucytosine.

Surgical Treatment

Neurosurgical procedures can play an important role in the diagnosis and treatment of some CNS fungal infections. Obtaining appropriate CSF or tissue samples for diagnosis using neurosurgical procedures may be required in some cases. The placement of CSF-diverting shunts may be needed in cases of hydrocephalus or increased intracranial pressure, even during the period of active drug treatment of infection. The placement of reservoirs to allow for chronic intrathecal administration of antifungals may also be required in certain CNS infections.

Surgical resection of parenchymal lesions has been undertaken to reduce mass effect in some cases of *Histoplasma*, *Cryptococcus*, and *Aspergillus* infection, but for these fungi the presence of parenchymal CNS lesions usually does not routinely indicate the need for neurosurgical excision. In contrast, when black molds such as *Cladophialophora* or *Rhinocladiella* species and other dematiaceous fungi cause mass lesions, surgical resection or debulking is usually encouraged for cure. Rhinocerebral infections due to mucormycosis also require prompt debulking of necrotic tissue in the brain.

Fungal infections of CSF shunts and reservoirs are uncommon and are most often due to *Candida* species. Shunt infections should be treated with removal of the shunt and systemic antifungal therapy when possible. However, there are cases in which shunt removal is not possible or in which shunt placement occurs during periods of active drug treatment of meningitis. It is recommended that in the setting of a CNS fungal infection, the shunt should be removed if it was placed prior to the initiation of antifungal therapy.

Parasitic Infections of the Central Nervous System

ANITA A. KOSHY

PROTOZOAN INFECTIONS
- Cerebral Malaria
- Cerebral Toxoplasmosis
- African Trypanosomiasis
- Primary Amebic Meningoencephalitis and Granulomatous Amebic Encephalitis
- Cerebral Amebiasis due to *Entamoeba histolytica*

HELMINTHIC INFECTION
- Cestodes
  - *Cysticercosis*
  - *Echinococcosis (Hydatid Disease) and Sparganosis*
- Nematodes
  - *Disseminated Strongyloidiasis*
  - *Trichinosis*
  - Angiostrongylus cantonensis
  - Gnathostoma *spp.*
  - *Visceral larval migrans:* Toxocara *spp. and* Baylisascaris procyonis
  - Onchocerca volvulus *and* Loa loa
- Trematodes
  - *Schistosomiasis*
  - *Paragonimiasis*

Protozoans and helminths are responsible for a significant burden of human disease, disproportionately affecting resource-limited countries worldwide. These agents are collectively referred to as parasites, implying dependence on an adversely affected host, but in this context they are no different from other infectious agents, such as bacteria and viruses.

Protozoan parasites are single-celled, microscopic organisms that generally undergo multiplication in the mammalian host. In contrast, helminthic parasites are multicellular, vary tremendously in size, and, in general, are less capable of multiplying within the mammalian or definitive host.

Protozoa and helminths have complex life cycles and have adapted to exist within the hostile environment of one and sometimes several hosts. The distribution of these infectious agents parallels the poor socioeconomic conditions in the developing world. However, with widespread travel, infections due to these agents are being seen more frequently in nonendemic settings. In addition, with the increasing number of immunosuppressed patients resulting from infection with human immunodeficiency virus (HIV) or after transplant or chemotherapy, disease manifestations can be more frequent, severe, and aggressive. Central to the clinician's approach to the patient with a central nervous system (CNS) infection with a protozoan or helminthic organism is a thorough travel history and an increased index of suspicion. Once such an infection is suspected, an appropriate work-up can be initiated.

The protozoa and helminths that cause the bulk of CNS disease are summarized in Table 46-1.

PROTOZOAN INFECTIONS

Cerebral Malaria

Malaria is the most important parasitic infection worldwide. In 2017 an estimated 219 million cases were reported, about 90 percent of which were from Africa. About 435,000 deaths were due to malaria, with approximately 60 percent occurring in children younger than 5 years of age. While Southeast Asia continues to see steady declines in malaria cases, declines in Africa have slowed or reversed recently.[1]

Malaria infection is widely distributed (Fig. 46-1). Five species of malaria infect humans: *Plasmodium falciparum*,

TABLE 46-1 ■ Parasitic Infections of the Central Nervous System

Organism	Geographic Distribution	Major CNS Syndromes	Mode of Infection
Protozoans			
Plasmodium falciparum	Africa, Haiti, South America, Southeast Asia, Oceania	Encephalopathy, coma, seizures	Mosquito
Toxoplasma gondii	Cosmopolitan	Congenital: retinopathy, intracranial calcification, intellectual developmental disability, seizures Immunocompromised: encephalitis, meningoencephalitis, mass lesions	Undercooked meat; contaminated water; vertical transmission
Trypanosoma brucei gambiense, *T. brucei rhodesiense*	Democratic Republic of Congo > Chad, Central African Republic (*T.b.g.*); Malawi, Uganda (*T.b.r*)	Personality changes, indifference, stupor, and coma in late stages	Tsetse flies
Naegleria fowleri	Southern United States, Australia, Great Britain, former Czechoslovakia	Acute rapidly progressive meningoencephalitis	Fresh water
Acanthamoeba spp.	Cosmopolitan	Subacute, chronic meningoencephalitis	Fresh water, soil
Balamuthia mandrillaris	Southern United States, South America	Subacute, chronic meningoencephalitis	Soil > water
Entamoeba histolytica	Africa, Mexico, South America, India, Southeast Asia	Brain abscess	Fecal–oral
Helminths			
Taenia solium	Cosmopolitan	Neurocysticercosis: seizures, hydrocephalus, chronic meningitis	Fecal–oral
Trichinella spp.	Cosmopolitan	Seizures, meningoencephalitis	Uncooked meat
Angiostrongylus cantonensis	Southeast Asia, Pacific Basin (including Hawaii)	Eosinophilic meningitis	Uncooked snails, crustacea
Gnathostoma spinigerum	Southeast Asia > Mexico, Central and South America	Eosinophilic meningitis	Uncooked fish, frog, bird, snake
Toxocara spp., *Baylisascaris procyonis*	Cosmopolitan	Seizures, palsies, retinal mass	Fecal–oral
Schistosoma species	Africa, Asia, Brazil	Seizures, cerebritis, tumor, spinal cord compression	Exposure to infected fresh water
Paragonimus species	Asia, Central and South America	Meningitis, mass lesion, infarction	Uncooked crustacea

CNS, central nervous system.

Plasmodium vivax, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium knowlesi*, although *P. knowlesi* is predominantly zoonotic. *P. falciparum* predominates in sub-Saharan Africa (>99% of cases), Haiti, New Guinea, Southeast Asia, South America, and Oceania. *P. vivax* predominates in the Americas and is common in endemic areas outside of Africa. Approximately 1,700 cases of malaria are diagnosed in the United States per year, primarily in recent travelers to and immigrants from areas in which malaria is endemic.

The life cycle of *Plasmodium* is similar across species. The infective sporozoites are injected by female *Anopheles* mosquitoes into subcutaneous tissue or directly into the blood stream, and thereafter circulate to the liver to invade hepatocytes. Parasites multiply, and after 1 to 2 weeks, schizonts rupture and release thousands of merozoites, which then enter the blood stream to infect erythrocytes. Of the five *Plasmodium* spp. that infect humans, *P. vivax* and *P. ovale* can establish a latent liver stage, which must be treated to avoid recrudescent infection.

Invasion of erythrocytes by merozoites requires specific surface receptors on the parasite and erythrocyte. In contrast with other *Plasmodium* species, *P. falciparum* uses multiple redundant pathways to invade, including sialic acid-dependent glycophorin pathways and nonsialic

🟩 Malaria transmission is not known to occur

FIGURE 46-1 ■ Global map of malaria transmission. (From the US Centers for Disease Control and Prevention.)

acid-dependent ones. In addition, *P. falciparum* can invade erythrocytes of all ages, and parasitemia can reach high levels. The magnitude of parasitemia was previously thought to relate to the degree of morbidity and mortality, but other factors such as the degree of metabolic stress in nutritionally deficient children, presence of parasitic coinfections, and other less-understood mechanisms may play significant roles in adverse outcomes.

Within the erythrocyte, merozoites eventually develop into schizonts, which rupture to release merozoites capable of infecting new erythrocytes. Only the asexual erythrocytic stages are directly deleterious to the host, and the mechanisms involved in the development of clinical manifestations are related to fever, anemia, and tissue hypoxia, as well as to host factors including immunopathologic events.

While high fever and rigors are the hallmarks of acute malaria, some patients with acute malaria, often those under age 5, will develop severe malaria, which is defined as having clinical or laboratory evidence of organ dysfunction (e.g., renal failure, pulmonary edema, coma). Most severe malaria, including cerebral malaria, occurs in patients with *P. falciparum*, though *P. vivax* can also cause severe malaria.

Cerebral malaria occurs in 0.5 to 1 percent of *P. falciparum* cases and is associated with a 15 to 20 percent mortality. Significant neurologic sequelae develop in around 10 percent of cases. Sequestration of parasitized erythrocytes within the capillaries of the cerebral cortex is typically observed, but is likely not the only pathogenic mechanism. While the pathogenesis of cerebral malaria is incompletely understood and remains highly speculative, it is postulated that parasitized red blood cells express parasite-derived variant surface antigens, causing the erythrocytes to adhere to endothelial cells of venules, resulting in microvascular obstruction. Specific *var* genes, the gene family that encodes the malarial cytoadherence protein *P. falciparum* erythrocyte membrane protein 1, and host receptors are postulated to play key roles in cerebral malaria pathogenesis. In addition, recent data suggest that endothelial cells are a major site of pathology as these cells show signs of activation, including characteristic morphologic changes, upregulation of surface adhesion molecules and antigens, and production of numerous cytokines and other mediators of inflammation.[2]

The World Health Organization (WHO) defines cerebral malaria as unarousable coma in a person with *P. falciparum* asexual parasitemia in whom other causes of encephalopathy have been excluded. Children under 5 have the highest rates of cerebral malaria, though adults and older children can also develop the disease. As noted earlier, it remains unclear as to what host or parasite factors determine the development of cerebral malaria. Presenting features may include seizures (15 to 20% in adults, 80% in children), disturbances of consciousness, acute delirium, meningismus, and, infrequently, focal neurologic abnormalities, including pyramidal signs, cranial nerve abnormalities, or movement disorders. Decorticate posturing or decerebrate posturing is more common in children and may indicate increased intracranial pressure or hypoglycemia. Adults are more likely than children to present with diffuse encephalopathy and no focal neurologic signs. As severe malaria affects other organs, concomitant findings can include hepatosplenomegaly, pulmonary edema, renal dysfunction, severe anemia, and hypotension. Hypoglycemia is often also seen in cerebral malaria and severe malaria, especially in pregnant women. Other causes of CNS infection and encephalopathy must be excluded, and biochemical screening of blood and examination of cerebrospinal fluid (CSF) are mandatory.

Although cerebral malaria should be suspected in any person with impaired consciousness, fever, and recent travel to or residence in a *P. falciparum*-endemic country, confirming the diagnosis can be difficult. While demonstration of *P. falciparum* parasites in thick and thin blood smears should establish the diagnosis, one must consider the possibility of another cause for the impaired consciousness with coincident parasitemia. This concern is especially high for children from countries with high levels of asymptomatic parasitemia. In addition, the sensitivity and specificity of microscopy are operator dependent and can be problematic in nonendemic countries where laboratory technicians are not experienced in microscopic evaluation, or in resource-limited settings where diagnostic equipment is substandard or unavailable.

Several point-of-care diagnostics (now called rapid diagnostic tests or RDTs) based on immunoassays that detect specific parasite proteins have been developed and field-tested. These tests use a small amount of patient blood to determine if the patient is infected with a malaria species and if that species is *P. falciparum*; they are rapid and inexpensive. However, these tests are considered complementary to microscopy as they have poor sensitivity in patients with low parasite burdens; cannot determine the level of parasitemia; and do not differentiate between the non-*falciparum* species of malaria. Like microscopy, RDTs do not distinguish between cerebral malaria and coincidental parasitemia.

When cerebral malaria is a consideration, lumbar puncture should be performed to exclude other causes of encephalopathy. In cerebral malaria, CSF examination occasionally reveals elevated protein concentration or mild pleocytosis, especially if seizures have occurred. Hypoglycorrhachia is not a feature and indicates other causes.

A variety of abnormalities in laboratory tests may be observed in cases of *P. falciparum* malaria, including a normocytic, normochromic hemolytic anemia, leukopenia, monocytosis, thrombocytopenia, proteinuria, azotemia, elevated liver enzymes, and disseminated intravascular coagulation. With severe *P. falciparum* malaria, lactic acidosis, elevated blood creatinine, and hypoglycemia may be observed. Hypoglycemia, which is often seen in children and pregnant women or as a result of intravenous quinine therapy, may be responsible for deteriorating neurologic status and so must be recognized and treated.

Currently there is no diagnostic role for brain imaging in cerebral malaria, but there are studies using imaging to try to discern abnormalities specific to cerebral malaria, including prognostic factors and even pathophysiology. Fundoscopy should be performed since the presence of malaria retinopathy is the only reliable clinical feature that distinguishes cerebral malaria from other CNS pathologies.[2]

Severe malaria, including cerebral malaria, should be treated parenterally. The standard of care is now intravenous artesunate. To obtain artesunate in the United States, the CDC Malaria Hotline should be called (770-488-7788 anytime or 855-856-4713 Monday through Friday 9 A.M. to 5 P.M. EST). The dose of intravenous artesunate is weight based. For adults/children greater than 20 kg the dose is 2.4 mg/kg, while for children less than 20 kg the dose is 3.0 mg/kg. Appropriate doses are given at 0, 12, 24, and 48 hours. While awaiting the delivery of intravenous artesunate the CDC lists a number of enteral alternatives that can be given.[3] After the course of artesunate is administered, an oral course of antimalaria drugs should be given.[3] If oral medications cannot be given, then 7 days of intravenous artesunate, doxycycline, or clindamycin can be given.

After initiation of antimalarial therapy, patients with *P. falciparum* infection must be closely monitored for complications and response to treatment. Seizures should be treated with anticonvulsants, and frequent glucose monitoring is essential to manage hypoglycemia. Maintaining adequate fluid balance is critical in preventing further morbidity, especially in those with renal failure or pulmonary edema. Blood transfusions can be used to correct anemia, but can lead to significant fluid overload. The CDC no longer recommends exchange transfusions.

In an attempt to decrease the mortality and morbidity associated with severe malaria and cerebral malaria, many adjuvant therapies have been tried. Measures that have failed to show clinical improvement or made outcomes worse include broad immunosuppression (e.g., corticosteroids, intravenous immunoglobulins, cyclosporine), anti-TNF treatment (e.g., antitumor necrosis factor alpha antibodies or pentoxifylline), and prophylactic phenobarbital, mannitol, and antithrombotics (e.g., aspirin, ibuprofen, *N*-acetylcysteine, heparin). Other adjunctive therapies for severe malaria, not specifically cerebral malaria, are currently in trials or their outcomes have not yet been reported.

Cerebral Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan that naturally infects most warm-blooded animals from birds to humans. The prevalence of *T. gondii* infection in humans worldwide is estimated to be 25 to 30 percent but varies greatly by geographic location and socioeconomic status. Felids (i.e., cats) are the definitive hosts in which the sexual life cycle occurs, while the asexual life cycle occurs in intermediate hosts such as humans. Humans commonly become infected with *T. gondii* via ingestion of food or water contaminated with the persistent forms of *T. gondii* (i.e., bradyzoite-containing tissue cysts from intermediate hosts or sporozoite-containing oocysts excreted in the feces from acutely infected felids). As implied by being the "T" in the TORCH acronym for congenital infections, *T. gondii* can also be vertically transmitted in newly infected pregnant women, leading to the recommendation for pregnant women to avoid contact with cat feces. Infections have also been acquired through blood transfusions, organ transplantation, and accidental inoculation in laboratory workers, though these routes are quite rare.

Upon entry into humans, the sporozoite or bradyzoite, depending on the infective stage ingested, transforms into a tachyzoite that invades host cells and disseminates via the lymph and blood. The tachyzoite invades host cells and forms a protective parasitophorous vacuole within the cytoplasm. Like most intracellular microbes, the parasite modifies the host cell via the secretion of a number of effector proteins. How *T. gondii* crosses the blood—brain barrier to enter into the brain and retina has not been definitively determined, but evidence exists that *T. gondii*: (1) passes from the vasculature between endothelial cells; (2) infects endothelial cells and then ruptures across the basolateral side of the cell; or (3) is carried into the brain by infecting an immune cell that then travels across the blood—brain barrier. Tachyzoites infection is controlled by an intact T-cell response (CD8 cells more than CD4 cells) which produce interferon-γ. In skeletal and cardiac muscle and in the brain and retina, parasites switch to the bradyzoite form and establish cysts, which appear to provoke less of an immune response (Fig. 46-2). These cysts persist as reservoirs for reactivation or transmission.

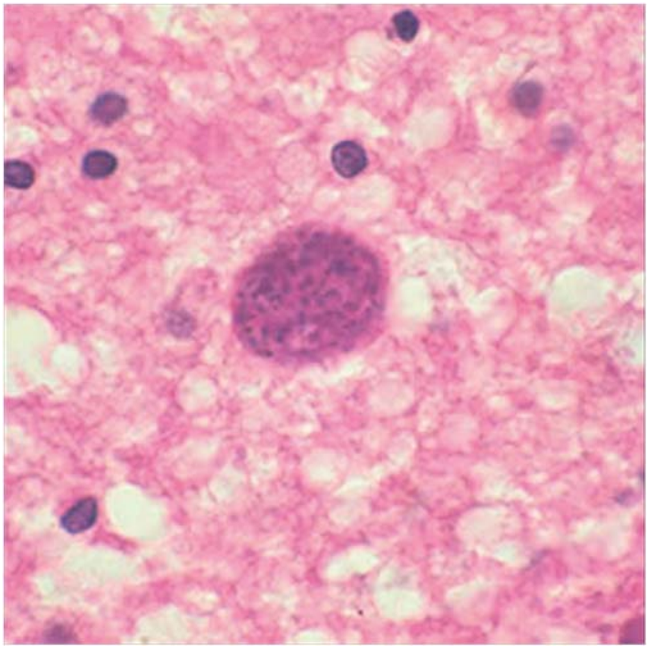

FIGURE 46-2 ■ *Toxoplasma gondii* cyst in brain tissue stained with hematoxylin and eosin. (From the US Centers for Disease Control and Prevention.)

Approximately 80 percent of primary toxoplasmosis infection is asymptomatic in immunocompetent adults. Nontender cervical adenopathy is most frequently seen among symptomatic individuals, but generalized adenopathy and a mononucleosis-like illness may occur. In the immunocompetent patient, the course of toxoplasmosis is usually benign and self-limited. A minority of patients can develop persistent lymphadenopathy or ocular toxoplasmosis. Ocular toxoplasmosis was previously thought to arise primarily from congenital infection, but more recent work suggests that it arises equally often from postnatally acquired *T. gondii* infection. Ocular lesions usually present as a focal, necrotizing retinitis with intense vitreal inflammation, showing a characteristic "headlight in fog" appearance. Relapses of chorioretinitis are frequent and are evident in the areas around the chorioretinal scars (Fig. 46-3).[4]

Congenital infection arises most commonly as a result of primary infection of the mother during gestation or 3 months prior to conception. Congenital infection can also occur in a chronically infected mother who is severely immunocompromised (e.g., AIDS) during gestation, or in a chronically infected pregnant woman

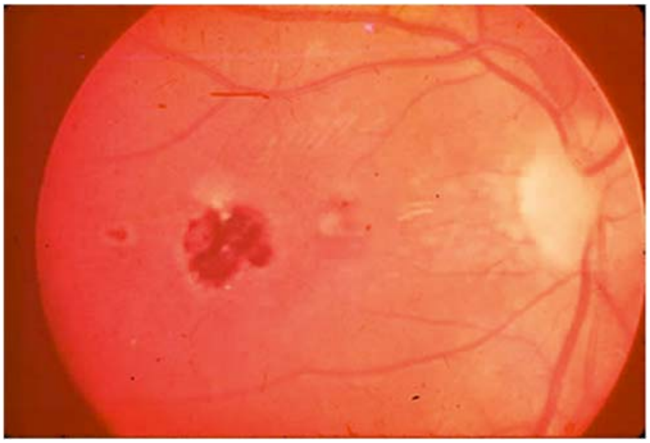

FIGURE 46-3 ■ *Toxoplasma* chorioretinitis: a pale, atrophied lesion containing black pigment. (From the US Centers for Disease Control and Prevention.)

who becomes infected with a new, highly virulent strain to which her prior infection does not confer immunity. Infection acquired in the first trimester is severe and can be associated with spontaneous abortion. Infection later in pregnancy shows more variable severity depending on individual factors. In the newborn, the presence of hydrocephalus, retinochoroiditis, or intracranial calcifications is suggestive of congenital toxoplasmosis and should be evaluated accordingly. Most infants are asymptomatic at birth but may present with overt symptoms, including severe developmental delay later in life.

Toxoplasmic encephalitis most commonly occurs as a result of reactivation of a latent infection which occurs in the setting of significant compromise of T-cell function (e.g., AIDS, organ transplant, and hematologic malignancies). In addition, immunosuppressants including steroids, mycophenolate mofetil, and adalimumab have been linked to rare cases of toxoplasmic encephalitis. In the immunocompromised, primary infection with *T. gondii* usually results in systemic or lung symptoms, rather than CNS involvement. Immunodeficient individuals with toxoplasmic encephalitis usually manifest with encephalitis, meningoencephalitis, or mass lesions (Fig. 46-4); therefore, toxoplasmic encephalitis often presents as a nonspecific decrease in mentation, seizures, or with focal neurologic findings. Frank meningismus is rare.

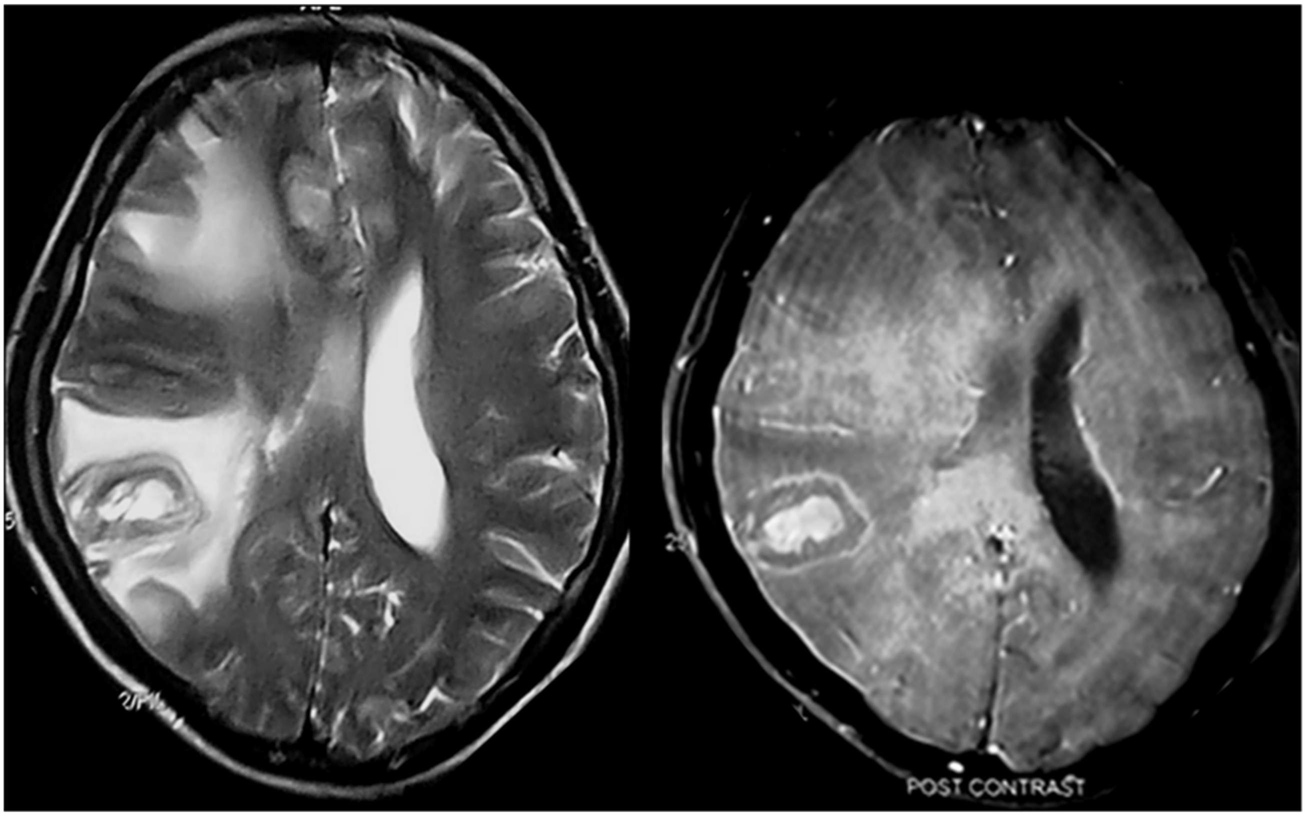

FIGURE 46-4 ■ Magnetic resonance imaging (MRI) of toxoplasmosis in a patient with AIDS. T2-weighted MRI showing the lesion with extensive perilesional edema (left); T1 contrast-enhancement of toxoplasmosis lesion (right). (Courtesy of Dr. Nicolette Mariano.)

The diagnosis of primary toxoplasmosis in immunocompetent hosts, transplant patients, and pregnant women is typically established through serology, either with a positive IgM to IgG seroconversion in paired sera or a twofold increase in IgG titers. Prenatal diagnosis can be confirmed by amniotic fluid polymerase chain reaction (PCR) or fetal ultrasound consistent with findings of congenital toxoplasmosis.[5] Most disease in immunocompromised hosts is reactivation disease, and the presence of IgG antibodies is suggestive of the diagnosis. Among HIV patients, toxoplasmic encephalitis usually occurs after the CD4 count has fallen to less than $100/\text{mm}^3$, although those with CD4 counts less than $200/\text{mm}^3$ are at risk for toxoplasmic encephalitis. If the patient is taking appropriate trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis, then even in the setting of a low CD4 count, toxoplasmic encephalitis is unlikely. Histology of brain biopsy specimens confirms the diagnosis but is impractical in most cases. PCR of serum, CSF, and biopsy tissue has been performed with varying degrees of success. CSF PCR is very specific, but the sensitivity is low (50%). For retinochoroiditis, the diagnosis is usually made by fundoscopic exam. Serology of aqueous humor in parallel with serum or PCR of the aqueous and vitreous can be used in cases where the clinical diagnosis is ambiguous.[4]

Cranial imaging should be performed in patients with suspected CNS toxoplasmosis. Neuroimaging usually reveals multiple ring-enhancing or solid lesions typically located in the gray matter; in HIV patients the cerebral cortex is more common than the basal ganglia, and thalamic locations are more likely than cerebellar (Fig. 46-4). In those with severe immunosuppression, atypical presentations with a lack of enhancement may occur. In infants, computed tomography (CT) is the method of choice, although ultrasound can be used. CSF findings are nonspecific and include mononuclear pleocytosis, elevated protein, and normal glucose. It should be noted that in the setting of mass lesions in the brain parenchyma, lumbar puncture is generally not recommended or indicated.

Definitive diagnosis of toxoplasmosis is made in the presence of a compatible clinical syndrome, consistent findings on magnetic resonance imaging (MRI), CT, or other imaging modalities, and detection of the protozoan in a clinical sample. AIDS patients with multiple enhancing cerebral lesions and with a positive IgG antibody should be presumed to have toxoplasmic encephalitis and started on empiric therapy and monitored for clinical and imaging improvement by 2 to 3 weeks following initiation of therapy. Biopsy is reserved for refractory cases, non-AIDS immunocompromised patients, or in AIDS patients with single lesions or those who are IgG negative.

Suspected or confirmed cases of ocular toxoplasmosis that is active and threatens vision should be treated. Several regimens have been used to treat it successfully, with a combination of pyrimethamine, sulfadiazine, and leucovorin being the most common regimen. Other regimens, including intravitreal clindamycin, are reviewed elsewhere.[4] The use of systemic steroids in combination with antiparasitic drugs is indicated for those with severe vitreous inflammation, affected vision, lesions close to the optic nerve or fovea, and large active lesions.[4]

Management of infected pregnant women varies considerably. Confirming a diagnosis of acute infection is essential due to the potential toxicity of the drugs used for treatment and for guiding decisions about termination of the pregnancy. Treatment indications and regimens for pregnant women and children with congenital toxoplasmosis are reviewed elsewhere.[5]

AIDS patients with CD4 counts less than 100 cells/mm^3 who develop reactivation toxoplasmic encephalitis should always be treated with at least two agents. The first-line treatment for toxoplasmic encephalitis is usually a combination of pyrimethamine and a sulfonamide. These antifolates are active against tachyzoites and are synergistic in combination. Pyrimethamine is lipid-soluble and readily penetrates the brain parenchyma even in the absence of inflammation. The usual regimen for adults is an oral loading dose of 200 mg of pyrimethamine followed by 50 to 75 mg daily for 3 to 6 weeks as well as sulfadiazine at a dose to 1 to 1.5 g orally every 6 hours for 3 to 6 weeks. The lower doses are for patients weighing less than 60 kg and the higher dose for those who weigh 60 kg or above. While patients are taking pyrimethamine and for 1 week after, patients should also receive folinic acid 10 to 20 mg orally daily; folinic acid alleviates some of the hematologic side effects associated with pyrimethamine. For those who are sulfa allergic, clindamycin orally or parenterally 600 mg every 6 hours or atovaquone 1,500 mg orally twice a day can be used in combination with pyrimethamine and folinic acid. In areas where pyrimethamine is not readily available, TMP-SMX (15 to 20 mg/kg daily of the trimethoprim component in three divided doses) has been found to be noninferior to pyrimethamine-based regimens.

For other alternative acute treatment options as well as for chronic treatment options for HIV/AIDS patients, please see the NIH guidelines.[6] Most non-HIV/AIDS immunocompromised patients will be treated with the same acute treatment regimens as listed above, but the chronic phase may differ and should be managed in conjunction with advice from other relevant medical specialists.

African Trypanosomiasis

Trypanosoma brucei is the causative agent of human African trypanosomiasis, which is also known as "sleeping sickness." Two distinct forms exist: western (chronic) sleeping sickness, due to infection by *T. brucei gambiense*, and eastern and southern (acute) sleeping sickness, caused by *T. brucei rhodesiense*. The tsetse fly, or *Glossina*, is the vector for *T. brucei*. Fewer than 1,000 new cases of human African trypanosomiasis were reported to the WHO in 2018, which represents a marked drop in cases over the last 20 years driven by sustained and focused efforts to treat patients with human African trypanosomiasis.

The majority of *T. b. gambiense* cases occur in the Democratic Republic of Congo, with the Central African Republic and Chad reporting far fewer cases. The disorder has a subacute course and is perpetuated mainly through chronically infected humans. East African trypanosomiasis (*T. b. rhodesiense*) occurs in the eastern and southern parts of equatorial Africa, especially Malawi and Uganda, and is typically acquired from zoonotic sources. It has a more fulminant course, with death occurring within a few weeks after infection, thereby decreasing the possibility of human reservoirs for infection. Most cases in travelers have been due to *T. b. rhodesiense*.

T. brucei undergoes several developmental stages in the tsetse fly over a life cycle of about 3 weeks. Upon ingestion with a blood meal, blood stream trypomastigotes become procyclic trypomastigotes in the insect midgut and divide rapidly. These then leave the midgut and transform into epimastigotes, eventually making their way into the fly's salivary glands. They change into metacyclic trypomastigotes, which are injected into the human or mammalian host with the blood meal. The metacyclic trypanosomes transform into the bloodstream form and invade extracellular spaces, including the blood, lymphatics, tissue fluids, and, eventually, the CNS via the CSF (Fig. 46-5).

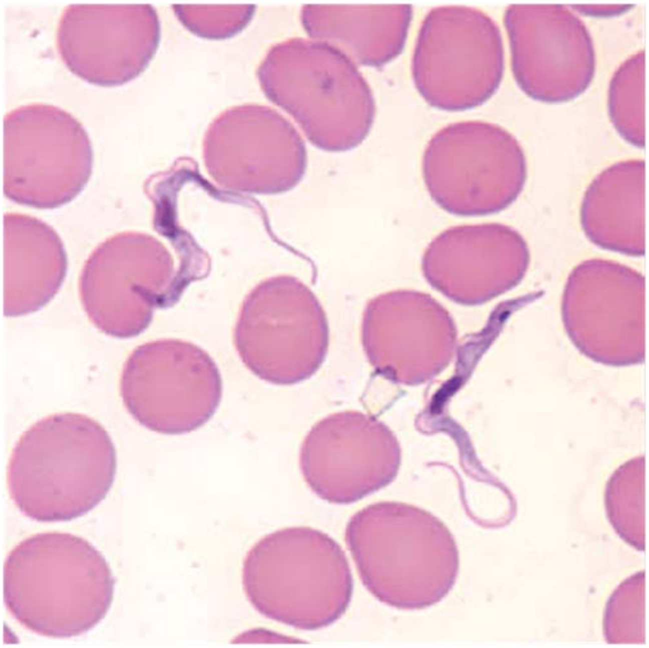

FIGURE 46-5 ■ African trypanosomes in thin blood smear. (From the US Centers for Disease Control and Prevention.)

Blood stream trypomastigotes evade the immune system by antigenic variation of their variant surface glycoproteins. In addition, *T. b. gambiense* and *T. b. rhodesiense* are resistant to killing by human apolipoprotein A1, which is a major trypanolytic factor that protects humans against other *T. brucei* subspecies infection. *T. b. gambiense* and *T. b. rhodesiense*'s resistance to this protein underlies their ability to cause systemic human infections.[7]

Clinically *T. brucei* disease is divided into two stages: the hematolymphatic stage (stage 1) and the meningoencephalitic stage (stage 2), with *T. b. gambiense* having a more prolonged course (mean time to death 3 years) and *T. b. rhodesiense* being relatively rapid (death within 6 months). While progressive untreated disease generally results in death, asymptomatic carriers and spontaneous cures have been reported for *T. b. gambiense* infections. The earliest clinical manifestation is a local, hard, painful lesion (trypanosomal chancre) at the site of the insect bite, which is more common in *T. b. rhodesiense* infection and rare with *T. b. gambiense*. Histologic examination of the chancre shows a lymphocytic infiltrate with dividing trypanosomes. Shortly afterward, widespread dissemination of the organism occurs via the blood stream and lymphatics. Lymphadenopathy of the posterior cervical regions (i.e., Winterbottom sign) is typical in *T. b. gambiense* infection, while *T. b. rhodesiense* more commonly causes submandibular, axillary, and inguinal lymphadenopathy. The first stage of *T. b. gambiense* infection can result in days to months of intermittent fever, headache, hepatosplenomegaly, and endocrine dysfunction. For *T. b. rhodesiense*, the first-stage symptoms are similar but less prolonged. Of note, travelers to endemic areas are more likely to present with chancres for either *T. brucei* infection and the incubation period is often shorter (<3 to 4 weeks). With progression of the disease, the systemic episodes decline in severity. The second stage occurs as the trypanosomes cross the blood–brain barrier and enter the brain. In this stage, sleep and neuropsychiatric symptoms predominate. These symptoms include daytime sleepiness, night-time insomnia, and abnormalities on polysomnography. In addition, a range of behavioral changes can also occur, including personality changes (e.g., emotional lability, aggression, apathy, or mania), confusion, and frank dementia. As the disease progresses, the neurologic manifestations become more severe, culminating with coma and death.[7]

Definitive diagnosis relies on observation of trypanosomes in aspirates from lymph nodes or concentration techniques used on blood or CSF. For *T. b. rhodesiense*, since the parasitemia level is higher, if concentration techniques cannot be done, motile trypanosomes may be visualized on nonconcentrated thin or thick blood smears in the early stages. The card agglutination trypanosomiasis test, which detects specific antibodies, is of value for screening of at-risk patients for *T. b. gambiense* but usually requires parasitologic confirmation as all areas of the world now have very low prevalence rates (<0.1%). CSF examination is essential for stage determination but cannot be used for definitive diagnosis of *T. brucei* disease unless trypanosomes are seen on microscopic examination.

Drug treatment is dependent on the stage of illness and the type of trypanosomiasis. The first stage is defined as patients with the diagnosis of *T. brucei* infection with a CSF leukocyte count of $5/\text{mm}^3$ or less and no trypanosomes visualized on CSF (i.e., no obvious CNS involvement), and the second stage is defined as those with CSF leukocyte counts greater than $5/\text{mm}^3$ or trypanosome visualization. For *T. b. gambiense*, with the approval of fexinidazole, second-stage disease is now subdivided in nonsevere (CSF WBC less than $100/\text{mm}^3$) or severe (CSF WBCs greater than $100/\text{mm}^3$). In *T. b. gambiense* infection, for people age 6 or older and body weight greater than or equal to 20 kg, those with first stage or nonsevere second stage should be treated with fexinidazole, while those with severe second stage (regardless of age or weight) should be treated with a nifurtimox-eflornithine combination therapy. Further details about *T. b. gambiense* treatment, including alternative therapies, are defined elsewhere.[8] For *T. b. rhodesiense*, first-stage disease is treated with suramin and second-stage disease with melarsoprol.[7] Melarsoprol is reserved for *T. b. rhodesiense* second-stage disease because it has a high rate of serious adverse reactions, including an encephalopathy syndrome that has a high mortality rate.

Primary Amebic Meningoencephalitis and Granulomatous Amebic Encephalitis

Primary amebic meningoencephalitis is an acute, rapidly progressive, necrotizing meningoencephalitis caused by the free-living ameba *Naegleria fowleri*. Despite the widespread distribution of *N. fowleri*, the disease is relatively rare and is associated with exposure to warm fresh water. In the United States, over 80 percent of the cases have occurred in the summer months and primarily in the most southern states, although Kansas, Missouri, and Minnesota have recently reported cases.

Infection is acquired when water containing the ameba is accidentally inhaled. Thus, most cases of *N. fowleri* are associated with recreational activities in warm freshwater lakes, though cases of *N. fowleri* have occurred in children bathing or playing in untreated well water or underchlorinated municipal water, as well as in adults who used *N. fowleri*–contaminated water for nasal irrigation. The ameba rapidly invades the olfactory neuroepithelium, gaining access to the brain through the cribriform plate. *Naegleria* infection initially involves the superficial gray matter with eventual extension to the deep matter and cerebellum. Prominent involvement of the frontotemporal areas, olfactory bulbs, and subarachnoid space has been observed. Neutrophil invasion, extensive necrosis, and vascular invasion are typical. The pathogenesis of infection likely involves multiple mechanisms, including secretion of lytic enzymes, elucidation of apoptotic factors, production of membrane pore-forming proteins, and direct feeding by the amoeba, resulting in a marked cytopathic effect.

Patients usually present within 5 days from exposure, although incubation periods of up to 14 days have been reported. The symptoms are commonly consistent with acute bacterial meningitis, including severe headache, fever, lethargy, nausea, and vomiting. Olfactory involvement, manifesting as nasal stuffiness or changes in smell, may be a clue to the etiology. Seizures, nuchal rigidity, and confusion, followed by coma, usually develop within days. Focal neurologic signs are rare. The patient then rapidly deteriorates and death occurs within a week. Brainstem herniation due to inflammation and increased intracranial pressure is the usual cause of death.

CSF findings are typical of acute bacterial meningitis with an elevated opening pressure, neutrophilic pleocytosis, low to normal glucose, and elevated protein levels. Elevated CSF red blood cells occur late in the course. If *N. fowleri* is suspected, a wet mount of CSF should be performed as it may show mobile trophozoites. Ideally the wet mount should be done rapidly after CSF collection as ameba may adhere to the container. Giemsa or Wright stain can help differentiate the trophozoite from host cells (Fig. 46-6). *N. fowleri* can also be identified through PCR of CSF or brain tissue or via commercially available next-generation sequencing of DNA or RNA obtained from CSF or brain tissue. Ameba can also be detected by immunohistochemical means on formalin-fixed brain.

Only a few survivors of primary amebic meningoencephalitis have been reported, likely because of delays in diagnosis, the rapid progression of symptomatic disease, and the lack of clarity regarding best treatments. Most survivors have received high-dose intravenous amphotericin as well a combination of additional drugs such as fluconazole, azithromycin, rifampin, and miltefosine. In addition, treatment should address elevated intracranial pressure and brain edema with the use of adjunct therapies such as dexamethasone, CSF drainage, hyperosmolar therapy, and even induced hypothermia. The Centers for Disease Control and Prevention Emergency Operation Center (open 24/7, 770-488-7100) can help with diagnostic and treatment recommendations. Of note, a recent case of supposed primary amebic meningoencephalitis, originally diagnosed as viral meningitis, with spontaneous recovery of the patient, was determined to be caused by a *Paravahlkampfia* species. This case raises the possibility that the rare survivors of primary amebic meningoencephalitis, in times prior to definitive molecular diagnostics, were infected with other free-living ameba rather than *N. fowleri*.[9]

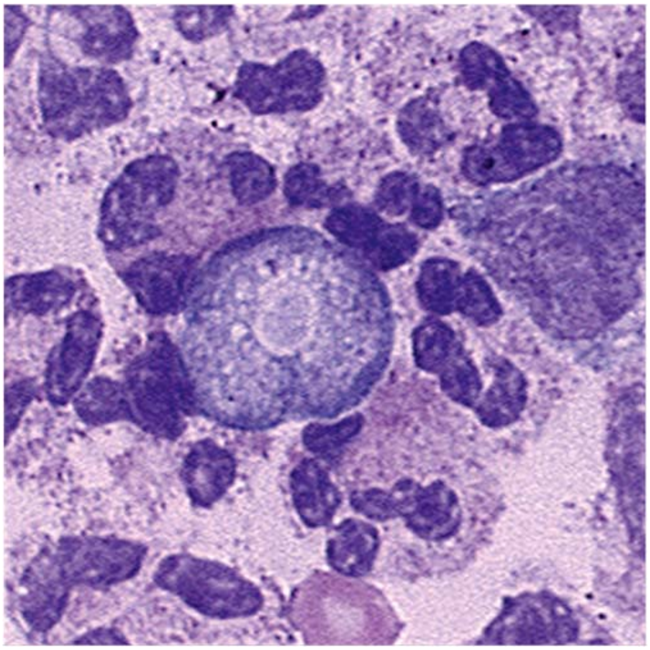

FIGURE 46-6 ▪ Primary amebic meningoencephalitis. *Naegleria* trophozoite in CSF. (From the US Centers for Disease Control and Prevention.)

Granulomatous amebic encephalitis is a subacute, indolent, usually fatal meningoencephalitis caused by either of two species of free-living ameba, *Acanthamoeba* spp. or *Balamuthia mandrillaris*.

Acanthamoeba spp. have been isolated across the globe from air, water, and soil. *Balamuthia* also is ubiquitous, though it is more commonly isolated from soil than water. Like *N. fowleri*, based on serology positivity, many people are presumed to be exposed to *Acanthamoeba* spp. and *Balamuthia* with the development of clinical disease being relatively rare. Humans are thought to become actively infected with either agents of granulomatous amebic encephalitis via the lower respiratory tract or broken skin. While *Acanthamoeba* disease primarily occurs in immunocompromised people, *Balamuthia* disease occurs more often in the immunocompetent, though it can also occur in the immunocompromised. In the United States, *Balamuthia* infection is seen more often in males, those of Hispanic race, and residents of the southern latitudes of the United States. The increased risk of *Balamuthia* infection in males and Hispanics may be due to an increased risk of exposure (i.e., more likely to be exposed to soil) or yet-to-be-defined genetic risk factors. Several cases of *Balamuthia* have occurred via transplantation of organs from persons not recognized to be infected with *Balamuthia*.

Acanthamoeba granulomatous amebic encephalitis has an insidious onset of symptoms, and presents with both nonspecific complaints, such as mental status changes and fever, as well as focal abnormalities including seizures, hemiparesis, and ataxia. As the disease progresses, increased intracranial pressure eventually causes lethargy and coma, with death occurring due to brain herniation. *Balamuthia* disease can present either with subacute or chronic symptoms as described earlier and can result in death within a week or over months after the onset of symptoms.

Space-occupying or ring-enhancing lesions, either single or multiple, on neuroimaging are characteristic of granulomatous amebic encephalitis. Rarely, *Balamuthia* infection can also demonstrate hemorrhage within the ring-enhancing lesions. CSF, when obtained, typically shows a lymphocytic pleocytosis, increased protein concentration, and slightly low or normal glucose level. Unlike primary amebic meningoencephalitis, identifying ameba in the wet mount is uncommon but has been reported. Serologic tests for either *Acanthamoeba* or *Balamuthia* are not helpful. Tissue diagnoses are most common, and unfortunately often occur at autopsy. To definitively distinguish the causative agent of granulomatous amebic encephalitis, either ameba-specific immunohistochemistry on tissue sections or molecular diagnostics (e.g., PCR, next-generation sequencing) on RNA or DNA isolated from tissue or CSF must be done. Of note, *Acanthamoeba* spp. and *Balamuthia* can both present with preceding skin lesions, which should be biopsied if present.

Akin to primary amebic meningoencephalitis, the limited number of patients diagnosed premortem and of survivors means no definitive treatment regimens have been defined. In general, treatment of granulomatous amebic encephalitis usually involves multidrug regimens that include some combination of pentamidine, an azole (e.g., fluconazole for *Balamuthia*), sulfadiazine, flucytosine, miltefosine, and amikacin (for *Acanthamoeba*) or azithromycin/clarithromycin (for *Balamuthia*). Even in the setting of early recognition and aggressive therapy, most patients with granulomatous amebic encephalitis will die.

Cerebral Amebiasis due to *Entamoeba histolytica*

Amebiasis is disease caused by *Entamoeba* spp., some of which are nonpathogenic and some of which cause diarrhea only. *Entamoeba histolytica* causes tissue-invasive disease, including cerebral abscesses. Amebiasis most commonly occurs in socioeconomically deprived communities in developing countries, travelers returning from these areas, chronically institutionalized individuals, and men who have sex with men.

Infection occurs by ingestion of cysts with sources including fecal–oral transmission and contaminated food or water. Excystation occurs in the small intestine, producing trophozoites. The parasite colonizes the colon where some trophozoites encyst and are passed in the stool to begin the cycle anew. Invasive disease begins when trophozoites invade the colonic mucosa leading to inflammatory colitis. Extraintestinal spread is rare and most frequently involves the liver, which can then lead to spread locally or distally (lungs, genitourinary system, skin, and brain). Approximately 80 percent of the patients with a liver abscess are young–middle aged men.

Cerebral abscesses occur in 1 to 5 percent of those with liver abscesses and present with the findings of a space-occupying lesion such as focal findings, seizures, mental status changes, and headache. CSF findings are nonspecific, including a pleocytosis and an elevated protein; lumbar puncture is not necessarily recommended. CT and MRI findings will be consistent with an abscess.

Cerebral amebiasis is often diagnosed clinically (e.g., cerebral abscess in a patient with an amebic liver abscess or recently treated liver abscess) as there is no specific, proven diagnostic test. In liver abscesses, PCR of the abscess fluid or antigen detection from the serum or abscess fluid can be performed. In addition, serologic testing can be a useful adjunct with the recognition that serologies can be negative early in disease and that a positive serology in a patient coming from an endemic region does not distinguish prior disease from current disease or unrelated coinfection. Stool microcopy is very low yield in these patients and is not recommended.

Like bacterial brain abscesses, the treatment is generally a combination of surgical drainage and antimicrobial therapy (metronidazole) for 6 or more weeks.[10]

HELMINTHIC INFECTION

Due to their relatively large size (50 μm up to 15 m), these parasites pose a distinct problem for host immunity. Helminths capable of causing CNS disease are diverse, with complex life cycles involving both human and nonhuman animal hosts during different stages of their development. Helminths are generally identified by taxonomic class [i.e., as cestodes (tapeworms), nematodes (roundworms), or trematodes (flukes)]. Except for disease caused by *Taenia solium* (tapeworm), helminth infections of the CNS are rare to extremely rare. Thus, this section will focus on *T. solium* with very brief comments about other helminths. Table 46-1 includes a summary of the most common helminths that cause CNS infections.

Cestodes

CYSTICERCOSIS

Humans are the definitive host for the tapeworm *T. solium*, meaning that adult tapeworms develop in the human intestine. The adult worm sheds proglottids, or eggs, which contaminate the environment. Pigs develop *T. solium* tissue cysts after ingesting food or water contaminated with *T. solium* eggs. Adult tapeworms then develop in humans who eat undercooked tissue cyst-containing pork, completing this part of the *T. solium* life-cycle. Like pigs, humans can act as intermediate hosts and develop invasive disease (cysticercosis) if they ingest eggs. Current epidemiology suggests that humans develop cysticercosis or neurocysticercosis from human-to-human transmission, rather than from the environment. *T. solium* is endemic in most of Central and South America, China, India, southeast Asia, and sub-Saharan Africa. Imported cases of *T. solium* disease are seen in many developed countries.

After the eggs are ingested, oncospheres are liberated, penetrate the bowel wall, and enter the blood stream. These disseminate widely, favoring muscle and subcutaneous tissue. Larval forms develop and mature into cysticerci. Neurocysticercosis occurs when cysticerci develop in the eye, brain, or spinal cord.

A cysticercus is made up of an invaginated scolex surrounded by a vesicular wall. In the brain parenchyma, vesicular cysticerci elicit little or no inflammatory reaction. As the cysticercus involutes, it passes into the colloidal stage characterized by a mononuclear infiltrate surrounding the cysticercus with surrounding edema and gliosis due to the release of parasite antigens. Neurologic symptoms begin to manifest at this point. As further involution occurs (granular and calcific stages), edema decreases but astrocytic changes lead to the formation of granulomas with multinucleated giant cells. Persistence of these abnormal areas of tissue results in foci that can lead to recurrent seizures. Ultimately, the lesion will be cleared, leaving parenchymal calcifications. The role of calcified parenchymal lesions in recurrent seizures is controversial.

While most cases of neurocysticercosis are parenchymal and present with seizures, extraparenchymal disease does occur and can lead to more severe manifestations including death. Extraparenchymal cysticerci may develop in the subarachnoid, ventricular, or basal cisterns, and can cause hydrocephalus, arachnoiditis, and meningeal inflammation. Subarachnoid cysts may grow abnormally, causing grape-like cystic masses referred to as racemose cysticercosis.

Seizures—focal or generalized—are the primary or sole manifestation in 70 percent of cases, though focal neurologic deficits, including stroke-like syndromes and cognitive decline, can also occur. The severity and type of manifestations are dependent on lesion location (e.g., parenchymal vs. subarachnoid), the quantity of the lesions, and the host immune response. Spinal cord cysticercosis may lead to compressive myelopathy or radiculopathy. Ocular disease can cause visual field defects, decreased acuity, and blindness from vitritis, uveitis, or endophthalmitis.

Neurocysticercosis is usually diagnosed by exposure history supported by compatible symptoms, serology, and neuroimaging. Travel to endemic areas or previous residence in an area of high prevalence should alert clinicians to the possibility of the disease. Clinical symptoms are nonspecific, and routine laboratory testing does not show any typical abnormalities (e.g., cysticercosis is not associated with eosinophilia). Diagnostic criteria that stratify patients into definitive or probable diagnoses of neurocysticercosis have been developed and are based on neuroimaging, fundoscopic findings, serology, and epidemiology.[11]

Neuroimaging is an important component of the diagnosis of neurocysticercosis. Most patients have fewer than 10 cysts, which may be up to 5 cm in diameter, and many will have a single lesion. Patients from endemic countries may show *T. solium*-related calcifications, which are usually less than 1 cm in diameter, round, and are rarely found in the brainstem or cerebellum. Extraparenchymal disease can cause hydrocephalus. Arachnoiditis can manifest as leptomeningeal enhancement.

The identification of a cyst with a scolex (head of the tapeworm) on MRI or CT definitively makes the diagnosis of neurocysticercosis (Fig. 46-7). Nondiagnostic imaging findings—cystic lesions without a scolex, multilobulated subarachnoid lesions, resolution of cystic lesions after antiparasitic treatment or spontaneously if a single enhancing cystic lesion—are considered consistent with a diagnosis of neurocysticercosis but require meeting other criteria (e.g., serology or known household member with *T. solium* infection) to make a definitive diagnosis.[11]

T. solium antibody detection performed with enzyme-linked immunoelectrotransfer blot (EITB) is the test of choice and more sensitive from serum than CSF and in patients with subarachnoid disease or more than one viable cyst. In a patient with a single lesion, the EITB sensitivity drops to less than 60 percent. If EITB testing is not available, and if the patient has multiple viable CNS lesions, detection of anti-*T. solium* antibodies in the CSF by ELISA shows high sensitivity (89%) and specificity (93%). Detection of *T. solium* antigen in CSF or serum remains controversial. CSF findings are otherwise nonspecific and include a monocytic pleocytosis, mild elevations in protein; sometimes the presence of eosinophils in the CSF is a clue to diagnosis.

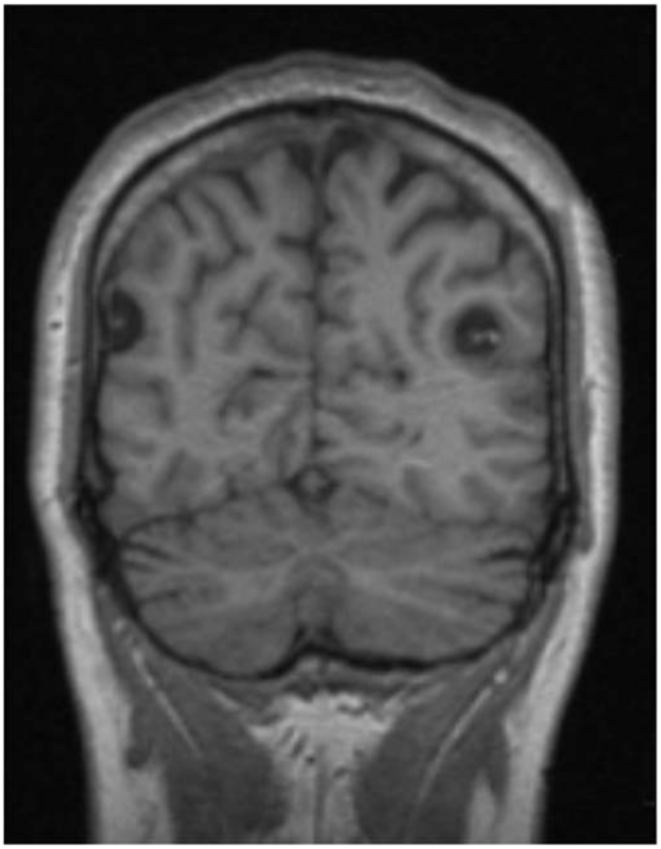

FIGURE 46-7 ▪ Coronal T1-weighted MRI showing neurocysticercosis.

Treatment guidelines have recently been updated for neurocysticercosis.[12] Prior to treating parenchymal disease with antiparasitic medications, fundoscopic examination should be done to rule out an ocular neurocysticercosis lesion. Treatment in patients with unrecognized ocular disease has the potential to provoke a strong hyperinflammatory ocular response that could lead to vision loss. Albendazole 15 mg/kg per day divided into two doses and corticosteroid treatment for 10 to 14 days are recommended for patients with one to two parenchymal viable or degenerating cysts. For more than two viable or degenerating cysts, combination therapy with albendazole (15 mg/kg per day), praziquantel (50 mg/kg per day), and corticosteroids for 10 to 14 days is recommended. For those with *T. solium* encephalitis (diffuse cerebral edema), corticosteroids alone are recommended. No antiparasitic or immunosuppressive therapy is recommended for those who only have neurocysticercosis-associated calcifications. Surgical removal of the cyst with no antiparasitic therapy is recommended for ocular disease. Intraventricular disease, subarachnoid disease, and spinal disease are considerably more complicated in terms of therapy and will require coordinated efforts from neurosurgeons, neurologists, and infectious disease specialists.[12]

First-line, single-drug anticonvulsant medication is usually adequate to control seizures. Optimal length of treatment is unclear, and withdrawal is typically followed by recurrence in about half of patients, despite an adequate antihelminthic course. Calcified parenchymal lesions may indicate the need for long-term antiseizure medication.

ECHINOCOCCOSIS (HYDATID DISEASE) AND SPARGANOSIS

Rarely, other cestodes may cause human CNS disease. Infection with *Echinococcus* spp. (most commonly *Echinococcus granulosus* and *Echinococcus multilocularis*), which are canine tapeworms, is called echinococcosis. Sparganosis is caused by infection with the diphyllobothroid tapeworms of the *Spirometra* genus. Humans are intermediate hosts for these worms and become infected through eating contaminated food. CNS disease in echinococcosis or sparganosis is extremely rare but can present with a variety of manifestations (e.g., focal brain or spinal cord symptoms or meningitis) depending on the location of the lesion and state of the inflammatory response. CNS cysts from *E. granulosus* are usually associated with cysts elsewhere in the body (Fig. 46-8).

E. granulosus is found in all continents, with the highest prevalence occurring in northeast Africa,

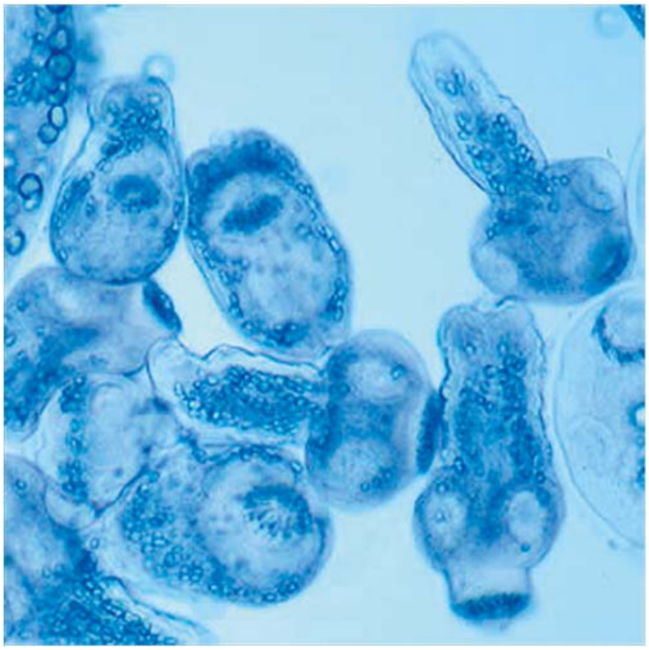

FIGURE 46-8 ▪ *Echinococcus* sp. protoscoleces. (From the US Centers for Disease Control and Prevention.)

South America, and Eurasia, while *E. multilocularis* is restricted to the northern hemisphere. Sparganosis is associated with eating undercooked frog or snake meat and primarily occurs in China and other parts of east and southeast Asia, though sporadic cases have been reported across the globe. Treatment for echinococcosis and sparganosis often requires both surgical interventions as well as antiparasitic therapy.

Nematodes

DISSEMINATED STRONGYLOIDIASIS

Strongyloides stercoralis is a gastrointestinal nematode endemic to humid tropical regions, including Southeast Asia, Africa, and Latin America, as well as the southeastern United States and southern Europe. Travel to or migration of patients from these areas accounts for most disease seen in temperate regions. Most infections are asymptomatic and may persist for decades due to the worm's ability to complete its full life cycle within humans. In the setting of human T-cell lymphotropic virus type 1 coinfection or immunosuppression—most commonly corticosteroids—*Strongyloides* can cause a hyperinfection syndrome in which autoinfection leads to increased numbers of worms in the gut (Fig. 46-9). This increase in gut worm burden can result in disseminated disease, which occurs when the larvae migrate away from the lungs and gastrointestinal tract into other organs. Large numbers of larvae migrating from the gut carry enteric bacteria into the bloodstream, which can cause acute bacterial meningitis and sepsis. The diagnosis of hyperinfection syndrome is usually made on finding larvae in stool in patients with a compatible systemic syndrome. Treatment includes aggressive antibiotic treatment for bacterial superinfection and ivermectin, the antihelminthic drug of choice.

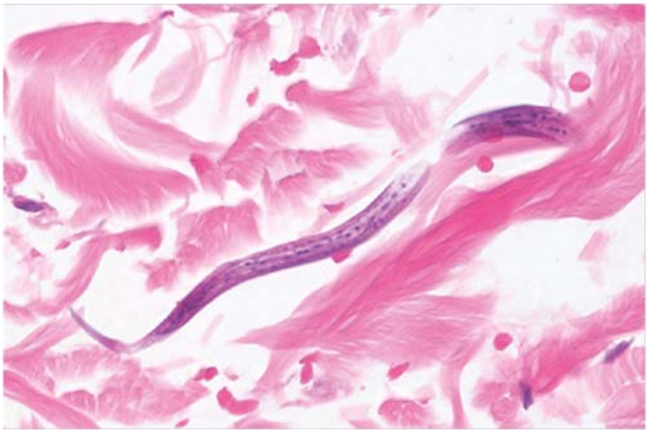

FIGURE 46-9 ■ *Strongyloides stercoralis* larva in tissue (intestine). (From the US Centers for Disease Control and Prevention.)

TRICHINOSIS

Trichinella spp. infection is acquired by ingestion of contaminated undercooked or raw pork (*Trichinella spiralis*) or game meat including walrus and bear meat. Infectious cysts in striated muscle tissue are digested, releasing larvae which mature into adults in the small intestine. The adult forms release newborn larvae in a few weeks. The newborn larvae disseminate in lymph and blood and cause symptoms of trichinosis by invading various body tissues. Modern farming practices have made cases of trichinosis increasingly rare, although outbreaks still occasionally occur.

Trichinosis has several phases. First, patients have gastrointestinal symptoms (from local infection) such as diarrhea, vomiting, and abdominal pain. Subsequently, with systemic dissemination, patients can experience fever, myalgias, malaise, headache, and periorbital and facial edema. The invasion of muscle can mimic an inflammatory myositis with an elevated creatinine kinase. Trichinosis is usually associated with peripheral eosinophilia. In patients with high parasite burdens, larvae can migrate into the CNS causing meningitis or encephalitis.

The diagnosis is made by positive serology (available through the CDC) in those who have a recent history of eating undercooked or raw pork or wild game meat. If necessary, a muscle biopsy demonstrating *Trichinella* larvae (Fig. 46-10) can be performed.

Treatment with albendazole or mebendazole, which kill the adult worms, is most effective during the gastrointestinal stage of disease. If the diagnosis is not made until the systemic phase of the disease, treatment may be less effective although it is still recommended. In the systemic phase of disease or in severe disease, adjunctive corticosteroids may be used.

ANGIOSTRONGYLUS CANTONENSIS

Angiostrongylus cantonensis is a rat worm in which snails and slugs are intermediate hosts. *A. cantonensis* is a common cause of eosinophilic meningitis in Southeast Asia and the Pacific Basin, which includes Hawaii. Humans become infected by eating infective larvae in raw or undercooked mollusks (intermediate hosts); other animals that eat the intermediate hosts (prawns,

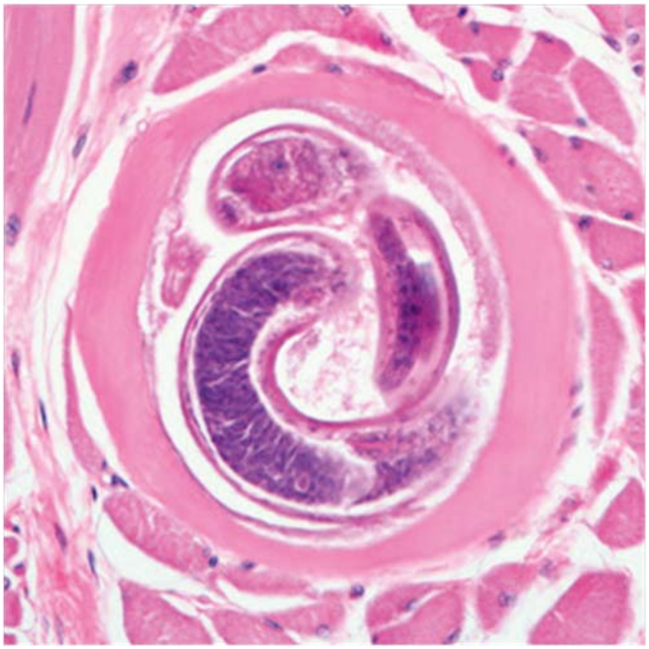

FIGURE 46-10 ■ *Trichinella spiralis:* encysted larva in muscle tissue. (From the US Centers for Disease Control and Prevention.)

crabs, frogs, lizards, flatworms); or contaminated vegetables. Patients commonly present 1 to 4 weeks after exposure and with signs and symptoms of acute meningitis. Patients often have sensory symptoms such as hyperesthesia or paresthesias and peripheral eosinophilia, though the lack of sensory symptoms or peripheral eosinophilia does not rule out *A. cantonensis* infection. Pleocytosis with or without eosinophilia, mild elevations in protein, and normal CSF glucose are commonly seen in *A. cantonensis* meningitis.

The diagnosis is primarily made clinically, although a recent outbreak and increased incidence in Hawaii led the Hawaii State Department of Health Laboratories to develop a PCR-based test for CSF.

Treatment is generally high-dose corticosteroids with emerging evidence for concurrent albendazole treatment. Given concerns regarding albendazole-related parasite death causing a hyperinflammatory response, albendazole treatment by itself is not recommended for neuroangiostrongyliasis. Most patients have a good recovery.[13]

GNATHOSTOMA *SPP.*

Gnathostoma spp. are nematodes with several definitive hosts (felids, canines, pigs, and boars) and a complex life cycle that involves two stages of intermediate hosts (copepods and then fish and frogs). *Gnathostoma* spp. are endemic in Southeast Asia, especially Thailand, with increasing infections in Mexico and Central and South America. Humans become infected by eating infective larvae in raw or undercooked intermediate hosts (primarily fish or frogs) or other animals that eat the intermediate hosts (birds, rats, snakes). Most commonly, *Gnathostoma* spp. cause early gastrointestinal symptoms followed by migratory subcutaneous swellings and peripheral eosinophilia about 3 to 4 weeks after exposure. *Gnathostoma* spp. migrate to the CNS less frequently than *A. cantonensis* but the disease caused by *Gnathostoma* is often more severe. Depending on where the larvae migrate, persons with gnathostomiasis can develop spinal cord or root syndromes and subarachnoid or intracranial hemorrhages.

Diagnosis of neurologic involvement of *Gnathostoma* spp. is usually made by the appropriate history (ingestion of raw food likely to be contaminated with infective larvae; migratory subcutaneous swelling) with a positive serology, though serologic testing is not available in the United States. CSF findings are akin to those seen with *A. cantonensis* except that frank blood or xanthochromia is more common in gnathostomiasis. Peripheral eosinophilia is also common. Neuroimaging studies can show hemorrhagic tracks consistent with worm migration.

Besides supportive care, there are no clear treatment guidelines for *Gnathostoma*-caused CNS disease. No evidence exists for the utility of corticosteroids, and antihelminth regimens (albendazole or ivermectin) may make the patient's neurologic status worse. Patients with mild or minimal neurologic symptoms/signs may recover, but those with severe symptoms have a poor prognosis.[13]

VISCERAL LARVAL MIGRANS: TOXOCARA *SPP. AND* BAYLISASCARIS PROCYONIS

Toxocara canis and *Toxocara catii* are dog and cat helminths, while *Baylisascaris* is a raccoon helminth. Humans, usually children, are infected by ingestion of eggs shed from the definitive hosts with *T. canis* being the most common cause of visceral larva migrans in the United States. *Toxocara* spp. commonly cause ocular toxocariasis and very rarely eosinophilic meningitis. Symptomatic *Baylisascaris* disease, which is extremely rare, can cause ocular infection as well as meningitis and spinal cord disease. Peripheral eosinophilia and

CSF eosinophilic pleocytosis can be seen with *Toxocara* or *Baylisascaris* CNS infection. *Toxocara* serologic testing is commercially available, while *Baylisascaris* serology from serum or CSF can be performed at the CDC. For ocular toxocariasis, corticosteroids are recommended, but their role in treatment of other CNS syndromes is unclear. For CNS disease with *Toxacara* spp. or *Baylisascaris*, the role of antihelminth drugs is unclear, but albendazole is the treatment of choice for either disease because it penetrates the CNS well and has low toxicity.

ONCHOCERCA VOLVULUS AND LOA LOA

Onchocerca volvulus and *Loa loa* are transmitted from human to human by biting flies *Simulium* and *Chrysops*, respectively. *O. volvulus* larvae can migrate to the eye where death of the larvae can cause ocular disease including blindness (commonly known as "river blindness"). *O. volvulus* primarily causes disease in sub-Saharan Africa, though Brazil, Venezuela, and Yemen are also sites of onchocerciasis. Loiasis is found in Central Africa, especially in the areas of Cameroon, Central African Republic, Democratic Republic of Congo, Equatorial Guinea, Gabon, and Sudan. Ivermectin treatment of onchocerciasis can precipitate severe adverse reactions (e.g., encephalitis, coma, and sometimes death) in patients with concomitant *L. loa* infections. Thus, in areas where both *O. volvulus* and *L. loa* are endemic, patients should be screened for *L. loa* microfilarie prior to commencing treatment with ivermectin for *O. volvulus*.

In addition to river blindness, limited evidence suggests that *O. volvulus* may play a role in nodding syndrome, which is a relatively uncommon pediatric disease primarily found in Uganda, Tanzania, and southern Sudan. It begins with "nodding episodes" which are frequent but brief bouts of loss of neck muscle tone associated with generalized seizure activity on electroencephalogram. Nodding syndrome can progress, with children showing cognitive decline, growth retardation, and psychiatric manifestations. Several studies have shown that patients with this syndrome are almost twice as likely to have skin snips with *O. volvulus* microfilarie compared to control patients, but no evidence for direct CNS infection by *O. volvulus* has been identified. Thus, how *O. volvulus* might cause nodding syndrome or even whether *O. volvulus* truly plays a role in its development remains unknown.[14]

Trematodes

SCHISTOSOMIASIS

Schistosoma spp. are trematode helminthic parasites acquired by contact with fresh water harboring infective larvae (cercariae). Cercariae are released by intermediate snail hosts. There are three major species: *Schistosoma mansoni*, endemic to Africa, the Eastern Mediterranean, the Caribbean, and South America; *Schistosoma haematobium*, found in the Middle East and Africa; and *Schistosoma japonicum*, found in China, Indonesia, and the Philippines. Two minor species, *Schistosoma mekongi* and *Schistosoma intercalatum*, have limited distribution in Southeast Asia and Central and West Africa, respectively.

After cercariae penetrate the skin, developing worms migrate to the mesenteric blood vessels (*S. mansoni* and *S. japonicum*) or to the venous system surrounding the ureters, bladder, and reproductive organs (*S. haematobium*). Rarely, adult worms can migrate to the vessels of the spinal cord or brain. More often, host morbidity results from parasite eggs lodging in surrounding host tissues with resultant granulomatous inflammation and scar formation.

CNS disease (neuroschistosomiasis) occurs from either adult worms migrating to the vessels of the spinal cord or brain (very rare) or from aberrant deposition of eggs in the spinal cord or brain, causing inflammation and fibrosis. Patients with schistosomiasis manifest with neurologic symptoms in less than 5 percent of cases, although neuroschistosomiasis may be underdiagnosed.

Cerebral schistosomiasis occurs primarily with *S. japonicum*, followed by *S. haematobium*. *S. mansoni* more commonly causes spinal cord lesions. As expected, the clinical presentation will be dictated by the location of the eggs and the host immune response. Cerebral disease can present with acute encephalopathy; seizures; headaches; focal motor, sensory, or visual deficits; or cerebral vasculitis. Spinal cord disease will present as an acute or subacute myelopathy or myeloradiculopathy and will often involve the cauda equina.

Diagnosis depends on considering neuroschistosomiasis in patients from endemic areas or in those who have traveled to such areas and present with an appropriate neurologic syndrome or imaging and have evidence of a schistosomal infection. Evidence of infection can be garnered through microscopic identification of eggs in stool (*S. japonica* or *S. mansoni*) or urine (*S. haematobium*); antigen detection by ELISA or lateral flow assay in stool, urine, or CSF; or serology (at CDC, some commercial labs) in patients who do not live in endemic countries. Importantly, serology will not help distinguish symptomatic versus asymptomatic coinfection in a patient from an endemic country. Definitive diagnosis is through the demonstration of eggs in neural tissue, but such testing is highly invasive and rarely necessary.

Treatment for neuroschistosomiasis will generally involve corticosteroids and the antihelminth drug praziquantal. Oxamniquine is an alternative to praziquantel but is only effective against *S. mansoni*. In patients with hydrocephalus or cord compression, surgical interventions may also be part of the treatment.[15]

Paragonimiasis

Paragonimus species are endemic in areas of Asia (particularly China and Southeast Asia), sub-Saharan Africa, and South and Central America, and are transmitted through the consumption of raw or undercooked crustaceans. Paragonimiasis transmission has also been documented within the United States, from eating undercooked crawfish in the Midwest (Mississippi River drainage basin). Disease occurs as maturing larvae migrate through host tissues from the gastrointestinal tract to the lungs. Cerebral paragonimiasis is rare and caused by aberrant migration into the brain or, rarely, the spinal cord. Patients can present with an eosinophilic meningitis or meningoencephalitis, encephalopathy, seizures, or focal findings in the case of cerebral disease or a spinal cord syndrome in spinal disease.

Diagnosis depends on a history of exposure, along with parasitologic or serologic (CDC) evidence of infection. Sputum examination for ova can identify the lung fluke *Paragonimus westermani*, but multiple sputum specimens may be needed. Neuroimaging is generally nonspecific and may reveal calcifications (chronic lesions), enhancing or hemorrhagic lesions, and possibly a migration tract. Recommended treatment is corticosteroids and praziquantel.

DRUG-INDUCED MENINGITIS
RECURRENT MENINGITIS
CONCLUDING COMMENTS

Chronic meningitis is a challenging condition in which the etiology often eludes the treating physician. There are a multitude of potential causes that span several specialties, sometimes leading to input from colleagues in neurology, internal medicine, infectious diseases, rheumatology, immunology, and oncology (Table 47-1). A meticulous approach to the history, exam, and ordering of correct investigations may help lead to the diagnosis

and prompt treatment of these patients. This chapter outlines an approach to the patient with chronic meningitis along with some pearls and clues that may aid in the diagnosis of particularly common and important causes of chronic meningitis. Other chapters that contain more detailed discussions of particular disorders are highlighted throughout.

DEFINITION

The meninges are composed of the dura mater, the arachnoid, and the inner most layer, the pia mater. The term "meningitis" typically refers to inflammation of the leptomeninges (i.e., the arachnoid and pia mater) and can be detected by a pleocytosis in the cerebral spinal fluid (CSF), enhancement on contrast magnetic resonance imaging (MRI), or through the discovery of inflammatory cells on meningeal biopsy. Meningitis is considered chronic when the CSF pleocytosis, or the symptoms found to be associated with the meningitis, last greater than 1 month. However, the strict definition of 1 month should not dissuade the clinician from considering the differential diagnosis associated with chronic meningitis if there is clearly chronicity to the symptoms. The category of subacute meningitis encompasses almost all of the same etiologic agents as chronic meningitis and frequently progresses to chronic meningitis if not treated. Chronic meningitis symptoms may sometimes wax and wane, making it appear as if the patient is suffering from recurrent attacks of acute meningitis; however, there is usually no resolution of the CSF pleocytosis in between these attacks. This situation differs from *recurrent meningitis* in which there is a clear resolution of symptoms and CSF pleocytosis in between symptom worsening.

Pachymeningitis is inflammation of the dura. As this layer of the meninges is not in direct contact with the CSF space, which lies between the arachnoid and pia, CSF pleocytosis is rare unless there is also leptomeningeal involvement. Pachymeningitis is diagnosed based on neuroimaging and sometimes meningeal biopsy; its differential diagnosis is distinct from chronic leptomeningitis (Table 47-2).

APPROACH

Since there are a multitude of causes of chronic meningitis it is important to take a systematic approach to evaluating these patients. There are three broad categories of disease that cause chronic meningitis: infectious, autoimmune, and neoplastic. In addition, clinicians should carefully screen the medication list for compounds that are known to cause a chemical meningitis. It is not recommended that the clinician test for every possible etiology on the first consultation. Rather, systematically thinking through the entire array of causes and querying whether they are more or less likely based on the history, physical exam, neuroimaging, and initial CSF studies will help narrow down which specific diagnostic tests will be most high yield.

A great deal of information and possible clues can be elicited from the history and examination. An extensive history centered on exposures to possible infections

(e.g., travel, animal exposures, tick and mosquito bites, intravenous drug use, occupational exposures) must be performed. A detailed history probing for evidence of autoimmune disease or other systemic disorders that may be related to chronic meningitis should be taken, as well as a thorough review of both prescription and over-the-counter medications. A prior history of any systemic malignancy, both active and in remission, may prompt the suspicion of metastatic disease to the meninges while also recognizing that leptomeningeal carcinomatosis can be the presenting syndrome of a previously undiagnosed systemic cancer. Neuroimaging features, best captured by MRI with and without contrast of the brain (and often the spinal cord), and the basic CSF profile (i.e., cell count and differential, glucose, protein) can also help to narrow the list of potential causes.

Given the weeks- or months-long investigations that are often performed to identify a chronic meningitis etiology, it is important to systematically track all results and pending investigations. It is also important to understand the specificity and sensitivity of the tests ordered to avoid misdiagnoses. Early in the investigation, consideration should be given to the utilization of wide-ranging polymerase chain reaction (PCR) assays for bacteria or fungi or even more agnostic, hypothesis-free diagnostic testing with metagenomic next-generation sequencing, to comprehensively screen for the whole range of infectious etiologies.[2] These broad tests can increasingly provide quick and actionable results that avoid a long and arduous journey with multiple investigations. Occasionally a meningeal biopsy is needed to make the diagnosis. Whole-body imaging through CT, PET, or both can sometimes identify peripheral sites of inflammation that might be amenable to biopsy rather than a more invasive biopsy of the central nervous system (CNS).

INFECTIOUS CAUSES OF CHRONIC MENINGITIS

Infectious causes of chronic meningitis include fungal, atypical bacterial, viral, and parasitic disorders. It is critical to assess the patient for an immunocompromised state, helping to narrow down the most likely organisms responsible. However, many infectious causes of chronic meningitis can occur in immunocompetent patients, and a normal immune system should not dissuade the physician from an infectious cause. A detailed social history is also critical, including travel history, occupational history, sick contacts, animal contacts, and drug abuse history.

Cryptococcus Species

Fungal infections that can occur in immunocompetent patients include *Cryptococcus* species, *Candida* species (e.g., following neurosurgical interventions or in those with an injection drug use history), *Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis,* and *Sporothrix schenkii. Cryptococcus neoformans, Candida* species, and *Aspergillus* species should be considered in immunocompromised patients.

Certain fungi are endemic to specific regions in the United States. *C. immitis* is predominantly located in the Southwest; *H. capsulatum* in the central, southeastern, and mid-Atlantic states; *B. dermatitidis* is primarily located along the Ohio and Mississippi Rivers and Great Lakes; and *C. gattii* has usually been seen in the Pacific Northwest and in the southeastern United States.[3] A more extensive discussion of fungal infections and their neurologic manifestations other than chronic meningitis can be found in Chapter 45.

Cryptococcus species are yeast-forming organisms. There are two major types that are neuroinvasive: *C. neoformans* and *C. gattii. C. neoformans* is the major cause of cryptococcal meningitis in immunocompromised patients (including the elderly), whereas *C. gattii* can cause infection even in immunocompetent patients.[4] The yeast is an intracellular pathogen that infects macrophages.

RISK FACTORS

Cryptococcus often causes opportunistic infection in human immunodeficiency virus (HIV)–infected patients. As a result of the high prevalence of HIV, cryptococcal meningitis is the most common cause of subacute and chronic meningitis in sub-Saharan Africa. Any form of significant immunosuppression, specifically T-cell-mediated immunosuppression, can lead to a propensity for cryptococcal meningitis. *C. neoformans* can be contracted from pigeon droppings. *C. gattii* is found in red gum trees and soil, and it is endemic in tropical and subtropical regions throughout the world *C. gattii* can cause infections in immunocompetent individuals.

PRESENTATION

Cryptococcal meningitis presents with insidious, progressive, subacute-to-chronic meningitis. Patients can present with a basilar meningitis with cranial nerve entrapment. The encapsulated yeast forms frequently block the arachnoid granules and CSF reabsorption, leading to very elevated intracranial pressures. Even in patients taking antifungal therapy, elevated intracranial pressure is a frequent cause of mortality if frequent therapeutic lumbar punctures are not performed. Elevated intracranial pressures in cryptococcal meningitis can manifest with headache, hydrocephalus, papilledema, unilateral or bilateral VIth nerve palsies, and progressive coma. In addition to symptoms of meningitis, patients can present with cryptococcomas in the brain parenchyma (most frequently in the basal ganglia) leading to focal neurologic signs and symptoms. HIV-infected patients with low CD4 counts can present with cryptococcemia, and pulmonary and ocular cryptococcal infections can also occur.

DIAGNOSTIC TESTING

CSF typically displays a lymphocytic pleocytosis with low glucose and elevated protein but can be bland in severely immunocompromised patients in whom the index of suspicion must remain very high. Opening pressures are generally elevated. In HIV-infected patients, the cryptococcal antigen (CrAg) test is very sensitive (98%) and specific (99%). It can be performed as a bedside lateral flow assay and is the test of choice for the diagnosis of cryptococcal meningitis. The CrAg can remain positive in the CSF for years despite successful treatment, and therefore, it is not recommended as a follow-up test to assess for treatment success or failure. Fungal cultures may detect cases of low fungal burden that are CrAg negative.

On MRI, patients may display leptomeningeal enhancement, although in highly immunocompromised patients, neuroimaging may be unremarkable. Cryptococcomas can vary in location but have a propensity for the basal ganglia and typically present as enhancing circumscribed lesions.

TREATMENT

Treatment is separated into induction, consolidation, and maintenance phases. Gold standard induction therapy involves intravenous amphotericin B and flucytosine, typically for 2 weeks duration. Oral fluconazole is then used for consolidation and maintenance therapy. In HIV-infected patients not on treatment, initiation of antiretroviral therapy should be delayed until after 4 weeks of antifungal treatment to reduce the risk of the immune reconstitution inflammatory syndrome (IRIS). Adjunctive dexamethasone use in HIV-infected patients is not recommended.

Symptomatic management is critical, especially management of elevated intracranial pressure which may initially require daily lumbar punctures or an extraventricular or lumbar drain. A worsening of neurologic function does not necessarily suggest treatment failure or another pathogen, as it may represent IRIS, especially if worsening occurs 2 to 4 weeks after starting antiretroviral medications.

Aspergillus fumigatus

Aspergillus fumigatus is a mold that is ubiquitous in soil. The fungus releases airborne spores that are inhaled, causing either pulmonary or sinus disease as well as invasive disease in immunocompromised patients. CNS disease occurs through hematologic spread or via direct spread from the contiguous nasal sinuses.

Risk Factors

Individuals at highest risk are those with hematologic malignancies, post-stem cell or solid organ transplant, HIV infection, and chronic granulomatous disease.

Presentation

Presentations can vary, however there is a propensity for associated vasculitis and infarcts, especially involving the basal ganglia. Direct CNS invasion can present as a basilar meningitis. Mass lesions (aspergillomas) and abscess formation are common, sometimes manifesting with focal neurologic deficits and seizures.

Patients can have pulmonary or nasal sinus involvement. With hematogenous spread, additional sites by seeding are possible, and ophthalmic manifestations are particularly common, including endophthalmitis.

Diagnostic Testing

The diagnosis of *Aspergillus* can be challenging. Cultures, PCR-based testing, or attempting to biopsy tissue at a non-CNS site is preferable; the lung (via bronchoalveolar lavage) and nasal sinus sampling are the most common sources of tissue. Brain biopsy may be required if a diagnosis cannot be made. CSF testing for galactomannan and 1,3-β-D-glucan are antigen assays that assess for components of the fungal cell wall, carrying sensitivities of 70 and 85 percent, respectively.

Radiologic presentations include basilar or diffuse leptomeningeal enhancement, aspergillomas, abscess formation, and vasculitis with infarctions and hemorrhages. A high-resolution thin-slice CT scan of the sinuses may demonstrate a breech in the bone allowing for, or the result of, direct fungal invasion. Contrast enhancement of the dura in a similar region on MRI may represent direct spread.

Treatment

Voriconazole is the mainstay of treatment for invasive *Aspergillus* therapy; however, the condition still carries a high mortality rate despite optimal treatment.

Candida Species

Candida albicans is a yeast that is a commensal organism found commonly in mucosal regions of the body. Disruption to the regional microbiome or immunosuppression can lead to overgrowth and disease by this and other *Candida* species. Invasive *Candida* infections are spread hematogenously and can seed multiple areas, including the CNS.

Risk Factors

Risk factors include hematologic and solid organ malignancies, significant immunosuppression, prolonged ICU stay with invasive instrumentation, broad-spectrum antibiotics or antifungals, and organ failure. Intravenous drug use is also a risk factor for all *Candida* species, either from skin flora being introduced intravenously, poor injecting habits (licking the needle before use), or from lemon juice used to break down impure heroin (generally leading to *C. albicans*).

Presentation

A presentation of acute-to-chronic meningitis is common. Vasculitis presenting with ischemic or hemorrhagic strokes is less common. Subarachnoid cysts causing a compressive myelopathy have also been reported.

Due to hematogenous spread, *Candida* can seed systemically to multiple locations including the skin and the heart. Infectious endocarditis can serve as an ongoing source of infectious emboli. Endophthalmitis commonly occurs, and all patients with fungemia or CNS disease should undergo a thorough ophthalmologic examination.

Diagnostic Testing

Definitive diagnosis through blood cultures, vitreous, bone, or skin biopsies is preferable to a brain biopsy if there are indications of systemic involvement. The CSF displays a similar profile to other fungal infections although a neutrophilic pleocytosis is sometimes possible. Fungal cultures are helpful in growing the organism. 1,3-β-D-Glucan is a component of the *Candida* cell wall and can be a sensitive assay for *Candida* spp. when tested in the CSF.

Leptomeningeal enhancement and microabscess formation can be seen on neuroimaging. Cases of ventriculitis, either from direct neurosurgical intervention from an external ventricular device or via hematogenous spread has been reported. Mycotic aneurysm formation and vasculitis can occur from infectious emboli, often in the setting of endocarditis. Loculated cysts in the subarachnoid space can rarely be seen.

TREATMENT

The treatment of CNS candidal infection is intravenous amphotericin B with or without flucytosine, although because of the common development of drug resistance, combination antifungal therapy is now favored. Fluconazole is frequently used as a long-term maintenance therapy.

Mycobacterium tuberculosis

Mycobacterium tuberculosis is an acid-fast, slow-growing, aerobic bacterium that spreads mainly through the air. Pulmonary tuberculosis (TB) is the most common manifestation, with only 1 to 5 percent of cases involving extrapulmonary sites, including approximately 100,000 cases of TB meningitis per year. TB meningitis carries a high morbidity and mortality if not treated early.[5] Further discussion of the many neurologic presentations of TB can be found in Chapter 40.

RISK FACTORS

Pulmonary TB risk factors include time spent in an endemic region, close contact with a person with active TB, groups with high rates of infection including homeless persons, HIV-infected persons, those who use intravenous drugs, and persons who reside in correctional facilities, nursing homes, and homeless shelters. Immunosuppression with HIV is a major risk factor for disseminated disease and TB meningitis. TNF-α inhibitors and long-term steroid use can lead to TB reactivation.

PRESENTATION

Patients generally present in a subacute manner with constitutional symptoms and progressive meningismus for greater than 1 week. Basilar meningitis is the classic presentation for TB meningitis; however, there can be multiple other manifestations involving the leptomeninges and pachymeninges. Secondary vasculitis and arachnoiditis can lead to strokes and cranial nerve palsies due to compression and inflammation of the vessels and nerves as they traverse the subarachnoid space. Tuberculomas can lead to focal neurologic signs and mass effect. Hydrocephalus and raised intracranial pressure can progress to coma and death.

Only 50 percent of patients with TB meningitis will have an abnormal chest x-ray. On more detailed systemic imaging, extrapulmonary TB may be evident with regions of prominent lymphadenopathy, including the abdomen.

DIAGNOSTIC TESTING

Diagnosis is notoriously difficult due to the paucibacillary nature of the disease. CSF typically displays a lymphocytic or neutrophilic pleocytosis with low glucose and elevated protein, but can be relatively bland in severely immunocompromised patients in whom the index of suspicion must remain very high. The automated PCR assay (GeneXpert MTB/RIF Ultra) is currently the single most sensitive and specific CSF assay for diagnosing TB meningitis, but it will still fail to identify at least 30 percent of clinically-suspected cases. Diagnosis from pulmonary sites or other extrapulmonary regions is helpful, and therefore systemic imaging and biopsy should be considered early in the work-up. A negative PPD or IFN-γ release assay does not rule out the disease. Cultures take 4 to 8 weeks to grow and are therefore used mainly as a retrospective diagnosis. TB is a reportable disease in most jurisdictions with implications for close contacts of the patient including exposed healthcare workers.

Enhancement along the basilar meninges is the most common radiologic finding followed by hydrocephalus. Posterior circulation and basal ganglia strokes may occur from vasculitis. Mycotic aneurysms can be evident later in the disease process. Although leptomeningitis is more common, TB meningitis can also lead to pachymeningitis.

TREATMENT

Empiric treatment is often started even with negative TB testing if clinical suspicion remains high. First-line therapy is a combination of rifampicin, isoniazid, pyrazinamide, and ethambutol. Steroids are given concomitantly when antimicrobial therapy is initiated to prevent paradoxical clinical worsening. Clinical improvement that wanes after these adjunctive steroids are discontinued should prompt the physician to consider paradoxical clinical worsening, multidrug-resistant TB, and alternative infectious and noninfectious meningitis etiologies that may have symptomatically improved with glucocorticoids. Ongoing supportive care is critical to detect and manage the many potential neurologic sequelae which may result from TB meningitis including raised intracranial pressures, strokes, IRIS, and hyponatremia.

Neuroborreliosis (Lyme) Disease

Lyme disease is caused primarily by the bacterium *Borrelia burgdorferi*, a spirochete transmitted by the *Ixodes scapularis* tick in North America and Europe (see Chapter 39 for further details).

RISK FACTORS

Exposure in endemic regions is the major risk factor for the disease, mainly in the east coast of the United States and Europe, although *B. burgdorferi* continues to spread throughout North America with an increased geographic range of its tick host.

PRESENTATION

Chronic meningitis with cranial nerve abnormalities is one of the most common presentations of neurologic Lyme disease. Bannwarth syndrome is a lymphocytic meningoradiculitis with painful radiculopathies that is an uncommon presentation in the United States.

The classic bullseye rash may not be recalled by patients or may be missed in around 30 percent of patients. Fevers, fatigue, arthralgias, and myocarditis can occur as the disease progresses. Neurologic manifestations can occur early in the disease course or be a more delayed presentation.

DIAGNOSTIC TESTING

Neurologic Lyme disease always has a CSF pleocytosis (usually lymphocytic) that will resolve with treatment. CDC criteria suggest the two-tier ELISA test followed by a confirmatory Western blot since the *B. burgdorferi* PCR is insensitive. The duration of illness is an important factor which relates to the number of bands that must be positive to meet criteria. A positive IgM alone is not enough for a diagnosis, and conversion to IgG is required. As neurologic Lyme disease can present early in the disease course, the IgG antibody may be negative, and patients living in an endemic area with a characteristic rash can be treated presumptively. An elevated IgG Lyme antibody index is diagnostic of neurologic Lyme infection. *B. burgdorferi* antibodies (including IgM) can remain elevated in the CSF despite therapy for up to a year and should not be used to monitor treatment effect.

MRI may show leptomeningeal and cranial nerve enhancement in addition to nonspecific white matter–predominant T2 hyperintensities in the brain and spinal cord.

TREATMENT

Although 14 days of parenteral ceftriaxone is standard of care for neurologic Lyme disease in the United States, European data suggest that doxycycline 200 mg twice daily for 14 days is equally as effective.

Neurosyphilis

Treponema pallidum is a spirochete, whose infection leads to syphilis, a sexually transmitted disease. Syphilis infection can be divided into primary, secondary, and tertiary stages, and neurosyphilis can occur during any stage of the disease.[6] HIV coinfection can accelerate disease progression and increases the risk of neuroinvasive disease.

RISK FACTORS

There is currently a worldwide epidemic of syphilis. Those with HIV infection, men who have sex with men, and persons with a serum titer rapid plasma reagent (RPR) titer greater than 1:32 have an increased risk of developing neurosyphilis. No prior treatment or incomplete treatment for syphilis should also increase suspicion for neurosyphilis.

PRESENTATION

Classic neurosyphilis presentations include meningitis, meningovascular disease with multiple strokes, otic and ocular forms, tabes dorsalis, and a syndrome of progressive cognitive deficits called general paresis. Chronic meningitis manifests with meningeal symptoms as well as cranial neuropathies (including optic neuropathy and hearing loss) and often culminates with a vasculitis of small and medium-sized vessels with associated strokes. A progressive myelopathy, tabes dorsalis, can occur during this stage as well. Further discussion can be found in Chapter 39.

Systemic symptoms are common with syphilis. A syphilitic chancre is only noted in around 30 percent of patients and presents with a nonpainful ulcer. Secondary syphilis is characterized by a pustular rash, fevers, and lymphadenopathy. Tertiary syphilis is associated with syphilitic aortitis and systemic gumma.

DIAGNOSTIC TESTING

A patient cannot have neurosyphilis if their serum *T. pallidum* particle agglutination assay (TPPA) test is negative. Thus, the serum TPPA is a quick rule-out test for the condition and should be sent in most neurologic presentations. The 2018 CDC diagnostic criteria for definite neurosyphilis require both a positive serum treponemal (TPPA, fluorescent treponemal antibody absorption antibody) and nontreponemal test (RPR; venereal disease research laboratory or VDRL) with a positive CSF VDRL. There is generally a CSF lymphocytic pleocytosis, but the diagnostic criteria do not require this feature if the CSF protein is elevated. A negative CSF VDRL does not rule out the disease as the assay only has a 70 percent sensitivity; if the CSF profile is abnormal, the patient may still warrant treatment as having "probable" neurosyphilis. Syphilis is a reportable disease.

Leptomeningeal enhancement is seen on MRI during the meningitis stage. Cranial nerve enhancement may be visible. Syphilitic gumma can resemble meningiomas when they are attached to the dura.

TREATMENT

Treatment is with aqueous crystalline penicillin G 3 to 4 million units every 4 hours for 10 to 14 days. In the United Kingdom and Australia, 40 to 60 mg of prednisolone is given for 3 days, with the first dose prior to the antibiotic infusion, to prevent a Jarisch–Herxheimer reaction, which can lead to an endotoxin-like product-mediated, occasionally dramatic, syndrome of fever and rash that lasts from hours to days.

Neurocysticercosis

RISK FACTORS

Residence in, or travel to, regions that are endemic with *Taenia solium* should lead to consideration of neurocysticercosis as a cause of chronic meningitis. The infection occurs in areas with poor sanitation and where pigs roam freely with humans. However, because *T. solium* spreads by the fecal-oral route, transmission can still occur amongst close contacts in nonendemic settings. See Chapter 46 for further details.

PRESENTATION

Neurocysticercosis can have an asymptomatic presentation in a large proportion of patients with parenchymal cysts being discovered incidentally on brain imaging done for another reason. The most common presentation is seizure after a cyst is recognized by the immune system and begins to degenerate and swell. Subarachnoid neurocysticercosis is the form of the disease that leads to chronic meningitis; it can have a variety of complications ranging from headaches secondary to obstructive hydrocephalus from ventricular cysts, nuchal rigidity, radiculopathies and cranial neuropathies secondary to nerve inflammation or compression by subarachnoid cysts, arachnoiditis, and vasculitis. Patients are typically afebrile and systemically well.

DIAGNOSTIC TESTING

The CSF displays a pleocytosis with a variable cell differential that may or may not include eosinophils. Hypoglycorrhachia can be seen. The cysticercal antigen and antibody tests are very sensitive in patients with subarachnoid disease with the former assay being much more useful for identifying active disease in a patient from an endemic area.

CT scans frequently show scattered small calcifications from degenerated parenchymal cysts. MRI of the brain in active disease reveals well-demarcated parenchymal cysts with a scolex in the center that may or may not have rim enhancement or surrounding edema. Patients with chronic meningitis and subarachnoid disease can present with a basilar meningitis and subarachnoid cysts that appear anywhere along the neuroaxis. Intraventricular cysts can account for dynamic and acute obstructive hydrocephalus that can be treated by surgical cyst removal or ventriculoperitoneal shunting. Intraventricular cysts can be difficult to visualize, and if there is a clinical suspicion, additional MR sequences such as fast imaging employing steady-state acquisition can more easily detect their thin walls. Two-thirds of patients with subarachnoid disease will have cysts along the spinal cord even without signs or symptoms of myelopathy or radiculopathy.

TREATMENT

Subarachnoid disease is very difficult to treat and requires long-term management and surveillance. Guidelines suggest albendazole (15 mg/kg per day) and concurrent praziquantel (50 mg/kg per day) until there is resolution of imaging abnormalities and improvement of CSF parameters including decreasing CSF pleocytosis and, ideally, negative CSF antigen testing. Steroids are given prior to commencement of antiparasitic medications and then intermittently throughout the chronic treatment course to manage recurrent flares of meningitis.

Before initiating therapy, patients should undergo an ophthalmologic examination to rule out intraocular infection that might require surgery. Consideration should be given to screening for latent TB as well as strongyloidiasis. Because serologies for strongyloides can have a slow turnaround time in the laboratory, empiric treatment with ivermectin is reasonable for patients who come from endemic areas. Methotrexate can be used as a steroid-sparing agent in cysticercosis patients, and there is recent evidence for the utility of TNF-α inhibitors as alternate steroid-sparing agents. Members of the patient's household and family should be screened with stool ova and parasite examinations to help limit spread of the disease.

Viral Etiologies

While viruses play a major role in the etiology of acute meningitis, chronic CNS viral infections are uncommon and typically present with both a meningitis and a parenchymal component so that patients more accurately are classified as having a chronic meningoencephalitis or meningomyelitis. Chronic viral causes of meningoencephalitis in immunocompetent patients include measles virus causing subacute sclerosing panencephalitis and various herpes viruses including varicella zoster virus. In severely immunosuppressed patients, HIV-1, herpes viruses (e.g., varicella zoster virus, Epstein–Barr virus, and cytomegalovirus), enteroviruses, orthobunyaviruses, polyomaviruses including JC virus (causing progressive multifocal leukoencephalopathy), and a variety of other very rare viral infections can occur. Human T-lymphotropic virus type 1 (HTLV) is an important cause of chronic meningomyelitis in immunocompetent individuals from endemic parts of the world that leads to tropical spastic paraparesis.

INFLAMMATORY CAUSES OF CHRONIC AND RECURRENT MENINGITIS

Neurosarcoidosis

Sarcoid is an autoimmune systemic granulomatous disease process characterized by noncaseating granulomas (see Chapter 49). Although initially thought to be incited by an unknown pathogen, it has become clearer over the last few decades that the disease is likely a primary autoimmune condition with specific HLA and other genetic associations. Diagnosis can be difficult, and infectious and other causes of chronic meningitis need to be carefully ruled out.

RISK FACTORS

African American and Scandinavian populations have a higher incidence of sarcoidosis. Women also have a somewhat higher incidence of the disease than men.

PRESENTATION

Neurologic manifestations can predate systemic manifestations in up to 30 percent of neurosarcoidosis cases. Chronic meningitis, mass-like lesions, pituitary involvement, cranial nerve involvement (specifically optic and facial), and myelopathy are common presentations. Vasculitis is a rare manifestation. Neurosarcoidosis tends to be localized to one region of the nervous system with relapses occurring in the same region in an individual patient. There can be a predilection for the basilar meninges. At onset especially, there is generally a clinical–radiologic dissociation with the patient appearing significantly more well than the disease burden on neuroimaging would suggest.

Pulmonary sarcoid is the most common systemic disease manifestation, often featuring hilar lymph node involvement. Cardiac, liver, spleen, skin, and ocular involvement can also occur. Bilateral parotid involvement, uveitis, and bilateral facial nerve involvement are termed Heerfordt syndrome and occur mainly in Scandinavian populations. Erythema nodosum can occur on the lower limbs. Constitutional symptoms of fevers, night sweats, and weight loss may or may not be present.

DIAGNOSTIC TESTING

Histologic review of pathologic tissue, the only true diagnostic test for neurosarcoidosis, shows non-necrotizing, noncaseating granulomas that are well formed. Biopsy-proven sarcoid from brain or leptomeningeal tissue is considered definite neurosarcoidosis. Neurologic manifestations, but with tissue confirmation only from peripheral sites, is classified as probable neurosarcoidosis.[7] Serum and CSF angiotensin-converting enzyme levels are not useful tests in the work-up or management of neurosarcoidosis. When concerns are raised for neurosarcoidosis with no prior history of systemic sarcoid, a whole-body PET scan is useful to look for hypermetabolic lymphadenopathy or other organ involvement in order to identify biopsy targets. Blind biopsies of muscle or conjunctiva have a low yield. A pleocytosis is typically present and may be lymphocytic or neutrophilic. Low CSF glucose and unique oligoclonal bands are seen in approximately 30 percent of cases. If CSF glucose is extremely low, then an alternate diagnosis should be sought.

On neuroimaging, the meninges or dura may appear inflamed with adjacent parenchymal involvement, with an appearance suggesting an "outside to in" process of inflammation. Persistent contrast enhancement, sometimes for months or years, is highly suggestive of neurosarcoidosis. Sarcoid myelopathy may resemble a longitudinally extensive transverse myelitis, but unlike neuromyelitis optica, nodular leptomeningeal enhancement may be seen.

TREATMENT

Neurosarcoidosis is typically steroid responsive. There can be difficulty weaning steroids due to the recurrence of meningitis or parenchymal inflammation. Steroid-sparing agents such as methotrexate, azathioprine, or mycophenolate mofetil are frequently used; recent data suggest that infliximab, a TNF-α inhibitor, can also be highly efficacious.[8]

Primary Central Nervous System Vasculitis

RISK FACTORS

There are no specific risk factors for primary CNS vasculitis, which is a rare and poorly understood entity discussed further in Chapter 50. The disorder typically involves small vessels of the brain and is distinct from systemic vasculitis syndromes such as ANCA-associated vasculitis that can also have CNS involvement.[9] Since secondary CNS vasculitis can also occur as a result of chronic infectious processes, including syphilis, varicella zoster virus, fungal infections, neurocysticercosis, amoebic infections, and TB, a careful exclusion of these entities is important in the work-up of CNS vasculitis.

PRESENTATION

The neurologic presentation of primary CNS vasculitis is incredibly varied and depends on the location of the vasculitis, the vessel size affected, and the specific areas of brain parenchyma at risk of ischemia. Although large-vessel vasculitides may present with a large territory stroke, vessel wall narrowing, and beading, the more common small-vessel involvement seen in primary CNS vasculitis manifests often as persistently contrast-enhancing lesions, including in the spinal cord, along with mass lesions in the brain and chronic leptomeningitis or pachymeningitis.

A thorough search for other causes of systemic vasculitis should be performed in suspected primary CNS vasculitis. Typically, in primary CNS vasculitis all specific and general markers of systemic inflammation are normal. ANCA-negative systemic vasculitis is difficult to diagnose, and an angiogram of peripheral sites (e.g., an abdominal angiogram in polyarteritis nodosum) may be required. Hepatitis B and C viruses should be screened to evaluate for the risk of cryoglobulinemia. Constitutional symptoms of fever, weight loss, and night sweats may indicate a systemic vasculitis with CNS involvement. An ophthalmologic examination is important to assess for ocular involvement.

DIAGNOSTIC TESTING

Leptomeningeal and brain biopsy is the mainstay of diagnosis. The three major pathologic subtypes include those featuring granulomas with multinucleated cells, cases with a lymphocytic predominance, and those demonstrating a necrotizing vasculitis.

Primary CNS vasculitis typically involves vessels whose diameter is difficult to image even with a formal angiography, and therefore normal vessel imaging does not rule out the disorder. Patients with primary CNS vasculitis can have scattered areas of persistently enhancing leptomeninges or parenchymal lesions in the brain or spinal cord seen on neuroimaging. Diffusion restriction and bloom artifact within the lesion may be found on DWI and SWI sequences, respectively.

TREATMENT

Based on treatments for systemic vasculitides, steroids and cyclophosphamide have long been the mainstay for the treatment for primary CNS vasculitis. However, rituximab is becoming more commonly used as an alternative to cyclophosphamide. Tocilizumab, an anti-interleukin-6 monoclonal antibody, has been shown to be effective for temporal arteritis and may have benefit for CNS vasculitis as well.

Rheumatoid Arthritis

RISK FACTORS

Development of rheumatoid arthritis is likely related to both genetic and environmental factors. Older age, female sex, family history, and smoking are risk factors. The development of CNS disease generally occurs in poorly controlled or severe disease and can occur during any stage of the disorder (see Chapter 50 for additional discussion).

PRESENTATION

Patients may present neurologically with leptomeningeal involvement, pachymeningitis, neuropsychiatric manifestations, and focal neurologic signs.

Rheumatoid arthritis is a symmetric, small-joint, inflammatory arthritis with extra-articular manifestations throughout multiple organ systems. Extra-articular manifestations are manifestations of moderate-to-severe disease and can occur during any stage of the disease.

DIAGNOSTIC TESTING

CSF may display a pleocytosis with a normal glucose. CSF anticyclic citrullinated peptide may be elevated in the serum as may rheumatoid factor. Rheumatoid meningitis typically involves the pachymeninges. There may be associated vasculitis and infarcts as well as structural abnormalities in the cervical spine seen on imaging associated with rheumatoid arthritis including atlanto-axial instability, cranial settling, or subaxial subluxation.

TREATMENT

High-dose steroids with a rheumatoid arthritis disease-modifying agent such as a TNF-α inhibitor or B-cell depleting therapy with rituximab may be beneficial for neurologic manifestations of the disorder.

IgG4-Related Disease

RISK FACTORS

IgG4-related disease is a recently recognized entity requiring a tissue diagnosis and a high degree of clinical suspicion. It is a systemic inflammatory disorder with dense infiltration of IgG4-positive plasma cells invading affected tissues. It is likely underdiagnosed and, as a result, risk factors for the disease are still being determined. The most common patient demographic is a middle-aged to elderly man.[10]

PRESENTATION

Symptoms associated with compression of various brain and spinal cord structures from IgG4-related pachymeningitis are the most common presentation. Orbital and neuroendocrine abnormalities associated with ocular and pituitary gland and stalk involvement, respectively, have been reported. Involvement affecting the orbit can result in multiple cranial neuropathies or compromise of the extraocular muscles from mass effect. Patients can have systemic manifestations of IgG4-related disease, but isolated CNS disease is common.

Pancreatitis was the first organ implicated in IgG4-related disease, but like neurosarcoidosis, it is now recognized to affect more than a dozen organ systems, including the thyroid, lungs, kidney, liver, and gall bladder.

DIAGNOSTIC TESTING

Although patients can have a normal CSF profile, a predominantly lymphocytic, mild pleocytosis is not uncommon with an elevated protein and unique oligoclonal bands. Unlike other neuroinflammatory diseases in which IgG4-predominant antibodies are thought to be pathogenic (e.g., chronic inflammatory demyelinating polyneuropathy, myasthenia gravis, autoimmune encephalitis associated with leucine-rich glioma inactivated 1 antibodies), IgG4-related disease does not appear to be autoantibody mediated. Patients may have normal or mildly increased serum IgG4 concentrations, and therefore meningeal biopsy is the primary diagnostic test. Since immunohistochemical staining is not standard for IgG- and IgG4-expressing plasmablasts, the treating physician may need to express the clinical suspicion to the pathologist.

IgG4-related disease can present on neuroimaging as a mass lesion in the pachymeninges (although isolated cases of leptomeningitis have been reported) or the pituitary gland. Less commonly, brain parenchymal or peripheral nerve masses are seen. The pachymeningitis observed is typically smoothly enhancing, with a hypertrophic or nodular appearance.

TREATMENT

Glucocorticoids are the mainstay of treatment with an emerging emphasis on B-cell depleting strategies like rituximab.

Malignancy

RISK FACTORS

Risk factors for leptomeningeal carcinomatosis mirror the risk factors for developing the wide variety of systemic malignancies that, in around 5 percent of cases, can present with, or later be complicated by, disseminated CNS disease. Lymphoma is also an important consideration, with Epstein–Barr virus infection being a special risk factor for CNS lymphoma in HIV-infected patients. Further discussion can be found in Chapter 26.

PRESENTATION

Patients typically experience an insidious onset of some combination of headache, nausea and vomiting, and altered mental status due to communicating hydrocephalus as well as sometimes multiple cranial neuropathies or radiculopathies.

In addition to typical constitutional symptoms associated with systemic malignancies such as fever, night sweats, and anorexia, systemic manifestations are largely dictated by the primary site of the tumor (e.g., shortness of breath and hemoptysis from lung cancer).

DIAGNOSTIC TESTING

The CSF frequently displays a lymphocytic pleocytosis and elevated protein. The glucose may be depressed. Definitive diagnosis relies on CSF cytology and flow cytometry. In patients for whom there is a high degree of clinical suspicion, three large-volume CSF samples should be sent and examined the same day to avoid the decreasing sensitivity that comes with cell lysis when samples sit overnight.

TREATMENT

Leptomeningeal carcinomatosis is highly morbid, with a life expectancy typically less than 2 to 3 months. In consultation with oncology, there may be a role for palliative intrathecal chemotherapy, radiation therapy, or both in addition to ongoing management of the systemic malignancy and its associated complications.

DRUG-INDUCED MENINGITIS

A wide variety of medications can induce a chemical meningitis, and a thorough review of the patient's medications (including supplements and over-the-counter medications) needs to be performed with a special emphasis on recently prescribed medications. Nonsteroidal anti-inflammatory medications (e.g., ibuprofen), intravenous immunoglobulin, immunosuppressant medications, various chemotherapeutics, antiepileptic medications (e.g., carbamazepine and lamotrigine), and antibiotics (e.g., trimethoprim/sulfamethoxazole) can all cause a chronic meningitis. Fortunately, the meningeal irritation typically quickly reverses after cessation of the drug.

RECURRENT MENINGITIS

Some patients with chronic meningitis can appear to have distinct meningitis episodes, but when their CSF is examined in between clinical flares, they are found to have a persistent CSF pleocytosis. There are a small number of disease entities that do cause true recurrent meningitis with interval resolution. The syndrome of recurrent episodes of acute, aseptic meningitis was first described by Pierre Mollaret in the 1940s and was later found to be most commonly secondary to herpes simplex virus type 2 infection.[11,12] In patients with recurrent meningitis, especially those with recurrent fungal, bacterial, and parasitic causes, a thorough immunologic evaluation needs to be performed to evaluate for underlying susceptibility factors. In addition, recurrent CNS bacterial or fungal infections should trigger a careful re-evaluation for potential exposures (e.g., intravenous drug use) as well as for anatomic susceptibilities like skull-base or neural tube defects. A dermoid cyst, or other lesion near the subarachnoid space, that periodically ruptures to cause a recurrent, chemical meningitis may be better visualized on MRI in between meningitis episodes once fluid has reaccumulated in the cyst. Led by the increasing availability of genetic testing, a variety of monogenic autoinflammatory disorders, including TNF receptor associated periodic syndrome (TRAPS) and cryopyrin associated periodic syndrome (CAPS), have been identified that can include chronic and recurrent meningitis as a feature of the syndrome. Particularly for younger patients who lack other obvious risk factors, a consultation with a medical geneticist may be appropriate early in the clinical work-up.

CONCLUDING COMMENTS

Evaluating a patient with chronic meningitis requires a holistic approach to the patient's history and physical examination as well as a wide-ranging consideration of underlying etiologies that span a number of medical subspecialties, especially neurology, infectious diseases, rheumatology, and oncology. A systematic, methodical, and persistent approach to the continuing evaluation of these patients, sometimes over weeks to months, can pay dramatic dividends as many of the responsible etiologies are amenable to treatment. As these evaluations play out over prolonged periods of time, empiric therapies including various antimicrobials and immunosuppressants (especially glucocorticoids) are often given, and transient clinical responses need to be interpreted with caution as some can temporarily mask the underlying etiology and lead the treating physician astray.

EMERGING VIRUSES
THERAPEUTIC VACCINATION
CONCLUDING COMMENTS

Infectious diseases have historically been the major cause of human morbidity and mortality, and vaccinations have added immeasurably to human health by preventing them. The benefits of vaccinations have not come without some costs, and rare adverse effects of vaccines occur. Many important adverse events are neurologic, and these are discussed in this chapter. The US Centers for Disease Control and Prevention (CDC) regularly update and publish useful summaries of vaccine recommendations.

HISTORIC BACKGROUND

The practice of inoculating microbial agents as a mean to prevent infections was described as early as 200 BCE. Several accounts from the 1500s suggest that smallpox inoculations were common in China and India.[1] In the late 1600s Emperor K'ang Hsi, who had survived smallpox as a child, had his children inoculated. That method involved grinding up smallpox scabs and blowing the matter into the nostril.[2] Inoculation, later called variolation, was introduced to Europe in 1721. This basic strategy of vaccination was employed to generate Louis Pasteur's rabies vaccine, Max Theiler's yellow fever vaccine, and the polio vaccines of Jonas Salk and Albert Sabin.

One of the earliest records of neurologic complications to vaccines was a patient who developed a neuroparalytic syndrome following rabies vaccine around 1889.[3] Since then, several neurologic syndromes have been recognized as occurring in close temporal relationship to vaccination. These complications have had a negative impact on vaccine acceptance, resulting in decreasing vaccination coverage and increases in vaccine-preventable diseases. Given the widespread use of vaccines and the growing concerns about vaccine safety, the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) tasked the Institute of Medicine (IOM) to create a Safety Review Committee to evaluate the evidence on possible causal associations between immunizations and certain adverse outcomes. In assessing vaccine safety, the committee performed an examination of the epidemiologic and clinical evidence regarding a possible causal relationship, as well as the possible biologic mechanisms that might support such an association. It also considered the background rates of the disease in the population in

order to determine legitimate concerns from events that could be temporally related but not caused by the vaccine. The committee released its report in 2012.[4] The findings indicate that measles, mumps, and rubella (MMR), varicella, influenza, hepatitis A, hepatitis B, human papillomavirus, meningococcal, diphtheria toxoid, tetanus toxoid, and acellular pertussis-containing vaccines are safe and that serious adverse events are quite rare. Ongoing efforts continue in order to provide an evidence-based approach to the potential complications of vaccinations.

TYPES OF VACCINES

The underpinning mechanism by which vaccines exert their benefits is by triggering the host's immune system in a way that generates protective immunity against the fully virulent pathogen without causing disease. However, the mechanism of action varies by the type of vaccines (Table 48-1). These include inactivated, attenuated, subunit, conjugate, toxoid, DNA, and vector vaccines.

Inactivated vaccines consist of pathogens that have been treated by chemical or physical methods so that they are nonviable. These treatments generally modify viral proteins essential to some critical function, such as attachment of the virus to the cell. In successful vaccines, these inactivated organisms still have sufficient antigenicity that protective immunity is achieved without the possibility of causing infection. Examples of inactivated vaccines include influenza vaccine, the Salk polio vaccine, rabies vaccine, and the whole-cell pertussis vaccine.

Attenuated vaccines use a virus (or other pathogen) that has been adapted to replicating in a different host system, such as in tissue culture or in chicken eggs. This is achieved by serially passaging the virulent (or wild-type) pathogen in an alternative host system. The pathogen is now "adapted" to the alternative host system and humans become an "unnatural host." The agent is unable to express its full virulence and therefore causes a mild infection while still stimulating full immunity. An example of an attenuated vaccine is the combined MMR vaccine.

Subunit vaccines are composed of subunits of a pathogen that are both nontoxic and immunogenic. They differ from inactivated whole-cell vaccines by containing only the antigenic parts of the pathogen. These parts are necessary to elicit a protective immune response. The older hepatitis B vaccine is an example. That vaccine consisted of a hepatitis B surface antigen that was originally purified from the plasma of hepatitis B carriers. Because of concerns about using human-derived material, the gene for the hepatitis B surface antigen was introduced into yeast that then synthesized

TABLE 48-1 ■ Types of Vaccines Along With a Brief Description of Their Mechanism of Action

Vaccine	Mechanism of Action
Inactivated Influenza Salk polio Rabies Whole-cell pertussis Hepatitis A	Inactivated vaccines consist of pathogens that have been treated by chemical or physical methods so that they are nonviable. Vaccines usually produce a transient antibody response
Attenuated Influenza (nasal) MMR Varicella VZV (Zostavax) Yellow fever Oral polio *Salmonella* (oral) Tuberculosis (BCG)	Pathogens are attenuated by inducing an adaptation to alternative host systems (tissue culture). Thus the agent is unable to express its full virulence in humans and therefore causes a mild infection while still stimulating full immunity
Virus-like particles (VLP) Hepatitis B HPV Chikungunya virus (CHIKV) Influenza (H5N1)	Composed of one or more structural proteins that resemble the structures of viruses and trigger a high humoral and cellular immune response. A key factor regarding VLP safety is the lack of viral genomic material
Recombinant Hepatitis B (Recombivax) HPV (Gardasil) VZV (Shingrix)	Developed by inserting genes from the antigen into a vector, often viruses with low virulence
Conjugate *Haemophilus influenzae*, type b (Hib) (polysaccharide) *Neisseria meningitidis* (polysaccharide conjugate) *Streptococcus pneumoniae*, heptavalent (conjugate polysaccharides) *Salmonella typhi* (capsular polysaccharide)	These vaccines are created by linking polysaccharide antigens to protein carriers, resulting in a robust immunogenic response
Toxoid Diphtheria Tetanus	Toxoid vaccines are made by weakened bacterial toxins. In general they are safe because they cannot cause the disease they prevent and there is no possibility of reversion to virulence. The vaccine antigens are not actively multiplying and do not spread to unimmunized individuals

MMR, measles-mumps-rubella; VZV, varicella zoster virus; HPV, human papillomavirus.

pure hepatitis B surface antigen. Subunit vaccines have also been developed in the hope that immune responses directed at certain antigens, such as Tat, that are expressed very early in the human immunodeficiency virus replication cycle might lead to containment, if not abortion, of infection. Other examples of subunit vaccines include viral envelop proteins, recombinant, and conjugate vaccines.

Viral envelope proteins are noninfectious multiprotein structures that are engineered to self-assemble and form virosomes or "virus-like" particles (VLPs). These virosomes stimulate both cell-mediated and humoral immune responses without triggering the side effects associated with the native virus. VLPs have been used in the human papillomavirus vaccine and hepatitis B vaccine. A recombinant vaccine is a vaccine produced through recombinant DNA technology. This involves inserting the DNA encoding an antigen (such as a bacterial surface protein) that stimulates an immune response into bacterial or mammalian cells, expressing the antigen in these cells, and then purifying it from them.

Conjugate vaccines usually consist of the capsular material of common bacterial pathogens. Antibodies to the capsules allow opsonization of the organism. Examples of component vaccines are those for *Pneumococcus*, *Meningococcus*, and *Haemophilus influenzae* B. These vaccines are often not sufficiently immunogenic in very young infants and have to be specially formulated by conjugation to peptides, which enhances their antigenicity.

Toxoid vaccines are bacterial toxins (e.g., diphtheria, tetanus) that have been rendered nontoxic through chemical treatment, but remain immunogenic.

DNA vaccines are DNA sequences of the gene for an immunogenic antigen that are injected into muscle, where they direct the synthesis of the antigenic peptide. This is then presented to the immune system by the "infected" muscle cell, mimicking a natural infection. DNA vaccines, however, have proved to be poorly immunogenic in humans and none are currently available for human use.

Vector vaccines consist of a nonpathogenic virus that has one of its genes replaced with a gene for an antigen of interest. Such vaccines are being investigated but are not yet available for human use.

More recently, the methods of "reverse vaccinology" have been exploited to make effective vaccines. The process involves sequencing the genome of a target pathogen and scanning for genes that may be useful for vaccines, such as those encoding for virulence factors or surface proteins. These proteins can then be separately expressed and screened for use in animal models, after which human trials can be organized. The advantage of reverse genetic methods is that all of the proteins are available for testing, rather than only an unsuitable subset expressed by a cell line. An example is that of vaccines against meningococcal meningitis, which are protective to all but one serotype, the capsular polysaccharide of which mimics certain neural antigens and is therefore poorly immunogenic.

NEUROLOGIC COMPLICATIONS OF VACCINATION

Possible Mechanisms

Inappropriate immune responses are well-recognized consequences of vaccinations, especially with vaccines made from viruses grown in neural tissue. The classic example is that of the old neurally derived rabies virus, which often resulted in "neuroparalytic accidents" of acute demyelination in either the central or peripheral nervous system. Both acute disseminated encephalomyelitis (ADEM) and Guillain–Barré syndrome (GBS) were observed after the use of these older rabies vaccines and most recently with influenza vaccines.

Two major mechanisms proposed to explain development or activation of autoreactive immune cells after immunizations are molecular mimicry and bystander activation. Molecular mimicry is a process by which antigenic epitopes in the vaccine resemble those in myelin. This structural similarity can result in the development of self-reactive, naïve T and B lymphocytes. Once activated, these cells expand in number and mature into effector T cells leading to pathologic responses mediated by cytokine release and cell-mediated cytotoxicity. Although this mechanism of mimicry has not clearly been shown to act in central demyelination (except possibly for measles, as discussed later), neurally derived vaccines contain myelin antigens themselves (rather than mimics) and therefore can trigger such disease. Peripheral demyelination is known to occur by this mechanism.

Bystander activation is a process by which the activation and expansion of self-reactive lymphocytes is produced by cytokine release and antigenic response to tissue damage. It is conceivable that vaccine antigens could trigger bystander activation just as an infectious agent does.

Detection of Vaccine Adverse Events

Detection of vaccine adverse events can be difficult as they are uncommon and often manifest as illnesses that are known to occur in the unvaccinated. Many of these illnesses are not reportable to health departments. Health officials, however, will take note of an unusually high incidence of disease and launch an investigation. Surveillance for any unusual disease activity can be active or passive. Active surveillance is when cases are actively sought by sending questionnaires to physicians' offices and hospitals or by systematically examining hospital records. Passive surveillance occurs when physicians or the public send unsolicited information about cases to health department officials. Passive surveillance provides very limited epidemiologic information, as it does not indicate the proportion of those with the complication who were actually reported (no numerator information) and how many were actually exposed to the vaccine (no denominator information); furthermore, the clinical details often are insufficient to make a secure diagnosis. The Vaccine Adverse Event Reporting System (VAERS) is a passive surveillance system in which complications are reported to the FDA. Table 48-2 summarizes selected neurologic syndromes reported to VAERS in association with various vaccines. Another passive surveillance system consists of the National Vaccine Injury Compensation Program, which compensates individuals who have had a serious and permanent adverse effect from a vaccine and who meet other criteria.

Case reports and case series of illnesses following a vaccination may be published, but it is difficult to establish causality on this basis and, in fact, such reports may be misleading. The older literature is replete with case reports of illness following vaccination but in which a causal connection was never made. Certain reports have generated considerable controversies that have led to a decrease in vaccine use and to outbreaks of disease, emphasizing the necessity of performing controlled studies that can address the issue of causality. Randomized, double-blind, placebo-controlled trials of vaccines are required as part of the FDA approval process and are very reliable, but only common adverse events are detected.

The establishment of extensive databases provides a new resource for vaccine safety studies. The CDC is operating a Vaccine Safety Datalink (VSD) project, which links to the databases of eight health maintenance organizations with 6 million members. This database has been used for a number of population-based studies, including vaccine safety studies.[5] General information on vaccinations and reporting of adverse events is available from various internet sites (Table 48-3).

TABLE 48-2 ■ Neurologic Disorders Reported to the Vaccine Adverse Event Reporting System (VAERS)

Vaccine	Selected Neurologic Disorders Reported
MMR	Encephalitis, panencephalitis, aseptic meningitis, ADEM, cerebellar ataxia, parkinsonism, seizures, mental retardation, autism, GBS
Varicella	Headaches, stroke, aseptic meningitis, encephalitis, cerebellar ataxia, autism, developmental abnormalities, neuropathies
Zoster (Varzos)	Ataxia, brachial plexopathy
Influenza (quadrivalent)	GBS, MS, optic neuritis, acute axonal neuropathy, alien limb syndrome, antiganglioside antibody, autism, seizures
Influenza (H1N1)	GBS, seizures, autism, autoimmune neuropathy
Hepatitis A (HEPA)	Dyskinesia, ataxia, ageusia, antineuronal antibody
Hepatitis B (HEP)	MS, encephalitis, strokes, cerebellar ataxia, seizures, GBS, transverse myelitis, peripheral neuropathies, Bell palsy, myasthenia gravis, autism
Poliomyelitis (OPV)	Neuroparalytic disease, seizures, encephalitis
Rabies (Semple)	Neuroparalytic disease, GBS, stroke, ADEM, transverse myelitis, seizures, cranial and peripheral neuropathies
HPV (recombinant)	GBS, syncope, headaches, ALS, demyelinating neuropathy, dyskinesia
Japanese encephalitis	Encephalitis, seizures, ataxia
Yellow fever	Encephalitis, ADEM, acute hemorrhagic fever, seizures, optic neuritis, GBS, CIDP
DtaP	Seizures, encephalitis, meningitis, GBS, CIDP, ataxia, dyskinesia
Meningococcal (Menactra)	Encephalitis, meningitis, seizures, AHLE, stroke, demyelinating neuropathy, mononeuritis multiplex, antiganglioside antibody, antineuronal antibody
Pneumococcal (Prevnar)	Encephalitis, meningitis, TIA, stroke, demyelinating neuropathy, seizures, dyskinesia
Hib	Seizures, encephalitis, meningitis, stroke, neuropathy, autism, dyskinesia
Lyme	Aseptic meningitis, neuropathy, seizures

MMR, measles-mumps-rubella; ADEM, acute disseminated encephalomyelitis; GBS, Guillain–Barré syndrome; MS, multiple sclerosis; HPV, human papillomavirus; ALS, amyotrophic lateral sclerosis; CIDP, chronic inflammatory demyelinating polyneuropathy; DtaP, diphtheria-tetanus-pertussis; AHLE, acute hemorrhagic leukoencephalitis; TIA, transient ischemic attacks; Hib, Haemophilus influenzae type B.

Adjuvants and Preservatives

In order to attract the attention of the immune system and build an immune response, most vaccines require

TABLE 48-3 ■ Vaccine Web Sites

the addition of an adjuvant. Aluminum salts such as aluminum hydroxide, aluminum phosphate, and aluminum potassium sulfate have been used safely in vaccines for more than 70 years. A recently developed adjuvant suspension used with the Shingrix vaccine is ASO1B. AS01B is made of up of monophosphoryl lipid A (MPL), an immune-boosting substance isolated from the surface of bacteria, and QS-21, a natural compound extracted from the Chilean soapbark tree. Adjuvants have to be carefully used and manufactured since they can lead to severe inflammation. The US Food and Drug Administration (FDA) does not currently approve the use of pure adjuvants outside of a vaccine.

Controversies around the safety of adjuvants have emerged in the last decades. The autoimmune/inflammatory syndrome induced by adjuvants (ASIA) is a term coined by Shoenfeld and co-workers. A careful review of over 300 cases of ASIA syndrome collected from an international registry revealed useful clinical information.[6] The mean age at disease onset was 37 years and the mean latency between adjuvant administration and development of symptoms was 16 months, ranging from 3 days to 5 years. The most frequent symptoms included arthralgias, myalgias, and chronic fatigue syndromes, but most patients had a concomitant autoimmune disorder, most commonly undifferentiated connective tissue disease (UCTD) and a positive antinuclear antibody test (ANA).

Perhaps the strongest evidence of the safety of aluminum in childhood vaccines came from a recent study that carefully assessed blood and hair aluminum levels, vaccination history, and cognitive, language, and motor development scores in children aged between 9 and 13 months. The authors found no correlation between infant blood or hair aluminum concentrations and vaccine history or between blood aluminum and overall developmental status.[7]

The mercury-containing preservative thimerosal has also been linked with neurologic complications, particularly with the risk of autism. Mercury is a naturally occurring element found in the Earth's crust, air, soil, and water. At high levels, it can be neurotoxic. Using standards for methylmercury, the FDA conducted an assessment of mercury content in vaccines and found that infants up to 6 months of age could receive quantities of mercury from vaccines that exceeded the recommended safety guidelines for methylmercury of the Environmental Protection Agency. Thimerosal, however, contains ethylmercury, not methylmercury. Ethylmercury is broken down and excreted much more rapidly than methylmercury and is therefore much less likely to accumulate in the body and cause harm.

Several efforts have been made to address concerns about the risk of autism and other developmental disabilities in children exposed to thimerosal. Reviews of the evidence by the Institute of Medicine concluded that evidence favored rejection of a causal association between thimerosal in vaccines and autism.[4] This conclusion was based on several factors. Large epidemiologic studies suggest that the incidence of autism in children who received thimerosal-containing vaccines is not different to those children that received thimerosal-free vaccines. Similarly, prenatal and early-life exposure to thimerosal from vaccines or immunoglobulins was not related to increased risk of autism.[8] In a US cohort study, standardized tests were administered to children between 7 and 10 years of age to assess the association between neuropsychologic performance and exposure to thimerosal from vaccines or immune globulins during the prenatal period, the neonatal period (0 to 28 days), and the first 7 months of life. The results did not support an association between early life exposure to mercury and deficits in neuropsychologic functioning at the age of 7 to 10 years.[9] As a precautionary measure, the United States has transitioned to a childhood vaccine schedule free of thimerosal. Currently, in the United States only multidose vial influenza vaccines contain preservative quantities (i.e., 25 μg per dose) of thimerosal, and thimerosal-free influenza vaccine preparations are widely available. Despite these changes, the incidence of autism continues to increase.

In conclusion, scientific evidence suggests that the presence of thimerosal in vaccines does not increase the risk of autism or other neurodevelopmental disorders.

Smallpox

Smallpox (or variola) is a highly contagious disease caused by a double-stranded DNA virus that is airborne.

Smallpox is mostly of historic significance at this time, but its potential as a weapon of biowarfare has drawn public health interest in smallpox vaccination issues. The illness begins abruptly with headache, fever, and back pain followed by a characteristic rash that begins on the face, followed by the arms and legs, and finally spreads to the torso. The rash begins with scattered macules and evolves into papules, vesicles, and finally pustules that then dry and crust over. The patient ceases to be contagious after the crusts fall off. There are two broad forms of the disease: the severe form, variola major, which had a mortality rate of about 30 percent, and a milder form, variola minor (alastrim), with a mortality rate of approximately 1 to 5 percent. There are several types of variola major, with the hemorrhagic smallpox form of the disease having a mortality of nearly 100 percent.

The original smallpox vaccination (variolation) involved the transfer of material from smallpox pustules or crusts into a scratch in the skin of the subject to be vaccinated. This method often resulted in a milder form of the disease, presumably because the preparation of the material from the smallpox lesions attenuated the smallpox virus contained therein. Variolation was the first example of an attenuated vaccine. However, the attenuation was often inadequate and some recipients developed full-blown smallpox as well as other diseases such as syphilis. Jennerian vaccination uses an animal poxvirus to induce cross-protective immunity against smallpox. The modern vaccine virus is not cowpox but vaccinia, a related virus; at what point cowpox was replaced by vaccinia or whether the original "cowpox" was some mixture of cowpox and vaccinia viruses is unknown.

Neurologic complications are uncommon. Recent series suggest that postvaccinal encephalitis can occur in 2 to 6 per million primary vaccinees, depending on age.[10] The risk in Europe is much higher, perhaps as high as 1 in 4,000, presumably because a different strain of vaccinia virus is used. There have been rare reports of isolation of vaccinia virus in the CSF in cases of encephalitis following vaccination. The overall death rate from all causes following smallpox vaccination is 0.5 to 5 per million vaccinees.

Measles, Mumps, and Rubella

Measles, mumps, and rubella were once common childhood illnesses in the developed world, but they became rare after the introduction of vaccines that prevent them. These vaccines are commonly given together in combination as the MMR vaccine. More recently, polyvalent vaccines have been introduced to minimize the number of injections to which small children are subjected. Formulations containing only some of these have been used in the past: measles (M) vaccine and measles plus rubella (MR).

MEASLES

Measles is a viral exanthem caused by an enveloped single-stranded RNA virus that is transmitted through the air and initially infects the respiratory epithelium, where it replicates. This replication gives rise to a primary viremia that implants virus in lymphoid tissues. A secondary viremia follows, and the virus is disseminated throughout the body. During measles a significant distortion of the immune system occurs, with paradoxic features. There is a nonspecific systemic immune activation, along with immunosuppression, causing susceptibility to bacterial and viral superinfections that are the main causes of morbidity and mortality and are enhanced by malnutrition, making measles a major cause of death in developing countries. The main complication of measles is pneumonia, due to bacterial superinfection in children and due to direct measles virus infection of the lungs in adults. Pneumonia occurs in roughly 10 percent of patients and causes more than 60 percent of the mortality resulting from the disease. Other complications include otitis media and laryngotracheobronchitis.

The main neurologic complication of measles, occurring in roughly 1 per 1,000 cases, is ADEM, in which multifocal inflammatory demyelination occurs within the central nervous system. ADEM may be due to molecular mimicry, since T cells from measles-associated ADEM patients proliferate upon exposure to myelin basic protein; cells from patients with uncomplicated measles do not. The mortality rate of ADEM is between 10 and 30 percent, and long-term sequelae are common and severe.

Measles virus was first isolated and propagated in tissue culture by Enders and Peebles in 1954, and efforts at making measles vaccine followed shortly thereafter. The first vaccines were made from the Edmonston B strain, which was obtained from the original Edmonston isolate (named after the individual from whom it was first obtained) by serial passage in primary kidney cells (24 passages), primary human amnion cells (28 passages), chicken embryos (6 passages), and then into chicken embryo cells. This vaccine was first introduced in 1963, but the high rate of fever and rash prompted its discontinuation. Other vaccine strains that were less reactogenic were then developed. One of these, the Moraten strain introduced in 1968, was derived from the Edmonston B strain by a further 40 passages in chicken embryo cells. Another strain, the Schwarz strain, was obtained from the Edmonston B strain by a further 85 passages in chicken embryo cells and was used from 1965 to 1976. The Moraten vaccine is the only one used in the United States today, although other vaccine strains are used elsewhere in the world. Before vaccination, 4 million cases of measles occurred annually in the United States, whereas there were only 309 cases in 1995 due to widespread vaccination.

Neurologic complications of measles vaccination have been reported but are uncommon. Case reports of encephalopathies do not, by themselves, provide evidence of causation. In order to better understand the risk of adverse events with measles vaccine, Weibel and co-workers analyzed data from claims of measles vaccine-induced encephalopathy submitted to the National Vaccine Injury Compensation Program.[11] In the years 1970 to 1993, 403 claims of postvaccination encephalopathy were reviewed; inclusion criteria included an acute encephalopathy 2 to 15 days after vaccination (M, MR, MMR) with permanent brain damage or death, with no other known cause that would explain the illness. Of these 403 purported cases, 48 met the criteria. The mean age of the cases was 17.5 months (range, 10 to 49 months).

Three main groups of complications were identified: ataxia, behavioral changes, and seizures. Fever preceded the encephalopathy in most, and one-quarter of the cases had a measles-like rash 1 to 2 weeks after vaccination. CSF was analyzed in most and was abnormal in 40 percent: pleocytosis was present in 70 percent, and protein concentration was elevated in more than one-third. No other viruses were found to be present. When the number of patients with encephalopathy was plotted against the day of onset, a typical epidemic curve was obtained with a peak at 8 to 9 days, suggesting a causal (rather than merely temporal) connection between the vaccination and the neurologic illness. Clinical and pathologic data do not point to any single neurologic disease entity. The risk of neurologic illness can be estimated from the fact that from 1970 to 1993, approximately 75 million children had measles vaccine by age 4 years, based on a 90 percent immunization rate and 83 million births. The limits of risk are, based on 48 claimants meeting criteria and on all 403 claimants, 0.64 to 5.37 cases per million vaccinees.

In a study of 1.8 million Finnish MMR vaccinees, actively surveyed from 1982 to 1996, adverse events included 77 that were neurologic and consisted mostly of febrile seizures with good recovery. One patient later developed Lennox–Gastaut syndrome. Four cases of encephalitis were reported, one of which was found to be due to herpes simplex virus; the others were uncharacterized. Some other neurologic complications were found to be due to other known causes (such as bacterial meningitis). Miscellaneous other neurologic disorders included cases of GBS (two patients, with eventual recovery), transient confusion, and transient ataxia. Interestingly, no cases of autism were found.[12]

MMR vaccine was proposed as a cause of autism, a complex and heterogeneous neurobehavioral syndrome. Much discussion has been stimulated by a report of 12 children who developed cognitive problems as well as inflammatory bowel disease a few days to a few months after receiving the MMR vaccine.[13] Questions were raised about the conduct of the study, with improper consent procedures, inconsistent use of data, irreproducibility of some laboratory findings, and failure to declare conflicts of interest. The interpretation of the paper as establishing a causal connection between MMR and autism was retracted by 10 of 12 authors who could be contacted. As further irregularities came to light, the paper was retracted in its entirety by the journal.[14]

The ages at which MMR vaccine is given are also the ages when autism manifests clinically; however, the beginnings of this behavioral disease occur much earlier in life. A report from the Institute of Medicine reviewed published and unpublished reports concerning the issue of MMR vaccine and concluded that there is no causal connection between the vaccine and autism.[4]

MUMPS

Mumps is an acute febrile illness caused by rubulavirus, a member of the paramyxovirus group. The clinical illness in children usually is self-limited, with fever, malaise, headache, and often an acute painful parotitis. The disease is complicated occasionally by meningitis and rarely by meningoencephalitis, which may lead to residual deficits. Sensorineural deafness is an uncommon sequela but can be a major cause of deafness in children during epidemics. In adults, mumps has a higher rate of systemic complications such as orchitis in men and oophoritis and mastitis in women, as well as pancreatitis and myocarditis. The main original vaccine virus strains were named the Jeryl Lynn and Urabe strains, after the hosts from which the original unattenuated viruses were isolated. Mumps vaccine was first licensed for use in 1967. The number of cases of mumps in the United States was over 150,000 in 1968 and decreased to less than 3,000 two decades later. The number of cases increased briefly after vaccination rates declined, but decreased again after mumps vaccination was required for school entry.

Aseptic viral meningitis is the main neurologic complication of mumps vaccination and is probably related to natural mumps frequently causing meningitis. The Urabe strain vaccine was discontinued in the United States after it was linked to aseptic meningitis in 1 case in 900 vaccinees in one Japanese series and 1 case in 200,000 vaccinees in another. For the Jeryl Lynn vaccine, the incidence is 1 case in 1.8 million vaccinees; by comparison, aseptic meningitis occurs in approximately 1 in 400 cases of natural mumps. This aseptic meningitis is self-limited and requires no specific therapy.

RUBELLA

Rubella is a self-limited viral infection in children, characterized by a fever and rash, caused by a single-stranded RNA virus. The virus causes most of its damage through prenatal infection. This congenital rubella syndrome is well described, and the triad of neurologic, eye, and cardiac defects is characteristic. The disease also includes a spectrum of uncommon disorders in all age groups including thrombocytopenic purpura, hepatitis, bone lesions, interstitial pneumonitis, diabetes mellitus, and thyroid problems.

The vaccine has very few complications in children, with rare mild rash and fever. In adults, the most common side effect of the vaccine is polyarthralgias. A few scattered reports of peripheral mononeuropathies and radiculopathy following rubella vaccination have been published,[15] but a review of these could not establish a causal relationship.[16]

Diphtheria, Pertussis, and Tetanus

DIPHTHERIA

Diphtheria is a disease caused by strains of *Corynebacterium diphtheriae*, which produce diphtheria toxin, a binary toxin consisting of two molecular components termed fragments A and B. Fragment B binds to the target cell and allows access of fragment A to the cytoplasm. Fragment A then inactivates elongation factor-2 (EF-2), inhibiting protein synthesis in the cell and leading to necrosis. Usually diphtheria infects the pharyngeal epithelium, where the superficial layers of the mucosa become necrotic and provide an excellent culture medium for the bacteria. These areas of tissue necrosis with exudation form the so-called diphtheritic "membranes." Systemic absorption of diphtheria toxin from the pharynx causes cardiac and neurologic effects. Patients with diphtheritic myocarditis may develop congestive heart failure; pathologic examination shows interstitial inflammation and hyaline degeneration of fibers. Diphtheritic "neuritis" includes several entities, including an isolated paralysis of the soft palate, ocular motor palsies, paralysis of the diaphragm, and a disorder resembling GBS. The pathogenesis of these various disorders is not understood.

In the 1920s, before diphtheria toxoid was introduced, there were approximately 100,000 cases in the United States annually. In the past few decades, no more than a handful of cases have occurred each year. When vaccine coverage decreases, large epidemics of the disease follow, as happened in Russia in the 1990s, when the public health infrastructure could no longer cover the population adequately. The mortality rate of the untreated disease is 30 to 50 percent. After the introduction of antitoxin therapy, the mortality rate declined to 10 to 20 percent; modern intensive care has reduced this rate further to 5 to 10 percent.

Vaccination against diphtheria was originally undertaken by injecting mixtures of toxin and antitoxin. In the early 1920s, it was found that treatment of diphtheria toxin with formalin resulted in a nontoxic immunogenic toxoid. This toxoid was incorporated with tetanus toxoid and inactivated whole-pertussis cells to make the diphtheria–pertussis–tetanus (DPT) vaccine that first became widely available in the mid-1940s.

There have been remarkably few neurologic complications from diphtheria toxoid, although they may be difficult to discern, as the toxoid is usually given in combination with pertussis and tetanus vaccines. Local injection-site reactions can be painful as they are intramuscular; infants may react with prolonged crying, irritability, drowsiness, loss of appetite, and vomiting. Limitation of abduction of the injected arm may occur regardless of age.

PERTUSSIS

Pertussis, or whooping cough, is caused by *Bordetella pertussis*, a commonly circulating bacterium that has multiple antigenic components. The disease begins with a seemingly minor upper respiratory infection, with minimal fever and an intermittent cough, that then becomes severe and progresses to paroxysms in which coughing becomes very vigorous, interfering with breathing and increasing intracranial pressure by continual coughing. This paroxysmal stage lasts between 2 and 6 weeks before resolving.

The disease was commonly lethal in the past. At the beginning of the 1900s, approximately 5 of every 1,000 liveborn infants died of pertussis before 5 years of age. Today, there are fewer than 10 deaths per year in the United States. When vaccine coverage declines, the disease re-emerges because pertussis vaccine protects only against bacterial toxins but does not necessarily eliminate the pathogen from the population (unlike smallpox, for example). The pathogenesis of the disease is not completely known, but is probably due to a toxic effect on respiratory epithelium with denudation of respiratory passages.

An important complication of pertussis is pertussis encephalopathy, a vaguely described syndrome of encephalopathy and seizures. In the years 1997 to 2000, pertussis encephalopathy and seizures occurred in 0.1 and 0.8 percent of cases, respectively. There appear to be two clinical forms, one with an abrupt onset of seizures and coma and the other with the gradual onset of somnolence progressing to coma. The prognosis appears to be rather poor, with death, permanent cognitive deficits, and recovery each occurring in one-third of cases. The pathologic changes are characterized by vascular congestion and brain petechiae. The pathogenesis probably involves the effects of anoxia and increased venous pressure in the brain caused by the severe cough. Interestingly, intravenous injection of toxin does not appear to cause neurologic complications.

Pertussis vaccine has dramatically decreased the burden of disease in vaccinated populations; it declined from about 200,000 cases in the United States in the mid-1930s to a nadir of 1,010 cases in 1976, with a subsequent increase to about 8,000 cases occurring in 2000 for unclear reasons. The original vaccine consisted of inactivated whole bacterial cells. Whole-cell vaccine is "reactogenic," causing painful local injection-site reactions and fever. The latter can lead to febrile seizures in children, who are especially susceptible. This reaction triggered reports of severe neurologic illnesses following pertussis vaccination which likely were related in many cases to the fever alone.

To ascertain the risk of neurologic illness attributable to pertussis vaccine, an active survey of encephalopathic illnesses was performed in all British children from July 1976 to June 1979 in the National Childhood Encephalopathy Study. A comparison was made of rates of vaccination in those with or without encephalopathy. A small excess of patients with encephalopathy was found following vaccination. All vaccines with a pertussis component, for example, pure pertussis vaccination, DPT vaccination, and diphtheria–pertussis (DT) vaccination, were counted as pertussis vaccination. The study's methodology has been criticized, and it is likely that other concurrent diseases in part explained the neurologic problems. In particular, some severe epileptic encephalopathies (Dravet syndrome), due to mutations in sodium channels, manifest themselves at the same age that pertussis vaccine is given. Furthermore, there were problems with choice of controls, blinding of investigators, misclassification of cases, and uncertainties regarding the onset of disease. These questions about the conduct of the study have been elaborated in published critiques and these risk estimates are no longer used by the British legal system as a basis for estimating liability.[16]

A new acellular vaccine consisting only of a subset of antigenic components of the bacterial cell was introduced in 1996 and appears to be much less reactogenic.

TETANUS

Tetanus is a neurologic disease caused by *Clostridium tetani*, which is present ubiquitously in soil. The organism has two toxins carried on a plasmid: tetanospasmin, the neurotoxic component, and tetanolysin, which is a hemolysin. Tetanospasmin is elaborated locally and transported to the CNS in the blood and via local axonal transport. It interferes with release of the presynaptic inhibitory neurotransmitters glycine and γ-aminobutyric acid (GABA), causing inappropriate disinhibition of spinal cord reflex arcs, with resultant greatly increased tone in the muscles and intermittent painful spasms. Respiratory compromise may lead to death. The toxin is very potent, a lethal dose being only 2.5 ng/kg. The case fatality ratio of the untreated disease is 25 to 70 percent overall and 100 percent at the extremes of age; with intensive care, the mortality rate decreases to 10 to 20 percent.

Tetanus toxoid consists of formalin-treated tetanospasmin, which induces an immune response that provides good protection lasting around 10 years. Adverse events are rare and are mostly anecdotal. Brachial plexopathy occurs in 1:100,000 vaccinees within 1 month of vaccination, and there may be a slightly increased risk of GBS (0.4 per million doses). One person had an illness resembling GBS on each of three vaccinations with tetanus toxoid.

Influenza

Influenza is an acute, febrile, debilitating viral infection of the upper respiratory tract that causes significant work and school absences each year. It can be complicated by pneumonia and, rarely, by ADEM. In children, the complications of influenza or its treatment include encephalopathies such as Reye syndrome as well as a toxic encephalopathy of unclear nature, possibly related to cytokine production in the course of disease. The virus was first isolated in 1933. In 1935, neutralizing antibodies were detected in subjects given subcutaneous injections of influenza virus. The first trial of an influenza vaccine demonstrated some degree of protection in 1936. The virus at the time was grown in a suspension of mouse lung and then injected into children. Further studies of influenza vaccination using inactivated virus were carried out by the military in the early 1940s with clear benefit, leading to the licensing of influenza vaccines in the United States in 1945. In 1947, a dramatic failure of the vaccine during an influenza epidemic led to the discovery that the vaccine produced immunity to the vaccine virus but not to the epidemic strain as a result of antigenic change in influenza virus. Such change can be of two types: (1) antigenic drift, in which the accumulation of mutations in the genes coding for the surface antigens of the virus renders it sufficiently different from the previous strains so that it can cause disease despite exposure to the previous virus, and (2) antigenic shift, in which there is reassortment of genes coding for the surface proteins from viruses circulating between birds and pigs. This experience led to the establishment of worldwide sentinel centers by the World Health Organization, which monitor for new strains of influenza virus every year so that the new strains can be incorporated into the updated vaccine. The recent circulation of the H5N1 strain in Southeast Asia is of great concern because of the highly lethal nature of the disease and its potential for human-to-human transmission.

Current vaccines are of two types. An inactivated vaccine uses two strains of influenza A and one influenza B virus, all grown in embryonated chicken eggs and inactivated with β-propiolactone. A cold-adapted attenuated vaccine, containing two influenza A and one influenza B attenuated strains, has been introduced and is given as a nasal spray.

In 1975, a fatal case of swine flu in a military recruit prompted the institution of a national swine flu vaccination program because of the fear that the outbreak would resemble the 1918 influenza epidemic that caused such widespread mortality. The vaccine was produced, and 45 million doses were administered by mid-December 1976. In late November and early December 1976, cases of GBS were reported to local health departments and prompted an investigation of the relationship to the flu vaccine. The results of an active surveillance of all such cases reported during the period of vaccination, prompted by reports of a possible causal connection and requested by a court in which a lawsuit had been filed, uncovered 1,300 possible cases, of which 944 could be evaluated.[17] There were 504 cases in vaccinees and 440 cases in nonvaccinees. Although the data were insufficient to diagnose GBS definitively, the cases could be classified by the extent of involvement into "extensive" and "limited" paresis. When the distribution of cases was plotted as a function of time since vaccination, the "extensive" cases followed a typical log-normal epidemic curve, whereas cases of limited paresis did not, implying a causal relationship between vaccination and GBS in a small number of cases. The effect of the vaccine lasted 6 to 8 weeks, and the actual risk of GBS attributable to vaccine was 4.8 to 5.9 per million vaccinees. Interestingly, no such increased risk was found in England and the Netherlands, as well as in 1.7 million US military personnel who received a double dose.[17] Furthermore, there was no increased risk of GBS following influenza vaccination in other subsequent seasons. The threat of severe influenza pandemics remains, and antigenic shifts are likely to challenge us with high-morbidity pandemics.

In the late 1990s, an H5N1 outbreak among chickens in Hong Kong led to a number of human deaths, although the virus was not easily transmissible to humans. Since then, the virus has appeared in many other countries but has not led to many human infections, which is fortunate since the case fatality rate is high in both humans and birds.

Despite a theoretical concern for the safety of influenza vaccines in patients with a history of multiple sclerosis and central demyelination, it appears to be quite safe. There was no increase in the onset or relapses of multiple sclerosis in a retrospective study following swine flu vaccine. There were also no increases in relapse rate in a double-blind trial involving 66 patients with multiple sclerosis.[18] Nonswine influenza vaccines are safe to use in multiple sclerosis, and a case-control study of influenza vaccine performed by the Vaccine Safety Datalink Study Group demonstrated no association with either multiple sclerosis or optic neuritis.[18] The same study also showed no association between vaccination against hepatitis B, tetanus, measles, or rubella and either multiple sclerosis or optic neuritis. The Immunization Safety Review Committee of the Institute of Medicine concluded that there was sufficient evidence to reject any causal relationship between such relapses and influenza vaccination.[4]

Hepatitis B

Hepatitis B is caused by a hepadnavirus, a partially double-stranded DNA virus, which is endemic worldwide, especially in sub-Saharan Africa and Southeast Asia. The virus is present in blood and semen and can thus be transmitted sexually and through inadequately processed blood products. The disease is usually self-limited in adults, with a clinical spectrum of asymptomatic infection to severe disease, followed by resolution and clearance of virus. However, in infants and children (80 to 90% of those infected before 1 year) as well as in some adults (approximately 5% of those infected), the acute infection is often asymptomatic but evolves into a chronic active hepatitis, with progression to cirrhosis and possibly hepatocellular cancer. In highly endemic areas such as sub-Saharan Africa and Southeast Asia, this is one of the most common cancers, leading to significant mortality.

In 1991, two cases of central demyelination were reported after receipt of the recombinant hepatitis B vaccine, one being in a patient with pre-existing multiple sclerosis. A report of eight patients with disseminated central demyelination with persistent activity on imaging studies caused much controversy in France.[19] After other cases were subsequently reported, calculations of the expected number of new cases of multiple sclerosis (1 to 3 per 100,000 annually) showed that the disease incidence in the vaccinees (0.65 per 100,000 annually) was actually less than would have been expected.[19] A population-based retrospective cohort study of 134,698 persons compared the rate of CNS demyelination in hepatitis B vaccinees with that in nonvaccinees and found no difference. In a case-control study from British Columbia, the rates of development of multiple sclerosis in adolescents vaccinated against hepatitis B in the years 1992 to 1998 (after universal hepatitis B vaccination became standard) were compared with those not vaccinated in the years 1986 to 1992 (before the vaccine was available); no statistically significant difference was found between the two groups.[19] A multicenter hospital-based study in France also found no evidence of an association between central demyelination and receipt of hepatitis B vaccine. There is therefore no evidence of causality between hepatitis B vaccination and multiple sclerosis. Other studies have found no evidence that hepatitis B vaccine triggers relapses in patients with established multiple sclerosis.[19]

Poliomyelitis

Poliomyelitis, caused by poliovirus type 1, 2, or 3, usually is asymptomatic or consists of a mild febrile illness in early childhood. In older children, adolescents, or adults, the febrile illness may be accompanied by damage to the anterior horn cells in the spinal cord. The disease is spread by fecal–oral contact and caused considerable morbidity before vaccination became widely available.

Early attempts at vaccination in the 1930s were disastrous—inadequate attenuation of the virulent virus led to polio in recipients (there was no test for attenuation of viruses), different serotypes were unknown and therefore not protected against, and there were no safety precautions against injecting neurally derived material. In the Cutter incident, which was associated with the Salk inactivated vaccine, 260 vaccinees and contacts contracted polio. These cases were thought to be related to the vaccine because they occurred in just a few western states, all were injected by vaccine supplied by a single manufacturer (Cutter Laboratories), the injected extremities were disproportionately affected, and the cases were traced to lots that were found to be inadequately attenuated.

The Sabin oral vaccine consists of attenuated virus that replicates in the gut and induces immunity in both the vaccinee and contacts (because the vaccinee sheds vaccine virus). Rarely, however, the virus reverts to a virulent form and may cause vaccine-associated paralytic poliomyelitis in 1 per 1 million doses in vaccinees or their contacts. Because the only polio seen in North America was vaccine associated, the Sabin vaccine was withdrawn from use in 1994. It is still in use in other parts of the world and has occasionally caused small epidemics of paralytic disease, with a recently reported outbreak occurring in China in 2004.

EMERGING VIRUSES

The global burden of viral disease is increasing. Arboviruses (arthropod-borne viruses) play an important role due to climate factors that encourage the growth of arthropod populations, greater access to various means of transportation, and exploration of previously isolated areas. Some of the most important of these viruses result in dengue fever, Japanese encephalitis, tick-borne encephalitis, and West Nile fever. These viruses have achieved prominence because of an increasing number of infections and disease with an increasing geographic spread.

Dengue, for instance, has not only reached a very high incidence rate but has become more severe, resulting in dengue hemorrhagic fever and dengue shock syndrome. Some dengue encephalitis cases have also been reported. Dengue hemorrhagic fever and dengue shock syndrome occur in areas where more than one (of four) serotypes cocirculate. Infection with one serotype confers protection against that serotype but enhances the effects of other serotypes. The implications for vaccine design are obvious. A phase 2 trial of an attenuated tetravalent vaccine in 3,673 participants, given at 0, 6, and 12 months, demonstrated that a safe vaccine against dengue is possible.

Another important threat to public health is enterovirus 71, which can cause an undifferentiated febrile illness, hand-foot-and-mouth disease, and has been associated with a brainstem encephalitis in children with a high case fatality rate (see Chapter 42). Already vaccines against enterovirus 71 are in phase 3 trials after demonstration of efficacy and safety in a 1,200-participant phase 2 trial.

THERAPEUTIC VACCINATION

Other potential uses for vaccines that are evolving include therapeutic vaccines, meant to modify or abolish an already established disease process, rather than to prevent the disease from beginning. Such a strategy has been attempted in the treatment of Alzheimer disease in which a β-amyloid fragment was used to immunize patients against disease-causing β-amyloid. Unfortunately, despite success in rodent models, several patients developed an immune-mediated encephalitis. A similar strategy may be useful in prion disease, if an appropriate antigen can be identified. A vaccine that could cause an immune deviation from a Th2 to a Th1 response may be useful in chronic intracellular infections that stimulate a humoral immune response (Th2) rather than the more effective cell-mediated immunity (Th1). Cancer vaccines have also been investigated and at least two are in clinical trials for prostate adenocarcinoma and melanoma.

CONCLUDING COMMENTS

Prevention of infectious diseases through active immunization is perhaps one of the greatest public health achievements to date. As a result of the development of new vaccines coupled with successful immunization programs, the epidemiology of various infectious diseases has been markedly altered. As an example, prior to the introduction of the conjugate vaccine, the incidence of Hib meningitis was between 10,000 and 20,000 cases per year in the United States and Canada, with a 3 percent mortality rate. Nowadays the incidence of invasive Hib disease is 0.08 cases per 100,000 in children younger than 5 years of age.

Like any other therapies, vaccination carries certain risks. It is biologically plausible that neurologic syndromes following vaccinations are caused by the active ingredient in the vaccine or the adjuvants. There is a theoretical basis by which vaccines could cause neurologic complications, often through immune-mediated mechanisms. In most cases, however, the lack of proven putative association between vaccinations and neurologic injury make it challenging to determine a coincidental or causative relationship (Table 48-4).

TABLE 48-4 ■ Potential Neurologic Complications of Vaccinations that Reached Public Concern

Vaccine and Potential Complication	Evidence
MMR vaccine and autism	Large epidemiologic studies have not found an increased risk of autism associated with MMR vaccine
Thimerosal and autism	Large epidemiologic studies have not found an increased risk of autism or other neurodevelopmental disabilities associated with thimerosal-containing vaccines.
Influenza vaccine and GBS	Increased risk was found with the 1976 swine influenza vaccine. Findings have been mixed with subsequent seasonal influenza vaccines
Influenza vaccine and MS	Epidemiologic studies have not supported the hypothesis that vaccines cause MS
HPV vaccine and autoimmune disorders	Several large population-based studies have not found increased risks of autoimmune or neurologic diseases
Aluminum and autoimmune disorders	No correlation found between infant blood or hair aluminum concentrations and vaccine history

MMR, measles-mumps-rubella; GBS, Guillain–Barré syndrome; MS, multiple sclerosis; HPV, human papillomavirus.

Concerns about vaccine safety can lead to decreased acceptance of vaccines and resurgence of vaccine-preventable diseases. This is often due to the fact that the public often underestimate the risk of naturally acquired infectious diseases and overestimate the risks of vaccines. The CDC recently released data on the greatest measles outbreak in the United States with over 1,200 patients reported in 2019. The majority of cases were among people who were not vaccinated against measles.[20] Given these issues, it is imperative to continue our efforts to increase surveillance of potential adverse events associated with vaccinations, continue to educate our patients on the potential risks of resurgence of certain infections, and continue efforts to deepen our understanding of biologic plausibility between vaccinations and neurologic complications.

IMMUNOSUPPRESSIVE AND IMMUNOMODULATORY TREATMENTS

GENERAL SUPPORTIVE CARE

PROGNOSIS

Sarcoidosis was first described in 1877 by Sir Jonathan Hutchinson as a disease of the skin. At the turn of the century, Caesar Boeck termed the disease *multiple benign sarkoid*, because of its histologic similarity to sarcoma, and from this is derived the modern term *sarcoidosis*. Boeck also demonstrated the unifying pathologic feature of sarcoidosis as epithelioid cell granulomas that could involve different organs. Sarcoidosis is today recognized as a multisystem granulomatous disorder of unknown etiology. Typical presentations include bilateral hilar adenopathy, pulmonary infiltration, and skin and eye lesions.

Neurologic involvement in sarcoidosis was first reported in the early 1900s by Heerfordt, who described patients with cranial nerve palsies. Varied neurologic manifestations of sarcoidosis are now recognized to occur in approximately 5 to 10 percent of patients. Neurosarcoidosis manifests in diverse ways, including with cranial neuropathies, aseptic meningitis, mass lesions, encephalopathy-vasculopathy, seizures, hypothalamic–pituitary disorders, hydrocephalus, myelopathy, peripheral neuropathy, and myopathy. Because its neurologic manifestations are so diverse, its etiology is unknown, and confirmative laboratory tests are lacking, neurosarcoidosis frequently poses a diagnostic challenge. The diagnosis of neurosarcoidosis is usually based on the identification of a characteristic neurologic presentation in an individual with systemic sarcoidosis; however, neurologic manifestations are the presenting feature in approximately 50 to 75 percent of patients with neurosarcoidosis. Optimal management of patients with neurosarcoidosis requires an understanding of the broad clinical spectrum of the disorder, the best methods of confirming the diagnosis, and the full range of treatment options.

SARCOIDOSIS

The 1976 internationally accepted definition of sarcoidosis remains of value today: "sarcoidosis is a multisystem granulomatous disorder of unknown etiology, most commonly affecting young adults and presenting most frequently with bilateral hilar adenopathy, pulmonary infiltration, skin or eye lesions. The diagnosis is established most securely when clinical and radiographic findings are supported by histologic evidence of widespread noncaseating epithelioid-cell granulomas in more than one organ." Sarcoidosis usually presents between the ages of 30 and 55 years but can occur in children as well as in older populations. The highest incidence and prevalence of sarcoidosis have been reported in Nordic European populations and African-Americans.[1] The clinical manifestations of sarcoidosis are similar across populations. Intrathoracic structures are most commonly affected, followed by lymph nodes, skin, and ocular disease. Approximate frequencies of organ manifestations are indicated in Table 49-1, although they vary across reported cohorts. Although a diagnosis of sarcoidosis is most secure when it is based on histologic confirmation, in around 30 percent of patients the diagnosis is based solely on clinical and radiologic findings—frequently in patients presenting with classic Löfgren syndrome (an acute form of sarcoidosis characterized by bilateral hilar lymphadenopathy, erythema nodosum, and polyarthralgia).

TABLE 49-1 ■ Frequency of Organ Involvement in Sarcoidosis

Manifestation	Approximate Frequency (%)
Intrathoracic	89–99
Hilar nodes	50–85
Lung parenchyma	45–55
Upper respiratory tract	5
Skin	16–35
Erythema nodosum	10–14
Ocular	5–60
Parotid gland	4–6
Liver or spleen	5–50*
Peripheral lymphadenopathy	12–60
Bone	3–13
Cardiac	5–40*
Hypercalcemia	10–20
Renal calculi	10–15
Neurologic	5–15
Hematologic, endocrinologic, and luminal gastrointestinal	Rare

*Involvement of these organs is frequently not clinically apparent and is only detected on imaging, biopsy, or autopsy.

Involvement of any organ by sarcoidosis is possible and may occur with or without symptoms. It is estimated that 20 to 40 percent of patients are asymptomatic at presentation, their disease being discovered by routine chest radiography. In fewer than 10 percent of patients, the onset of symptoms is neither systemic nor pulmonary. Neurologic presentations of sarcoidosis fall in this category.

Many laboratory abnormalities have been described in sarcoidosis, but no specific or highly sensitive diagnostic test is available. Active sarcoidosis may cause an elevation in serum angiotensin-converting enzyme (ACE), which can then serve as a marker of systemic disease activity, but serum ACE is nonspecific, and often elevated in patients with other conditions such as liver disease, diabetes mellitus, hyperthyroidism, systemic infection, malignancy, and Gaucher disease.

Most patients with systemic sarcoidosis have a good prognosis. For approximately two-thirds, the disease resolves spontaneously without major difficulties. This benign course is most common in Löfgren syndrome or in asymptomatic patients with only hilar adenopathy on chest radiographs; they have a high chance of spontaneous remission. However, for one-third of patients, symptoms persist or the disease progressively worsens. Pulmonary dysfunction is the major issue for most patients with a persistent or progressive clinical course. Mortality in systemic sarcoidosis is reported as below 5 percent. Deaths are most often due to respiratory failure, although neurologic and cardiac involvement can also be fatal.

The basis of treatment for all forms of sarcoidosis is immunotherapy, most frequently with corticosteroids. However, debate continues as to the precise indications for treatment, because many patients are asymptomatic at the time of presentation and the rate of spontaneous resolution is high. In addition, the clinical presentation and course are so varied that treatment studies—particularly large, well-controlled studies—are lacking. Corticosteroid treatment seems most clearly indicated for patients with significant functional impairment in any organ system, particularly with major pulmonary, cardiac, ocular, or central nervous system (CNS) involvement. Alternative immunosuppressive treatment options are discussed in detail later.

PATHOPHYSIOLOGY

Although the precise etiology of sarcoidosis remains unknown, major strides have been made in understanding its pathogenesis. There is strong evidence that sarcoidosis is caused by heightened immune processes at sites of disease activity. Environment and heredity are both likely to play a role in the etiology of the disorder, with potential complex interactions between environmental triggers and genetic, immunologic, and epigenetic factors.

Current understanding of the immunopathology of sarcoidosis derives largely from studies of pulmonary sarcoidosis. The initial lesion in pulmonary sarcoidosis is an alveolitis, an inflammation of the alveolar structures of the lung (Fig. 49-1). Undoubtedly, processes similar to those in the lung underlie the pathogenesis of other forms of sarcoidosis, including neurosarcoidosis (Fig. 49-2).

The central pathologic hallmark of sarcoidosis, the granuloma, consists of macrophages, macrophage-derived epithelioid cells, and multinucleated giant cells that secrete cytokines (Fig. 49-3). Surrounding this central core are $CD4^+$ and $CD8^+$ T lymphocytes, B lymphocytes, plasma cells, and fibroblasts.

Unfortunately, the inciting antigen or antigens remain unknown. Among the suspected causes have been infectious agents and environmental exposures such as pine pollen and silica. Of the various possible infectious inciting antigens, mycobacterial infections and *Propionibacterium* species have received the most attention. More recently, genetic research has linked several genes (particularly in the HLA region) to disease risk or phenotype.

It is thought that in reaction to an antigen, monocytes and macrophages form granulomas, and ultimately irreversible obliterative fibrosis can develop. Small foci of ischemic necrosis occur, probably as a consequence of in situ thrombosis due to perivascular inflammation. Importantly, granulomas are not specific for sarcoidosis, and nearly identical lesions occur in a variety of other conditions.

The pathology of neurosarcoidosis is characterized by noncaseating granulomas and the accompanying diffuse mononuclear cell infiltrates that can be found in any part of the neuraxis, including peripheral nerve or muscle. The most common site of inflammation is the meninges, especially in the basal region of the brain (Figs. 49-4 and 49-5). Sarcoid granulomas may be widely distributed or concentrated in one or more areas to form a mass lesion. Although sarcoidosis is not usually considered to be a primary vasculitis, arteriolar and venous infiltration can occur and may lead to infarction.[2] The granulomatous inflammation found pathologically may correlate directly with clinical deficits or may be subclinical.

Inflammation affecting primarily the leptomeninges may spread along Virchow–Robin perivascular spaces to invade the brain or spinal cord, or it may remain more localized, involving the cranial nerves. Inflammation can also extend to the cerebrospinal fluid

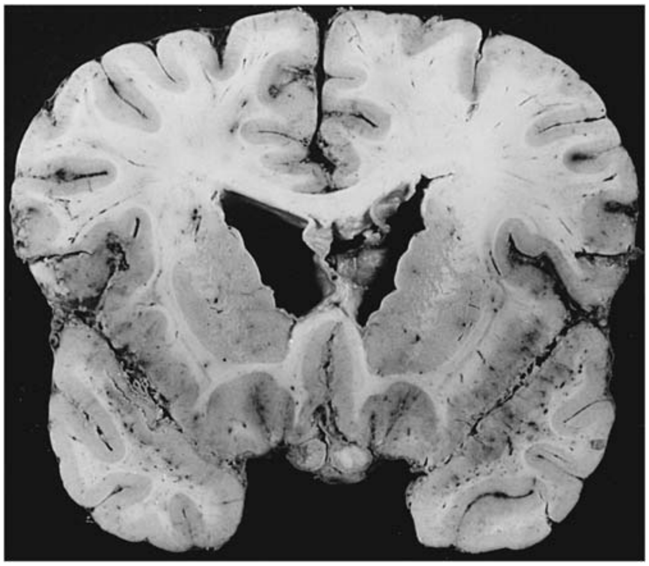

FIGURE 49-5 ■ Coronal midfrontal pathologic section of the brain of a patient with neurosarcoidosis, showing thickening and inflammatory changes of the basal meninges and optic chiasmal region.

(CSF)-containing spaces, leading to hydrocephalus. Brain or spinal cord disease may appear as discrete granulomatous mass lesions or as diffuse parenchymal disease with or without vasculopathy. The hypothalamic region is the most common site of parenchymal disease.

Granulomas can also be found in the epineurium and perineurium of peripheral nerves. The endoneurium may contain a mononuclear cell infiltrate. Perivascular and vascular inflammation may be seen in the epineurial and perineurial vessels. Nerve fibers of all sizes can be affected; a predominantly axonal neuropathy is usual, with only minor segmental demyelination.

Muscle pathology may also occur in sarcoidosis. Muscle biopsy of symptomatic patients reveals typical noncaseating granulomas. More diffuse inflammation can occur, with muscle fiber degeneration along with regeneration and fibrosis. Asymptomatic noncaseating granulomas are found in as many as one-half of all patients with systemic sarcoidosis undergoing muscle biopsy.

EPIDEMIOLOGY

The prevalence of sarcoidosis is estimated to be on the order of 60 per 100,000 population, with an annual incidence of approximately 11 per 100,000 population, although this incidence likely varies regionally and in population subgroups.[1] The exact prevalence and incidence are difficult to validate because of diagnostic challenges. Sarcoidosis can occur at any age, with peak onset between age 30 and 55.[1]

Population differences for sarcoidosis have been well-described. In the United States, incidence is increased in African-Americans compared with Caucasians. The disease also seems to be more severe in African-Americans.[1] Certain areas of the world, such as in Sweden and other Nordic European countries, have a higher incidence of sarcoidosis, whereas it is quite rare in China and Southeast Asia. First-degree relatives of patients with sarcoidosis appear to have a higher risk of the disease, as do monozygotic twins compared to dizygotic twins.[3] Genetic studies using a range of techniques including genome-wide association studies, HLA typing, and fine-mapping have identified multiple genetic variants associated with sarcoidosis risk, potentially accounting for 33 percent of disease heritability.[3] In addition, genetic variants such as HLA subtypes may be associated with disease phenotype.[3] Notably, a significant association with a variant in the *ZNF592* gene has been identified in patients with neurosarcoidosis.[4]

NEUROLOGIC MANIFESTATIONS

Neurologic symptoms are the presenting feature of sarcoidosis in around 50 to 75 percent of individuals with neurosarcoidosis, and in other patients neurologic manifestations often occur a short time after systemic diagnosis (usually less than 2 years).[5] Only rarely do patients with neurosarcoidosis have no evidence of even asymptomatic disease in other organ systems such as the lungs, a condition termed "isolated neurosarcoidosis." The approximate frequency of the various neurologic complications is presented in Table 49-2, although numbers vary across reported cohorts.[5,6] One-third to one-half of patients with neurosarcoidosis will eventually develop more than one neurologic manifestation of their disease.

Cranial Neuropathy

The most frequent neurologic complication of sarcoidosis is cranial neuropathy, occurring in over half of patients with neurosarcoidosis.[5] Any cranial nerve can be involved, but the facial nerve is most commonly affected. Around one-third to one-half of patients will have involvement of multiple cranial nerves.[5]

TABLE 49-2 ■ Complications of Neurosarcoidosis

Clinical Manifestation	Approximate Frequency (%)
Cranial neuropathy	50
Facial palsy	25
Aseptic meningitis	15
Hydrocephalus	10
Parenchymal disease	
Endocrinopathy	10–15
Mass lesion(s)	5–10
Encephalopathy-vasculopathy	5–10
Seizures	10
Myelopathy	15
Radiculopathy/neuropathy	15
Myopathy	10

Olfactory nerve dysfunction may occur secondary to meningeal sarcoidosis involving the subfrontal region. However, anosmia or hyposmia may also result from local nasosinus granulomatous invasion. *Optic nerve* involvement is much less frequent than other ocular manifestations of sarcoidosis such as uveitis, but is reported in around 15 to 20 percent of cases of neurosarcoidosis.[5] Optic neuropathy can present with visual loss that is acute, subacute, or chronic, can be painful or painless, and may be bilateral. The visual loss may be due to bulbar or retrobulbar invasion of the optic nerve by granulomas or extrinsic compression of the optic nerve by a granulomatous mass.[7] Intraocular inflammation such as anterior uveitis may co-occur. Optic disc edema may be secondary to papilledema from sarcoidosis-induced increased intracranial pressure (typically with meningitis) or result from direct local invasion by sarcoid. A chiasmal syndrome also has been reported.

Disorders of ocular motility may follow involvement of the *oculomotor*, *trochlear*, or *abducens nerves*. Typically, these nerves are damaged in their extra-axial course in the subarachnoid space as they traverse the meninges or the cavernous sinus (where mass-like inflammatory lesions can occur).[7] However, they may also be involved in local orbital disease, and rarely the brainstem nuclei themselves and eye movement pathways can be affected. Occasionally, pupillary dysfunction is present. Uncommonly, disordered ocular motility is due to sarcoidosis involving the extraocular muscles directly.

Trigeminal nerve disease may present as facial numbness or, rarely, trigeminal neuralgia. Headache may also represent trigeminal nerve dysfunction intracranially. Involvement of the muscles of mastication is unusual.

Of the cranial nerve syndromes, peripheral *facial nerve* palsy is the most common, and it is also the single most frequent neurologic manifestation of sarcoidosis. It develops in around one-quarter of all patients with neurosarcoidosis.[5] Although the condition is usually unilateral, bilateral facial palsy can occur, presenting with either simultaneous or sequential paralysis. More than half of all patients with facial palsy also have other forms of nervous system involvement. In patients with an isolated facial palsy, the spinal fluid is often normal, but when other manifestations of neurosarcoidosis are present, the CSF is abnormal in 80 percent of patients. The specific cause of facial nerve palsy in sarcoidosis is variable. Rarely, the facial palsy is caused by parotid inflammation. More commonly, the nerve is compromised as it traverses the meninges and subarachnoid space, or facial paresis is due to intra-axial inflammation of the facial nerve motor nucleus. In general, the prognosis for the facial palsy is good, with most patients experiencing recovery of function.

Eighth cranial nerve involvement may affect the auditory or vestibular portions of the nerve. Loss of hearing or vestibular dysfunction may be sudden or insidious and often fluctuates over time. If hearing loss occurs, it is typically of the sensorineural type.[7] As with facial nerve palsy, bilateral eighth nerve disease may occur, and bilateral seventh or eighth nerve dysfunction is suggestive of neurosarcoidosis.

Glossopharyngeal and *vagus nerve* involvement causes dysphagia and dysphonia but is quite uncommon. Hoarseness is more commonly due to laryngeal nerve dysfunction from intrathoracic disease than CNS inflammation involving the vagus nerve.

Eleventh and *twelfth cranial nerve* disease may occur but seems to be rare.

Meningeal Disease

Meningeal disease occurs in approximately 10 to 20 percent of patients with neurosarcoidosis and can present as aseptic meningitis or, less commonly, as a dural-based mass lesion. Aseptic meningitis is characterized by headache, occasional meningismus, and sterile CSF with a mononuclear pleocytosis. Occasionally neutrophils may predominate. Hypoglycorrhachia, or low CSF glucose concentration, is sometimes found, and there is often an elevation of the CSF protein concentration. Oligoclonal bands unique to the CSF may also be present.[6] Postcontrast magnetic resonance imaging (MRI) can delineate the type and extent of meningeal disease, with leptomeningeal involvement being more common than pachymeningeal involvement.[6] Leptomeningitis may have a nodular appearance on postcontrast MRI, and is often focused around the skull base, hypothalamic/pituitary region, and posterior fossa (Fig. 49-6).[6] Pachymeningeal involvement manifests with either mass lesions, or more widespread inflammation. Mass lesions may mimic intracranial tumors such

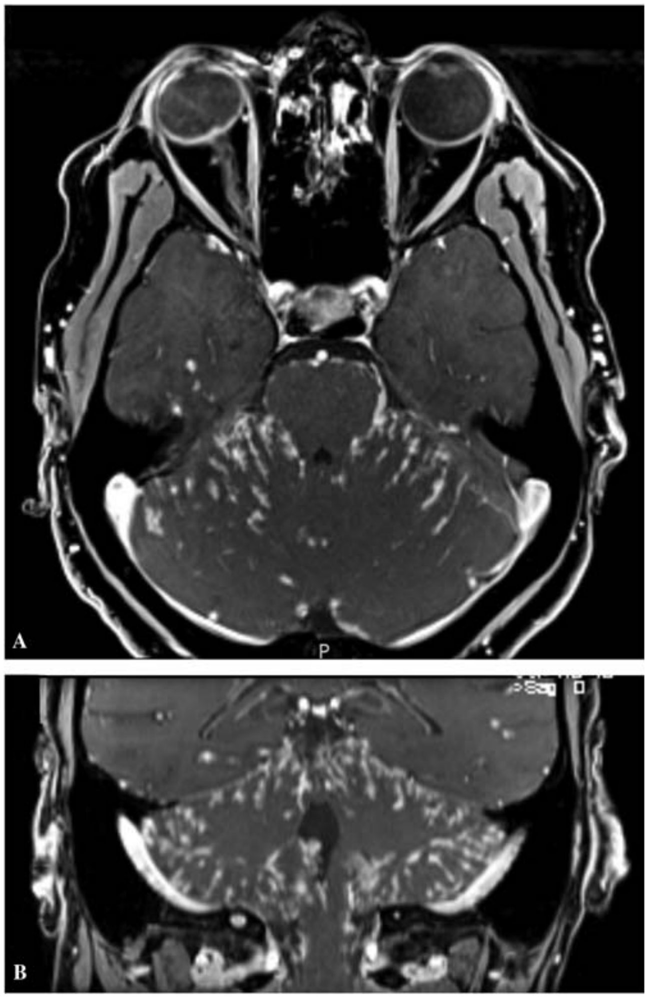

FIGURE 49-6 ■ Cranial MRI. *A*, Axial T1 volumetric interpolated brain examination (VIBE) image with gadolinium. *B*, Coronal T1 VIBE image with gadolinium, showing extensive leptomeningeal enhancement around the cerebellum and infiltrating the fourth ventricle.

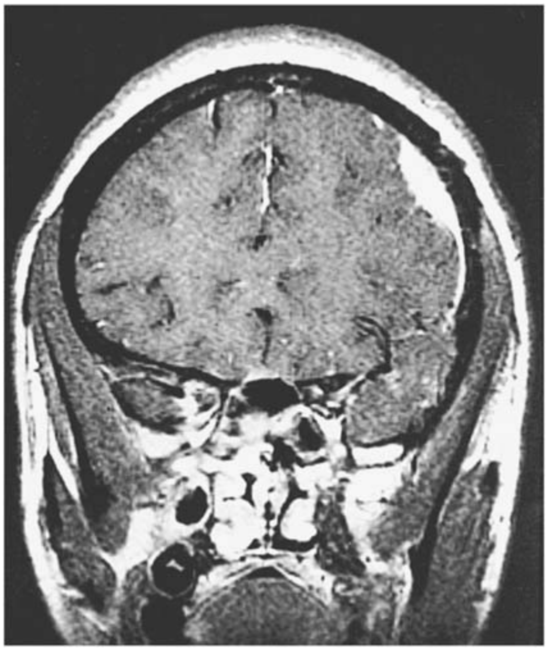

FIGURE 49-7 ▪ Cranial MRI, coronal section, T1-weighted image with gadolinium, demonstrating an enhancing convexity sarcoid mass lesion that was initially mistaken for a meningioma.

as meningiomas (Fig. 49-7), and are often located around basal structures such as the cavernous sinus or orbital apex.[6] It is not uncommon for there to be asymptomatic chronic meningitis within the context of other CNS manifestations of sarcoidosis.

Hydrocephalus

Hydrocephalus is noted in about 10 percent of patients with neurosarcoidosis and may have fatal consequences. Chronic basilar leptomeningitis with obliteration of subarachnoid CSF flow is a major cause of communicating hydrocephalus. In addition, infiltration of the ventricular system by granulomas, granulomatous compression of the aqueduct, or outlet obstruction of the fourth ventricle by granulomas may cause noncommunicating hydrocephalus. Patients with acute hydrocephalus may die suddenly of increased intracranial pressure, and even patients with chronic hydrocephalus have the potential for acute decompensation. Patients with hydrocephalus characteristically present with headache, altered mentation or consciousness, and impaired gait. On examination, papilledema or other signs of raised intracranial pressure may be found. Acute decompensating hydrocephalus is a medical emergency that necessitates prompt diagnosis and treatment. Once clinically suspected, the diagnosis of hydrocephalus is best substantiated with imaging studies, either computerized tomography (CT) or MRI.

Parenchymal Disease

Parenchymal brain disease can present in several forms, and is often associated with overlying meningeal involvement. Hypothalamic dysfunction is the most common manifestation of CNS parenchymal disease.

ENDOCRINE DISORDERS

Any of the neuroendocrinologic systems can be affected by sarcoidosis due to either a hypothalamic or pituitary granulomatous mass or a more diffuse local inflammation. Given the predilection of sarcoidosis for the basal meninges (Fig. 49-8), the relative frequency of such endocrinologic disturbances is not surprising. Anterior pituitary dysfunction is more common than posterior pituitary dysfunction.[8] Potential endocrinologic manifestations include gonadotropin deficiency, TSH deficiency, hyperprolactinemia, and diabetes insipidus.[8] Hypothalamic disorders vary in their effect on vegetative functions. A disorder of thirst is the most common hypothalamic disorder

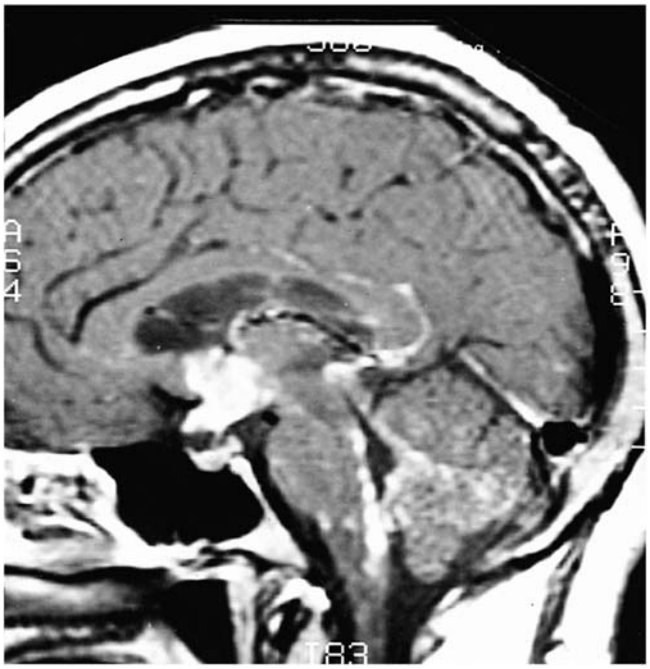

FIGURE 49-8 ▪ Cranial MRI, sagittal section, T1-weighted image with gadolinium, showing hypothalamic and pituitary involvement by sarcoidosis.

related to neurosarcoidosis and is attributed to a change in the hypothalamic osmostat. Less commonly, the syndrome of inappropriate secretion of antidiuretic hormone occurs. Neurosarcoidosis-induced disruptions of hypothalamic–pituitary function can also cause problems with appetite, libido, temperature control, weight regulation, and sleep. Because neuroendocrinologic involvement is relatively common in individuals with CNS sarcoidosis, patients with more than just an isolated facial palsy probably merit a thorough evaluation with specific attention to hypothyroidism, hypocortisolism, hypogonadism, and hyperprolactinemia. Furthermore, in affected patients, contrast-enhanced MRI may identify inflammation of the hypothalamic–pituitary structures or surrounding meninges. Unfortunately, hormonal abnormalities may persist even after effective control of neurosarcoidosis inflammation.[8]

Mass Lesions

An intraparenchymal lesion due to sarcoidosis may present as an isolated mass (Fig. 49-9) in any cerebral area or as multiple cerebral nodules. Such nodules may represent an inflammatory reaction in the Virchow–Robin spaces. Calcifications may be seen, mimicking infection or tumor. Although intraparenchymal mass lesions were historically considered rare in neurosarcoidosis, CT and MRI have shown parenchymal disease to be relatively frequent. The symptoms and signs in individual cases depend on the location of the lesion.

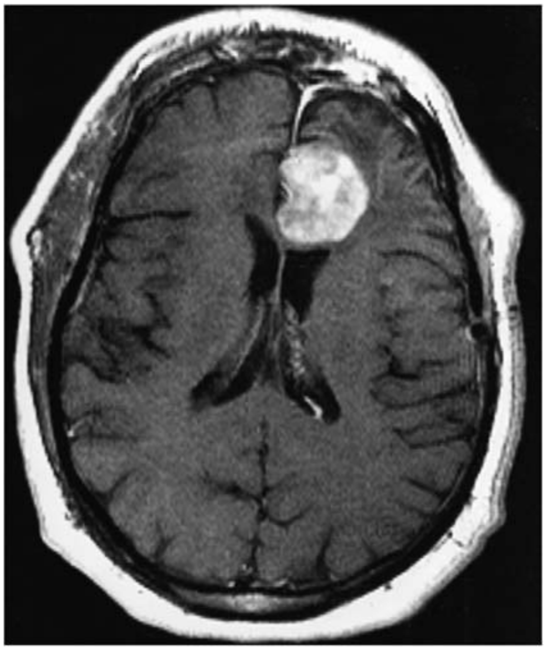

FIGURE 49-9 ■ Cranial MRI, axial section, T1-weighted image with gadolinium, demonstrating a frontal intracerebral mass that was proven by biopsy to be neurosarcoidosis.

Encephalopathy-Vasculopathy and Stroke

The diffuse encephalopathy and vasculopathy associated with neurosarcoidosis are not completely understood. It is often difficult, both clinically and pathologically, to differentiate clearly between these entities and they frequently co-exist. It is best therefore to consider them as a single overlapping entity, while recognizing that, in individual patients, one form or the other may predominate. The clinical presentation of vasculopathy in these patients can also be focal, manifesting with acute stroke.

The diffuse encephalopathy-vasculopathy found in neurosarcoidosis can involve the cerebral hemispheres or the posterior fossa. Patients may experience delirium, personality change, or isolated memory disturbance as a result of focal or diffuse parenchymal inflammation (Fig. 49-10). Clinical findings correlate with the extent of enhancement on imaging studies including hyperintensity on T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI sequences. In these patients,

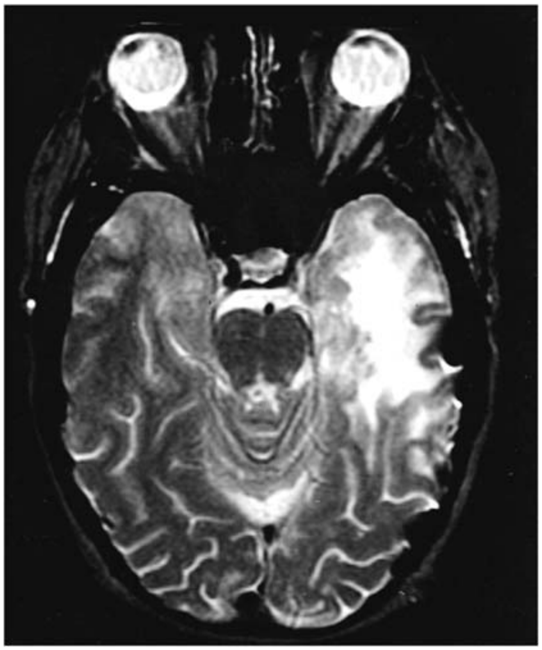

FIGURE 49-10 ■ Cranial MRI, axial section, T2-weighted image, showing a large area of hyperintensity in the temporal lobe that was proven by biopsy to be sarcoidosis manifesting with a focal encephalopathy-vasculopathy.

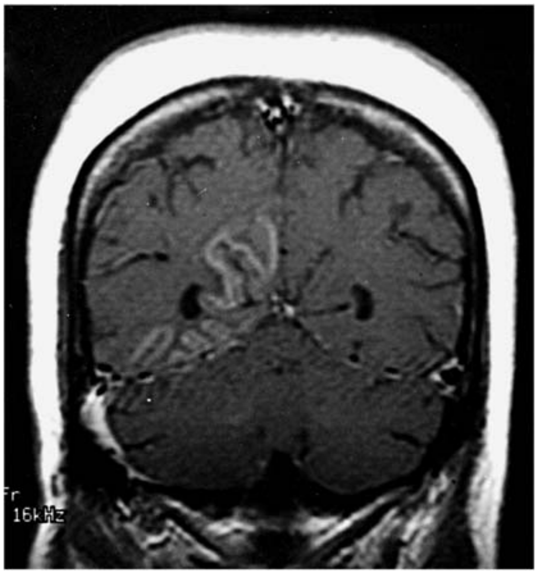

FIGURE 49-11 ■ Cranial MRI, coronal section, T1-weighted image with gadolinium, showing gyral enhancement in the distribution of a posterior cerebral artery branch stroke.

granulomatous inflammation is thought to infiltrate the brain parenchyma via perivascular spaces surrounding small and medium-sized arteries and veins.[9] Granulomas may also extend through the vessel walls, resulting in granulomatous arteritis (Fig. 49-11).

Transient ischemic attacks and ischemic and hemorrhagic stroke due to neurosarcoidosis have all been described. Stroke can occur due to thrombotic occlusion of a vessel secondary to perivascular inflammation, or by extension of granulomas through the vessel wall.[2,9] Ischemic infarcts frequently occur in small or medium-sized vessel territories (sometimes associated with perivascular enhancement seen on MRI), and multiple infarcts in individual patients are common.[2,9] Large-vessel ischemic strokes are more likely to result from compressive perivascular mass lesions, emboli from sarcoidosis-associated cardiomyopathy, or resultant cardiac arrhythmias. Venous infarctions or cerebral venous sinus thrombosis can also occur, and are likely related to phlebitis, which has been identified pathologically and radiologically in neurosarcoidosis. Hemorrhagic stroke may occur from an arterial or venous source, and asymptomatic microhemorrhages can also be seen on MRI.[2] Patients with stroke secondary to neurosarcoidosis are often encephalopathic, likely due to co-existing meningeal enhancement or hydrocephalus.[2,9] Neurosarcoidosis manifesting with stroke may be associated with substantial disability and mortality.[9]

SEIZURES

Seizures may be a manifestation of CNS parenchymal disease due to neurosarcoidosis. They may be focal or generalized and portend a relatively poor prognosis, reflecting the concurrence of severe CNS parenchymal disease or hydrocephalus. Seizures in patients with neurosarcoidosis are relatively easy to control when the underlying CNS inflammatory process is treated effectively.

MYELOPATHY

Spinal cord sarcoidosis may manifest as intramedullary, intradural but extramedullary, or extradural granulomatous masses. Intramedullary spinal cord disease can present with a myelitis that is analogous to the cerebral encephalopathy-vasculopathy described earlier. MRI typically demonstrates a longitudinally extensive spinal cord lesion with dorsal enhancement contiguous with the surface of the cord, sometimes termed “subpial enhancement” (Fig. 49-12).[10] When enhancement is also present in the central canal, the pattern may resemble a trident-head. Intraspinal mass lesions due to sarcoidosis may have a tumefactive appearance on MRI, with associated subpial or leptomeningeal enhancement.[11] In addition, sarcoidosis may present as a radiculopathy, polyradiculopathy, or cauda equina syndrome. Spinal arachnoiditis sometimes occurs. Spinal cord sarcoidosis may appear in late stages as focal spinal cord atrophy.

Peripheral Neuropathy

Large-fiber peripheral neuropathy in neurosarcoidosis may take the form of a chronic sensorimotor, pure motor, or pure sensory polyneuropathy; mononeuritis multiplex; or an acute demyelinating polyneuropathy. The neuropathy usually occurs without CNS involvement. The most common form of large-fiber neuropathy in neurosarcoidosis is a chronic sensorimotor polyneuropathy of axonal type. This condition typically begins months to years following an initial diagnosis, but in some instances, symptoms precede the discovery of systemic disease. The neuropathy is usually mild and classically manifests with distal paresthesias, decreased vibration and proprioception, and reduced ankle reflexes. Large-fiber neuropathy in sarcoidosis has been attributed to epineurial and perineurial granulomas with or without an associated

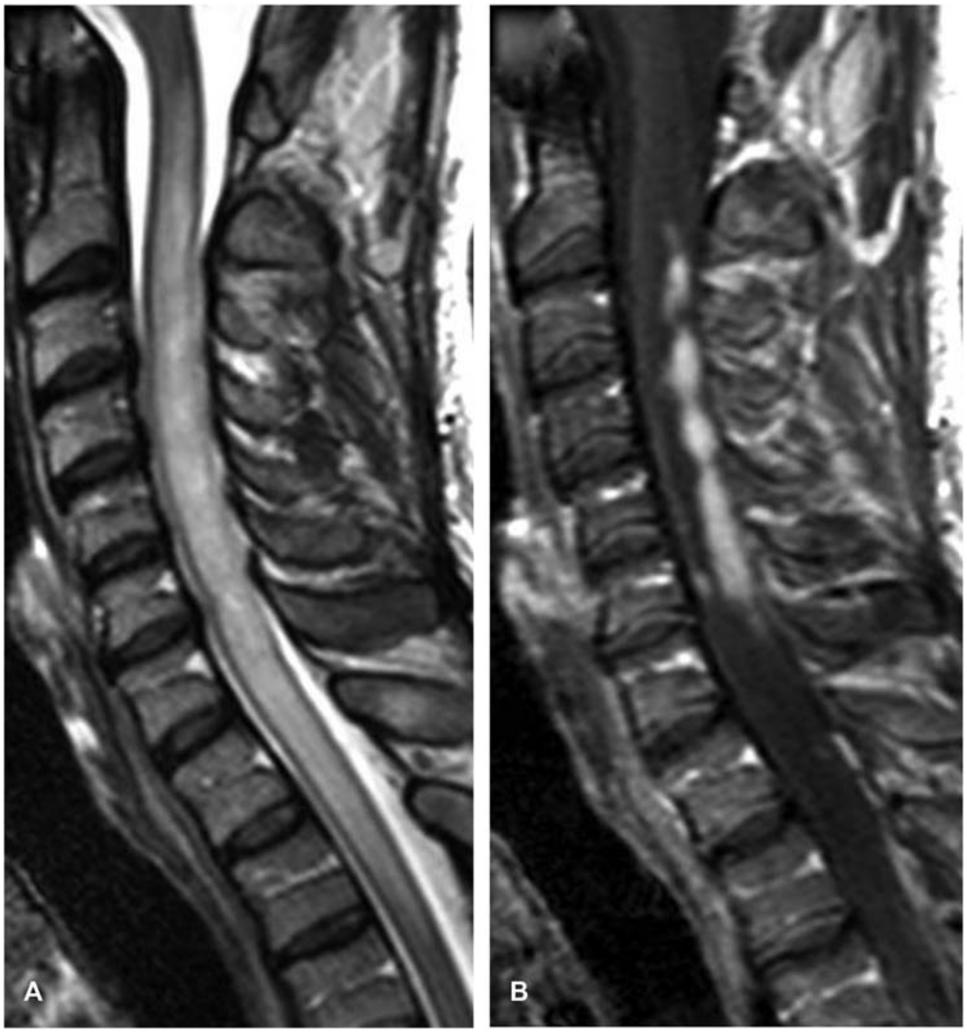

FIGURE 49-12 ■ Spinal MRI. *A*, Sagittal T2. *B*, Sagittal T1 with gadolinium, demonstrating longitudinally extensive myelitis with posterior enhancement due to sarcoidosis.

granulomatous vasculitis, producing axonal degeneration with associated demyelination. Endoneurial granulomas may also occur and are associated with primary segmental demyelination in patients with sensorimotor neuropathy. Nerve damage may be due to granulomatous vasculitis, the compressive effects of granulomas, or the local effects of inflammation.

Sarcoidosis-associated small-fiber sensory neuropathy is actually much more common than large-fiber neuropathy.[12] Small-fiber neuropathy in sarcoidosis manifests with pain and paresthesia, associated with impaired pain and temperature appreciation and variable autonomic dysfunction. However, small-fiber neuropathy occurs in the absence of pathologic evidence of granulomas in the skin or peripheral nerves and is not necessarily associated with other manifestations of neurosarcoidosis—therefore the pathophysiology is unclear. It is possible that the neuropathy is a response to inflammatory mediators, especially tumor necrosis factor alpha (TNF-α). Patients with sarcoidosis may have other risk factors for small-fiber neuropathy, including metabolic syndrome or diabetes mellitus secondary to corticosteroid treatment.[12]

Myopathy

Manifestations of sarcoidosis myopathy, although rare, include acute, subacute, or chronic weakness; fatigue; myalgia; muscle atrophy; and palpable muscle nodules. Severe muscle disease can result in fibrosis and contractures. Sarcoidosis may also manifest with myositis, muscle atrophy, or occasional pseudohypertrophy. Sometimes concomitant neuropathy is detected.

Muscle involvement by noncaseating granulomas can be demonstrated with muscle biopsy and is frequently asymptomatic. Differentiating between sarcoidosis myopathy, polymyositis, dermatomyositis, and inclusion body myositis may be difficult, and it is important to evaluate other organ systems carefully for evidence of sarcoidosis.

DIFFERENTIAL DIAGNOSIS

Diagnostically, two common clinical situations occur with neurosarcoidosis. In the first, a patient without established sarcoidosis has a clinical picture suggestive of neurosarcoidosis; the major goal is then to establish the presence of systemic sarcoidosis. In the second, a patient with already established systemic sarcoidosis develops neurologic symptoms, and it is then necessary to confirm that the neurologic problem is due to neurosarcoidosis rather than another cause.

Presence of Systemic Sarcoidosis

When a patient without documented systemic sarcoidosis develops a clinical syndrome suggestive of neurosarcoidosis, histologic evidence of sarcoidosis should be sought in other organ systems (Table 49-1). Sarcoidosis most frequently affects the intrathoracic structures (87% of patients), followed by lymph node, skin, and ocular involvement. Since corticosteroid therapy may mask signs of systemic disease, treatment should be postponed, if possible, while a search for systemic disease is initiated.

Pulmonary involvement is so common in sarcoidosis that this possibility should be considered first when attempting to establish the presence of systemic sarcoidosis unless there is obvious skin disease or palpable lymphadenopathy. Evidence to support pulmonary involvement can be obtained from chest radiographs or CT scans and pulmonary function testing, including lung diffusion capacity. When these studies suggest pulmonary or intrathoracic lymph node involvement, transbronchial or mediastinal biopsy can be used to confirm the diagnosis.

Other sites of involvement of systemic disease can be considered for biopsy on the basis of clinical assessments including the nasosinus mucosa, conjunctiva, lacrimal glands, liver, and muscle. A thorough ocular examination is indicated to search for uveitis, retinal periphlebitis, or superficial lesions for biopsy. Other ocular findings in sarcoidosis include iritis, retinal lesions (granulomas, vascular occlusions, and chorioretinitis), and optic disc pathology (edema, granulomatous nodules, and atrophy).

Gallium-67 scanning had previously been promoted as a valuable imaging method for the detection of systemic sarcoidosis, but current experience indicates that fluorodeoxyglucose positron emission tomography (PET) scanning is more sensitive for highlighting regions of increased metabolic activity due to sarcoidosis. Although increased activity on PET scans can represent neoplasia or infection as well as granulomatous inflammation, when used in the proper context, PET scanning can be a valuable tool for targeting biopsy. Furthermore, PET scanning may be useful in assessing organ involvement in sarcoidosis and even monitoring therapeutic response.

Various laboratory measures may be abnormal in sarcoidosis including increased serum ACE level; increased serum gamma globulins; hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia; and metabolic derangements such as hypercalcemia, hypercalciuria, and hepatic and renal dysfunction. None is highly specific for sarcoidosis, but the most specific is the serum ACE level. Serum ACE is thought to be produced by alveolar macrophages and epithelioid giant cells and, in effect, reflects the “granulomatous load” of a patient. However, neither serum nor CSF ACE is highly sensitive, with just 50 to 60 percent of patients with active sarcoidosis showing abnormalities, nor very specific, because it is also often elevated in patients with other conditions. Therefore, its utility in the diagnosis or monitoring of sarcoidosis has essentially been superseded by imaging studies in recent years.

Diagnosis of Neurosarcoidosis

Patients with well-documented systemic sarcoidosis who develop neurologic disease merit careful appraisal to exclude causes other than sarcoidosis for their neurologic problem. Neurosarcoidosis can be confused with many other neurologic diseases and, because it is often not possible or judicious to biopsy affected tissue from the nervous system, the diagnosis may need to be made on purely clinical grounds.

Consideration must be given to disease entities that may mimic neurosarcoidosis, particularly infection and neoplasia. Once such disorders have been excluded, treatment for neurosarcoidosis can be instituted. When the response to treatment is disappointing, the diagnosis of neurosarcoidosis should be reviewed and a more extensive evaluation, including nervous system biopsy, contemplated to exclude other causes of symptoms and signs.

Brain imaging studies can be particularly helpful in neurosarcoidosis, and MRI with contrast is the preferred technique. T2-weighted and FLAIR sequences may demonstrate parenchymal disease while postcontrast T1 or FLAIR sequences may demonstrate pachymeningeal or leptomeningeal enhancement (Figs. 49-6 and 49-13), cranial nerve enhancement, or parenchymal enhancement (Figs. 49-8 and 49-9). Enhancement presumably reflects a breakdown of the blood–brain barrier and implies active inflammation; hence, the presence of enhancement is frequently used as a biomarker of treatment response in clinical practice. MR angiography may demonstrate abnormalities in patients with vasculopathy.[9] Spinal MRI in patients with myelopathy may reveal meningeal or intramedullary disease with focal or diffuse enhancement (Fig. 49-12) or atrophy.[10] Enhancing nodules or thickened or matted nerve roots may be appreciated in the cauda equina.

CSF analysis is frequently helpful; most patients with CNS sarcoidosis have some CSF abnormality, and patients with leptomeningeal involvement demonstrate the most marked abnormalities.[6] Reported abnormalities include an elevated CSF pressure, a high protein level, hypoglycorrhachia, elevated albumin CSF/serum quotient, and a usually predominantly mononuclear pleocytosis (occasionally neutrophilic), with up to several hundred cells per mm^3. In addition, some patients have oligoclonal bands in the CSF or an elevated immunoglobulin G index. None of these abnormalities is specific for neurosarcoidosis.

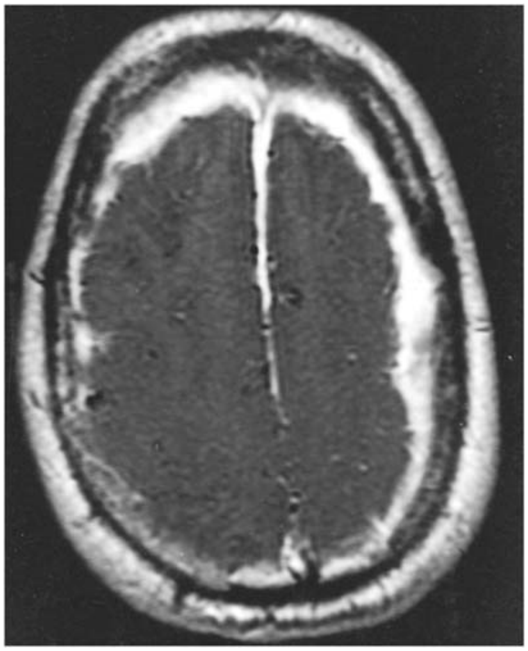

FIGURE 49-13 ■ Cranial MRI, axial view, T1-weighted image, with gadolinium, demonstrating marked dural enhancement due to sarcoidosis.

The CSF level of ACE activity tends to be raised in some patients with CNS sarcoidosis, although abnormalities are also seen in the presence of infection and malignancy. CSF ACE is thought to be produced by CNS granulomas, especially those near the meninges, and historically was used in the diagnostic evaluation of neurosarcoidosis. However, because of limited sensitivity and specificity, assay of CSF ACE activity is no longer recommended.

Visual evoked potentials (VEPs) or optical coherence tomography can reveal abnormalities of the anterior visual pathway in neurosarcoidosis. These studies are often abnormal in patients with symptomatic optic nerve disease and may be abnormal in some patients with CNS sarcoidosis but no clinical evidence of optic nerve dysfunction. Similarly, brainstem auditory evoked potentials (BAEPs) are often abnormal in patients with brainstem or eighth nerve symptoms and may be abnormal in neurologically ill patients without overt disease in these areas. Somatosensory evoked potentials have not been comprehensively studied in the assessment of patients with sarcoidosis; preliminary evidence suggests that their clinical utility is similar to that of VEPs and BAEPs in confirming the involvement of a specific sensory system.

Nerve conduction studies (NCSs) in patients with sarcoidosis-associated large-fiber neuropathy usually reveal changes compatible with an axonal neuropathy, although slowing is sometimes more pronounced and suggestive of demyelination. Electromyography may show denervation in patients with a neuropathy or radiculopathy and may demonstrate myopathic changes in patients with a symptomatic myopathy. Patients with sarcoidosis-associated small-fiber neuropathy typically have normal NCS but may have abnormalities on quantitative sensory (temperature threshold testing) and autonomic testing and a decreased number of small fibers in cutaneous nerves on skin biopsy of the extremities. MRI of muscles in myopathic patients is usually abnormal, sometimes showing a characteristic "star-shaped" pattern of muscle nodules. Muscle or nerve biopsy can be informative and muscle biopsy can be targeted to areas of MRI enhancement.

TABLE 49-3 ■ Diagnostic Criteria for Neurosarcoidosis

Diagnostic Certainty	Description
Possible neurosarcoidosis	1. The clinical presentation and diagnostic evaluation suggest neurosarcoidosis, as defined by the clinical manifestations and MRI, CSF, and/or EMG/NCS findings typical of granulomatous inflammation of the nervous system and after rigorous exclusion of other causes 2. There is no pathologic confirmation of granulomatous disease
Probable neurosarcoidosis	1. The clinical presentation and diagnostic evaluation suggest neurosarcoidosis, as defined by the clinical manifestations and MRI, CSF, and/or EMG/NCS findings typical of granulomatous inflammation of the nervous system after rigorous exclusion of other causes 2. There is pathologic confirmation of systemic granulomatous disease consistent with sarcoidosis
Definite neurosarcoidosis	1. The clinical presentation and diagnostic evaluation suggest neurosarcoidosis, as defined by the clinical manifestations and MRI, CSF, and/or EMG/NCS findings typical of granulomatous inflammation of the nervous system after rigorous exclusion of other causes 2. The nervous system pathology is consistent with neurosarcoidosis Type a. Extraneural sarcoidosis is evident Type b. No extraneural sarcoidosis is evident (isolated CNS sarcoidosis)

MRI, magnetic resonance imaging; CSF, cerebrospinal fluid; EMG/NCS, electromyography/neuroconduction studies.

The diagnosis of sarcoidosis is most secure when it is based on pathology and when more than one organ system is involved. However, since tissue from the nervous system is difficult to secure for pathologic analysis and other tests are not diagnostic of neurosarcoidosis, the diagnosis must sometimes remain tentative despite all efforts. In considering a diagnosis of neurosarcoidosis, it is useful to grade its likelihood. Consensus diagnostic criteria were outlined by the Neurosarcoidosis Consortium Consensus Group in 2018 and are outlined in Table 49-3.[13]

Isolated Neurosarcoidosis

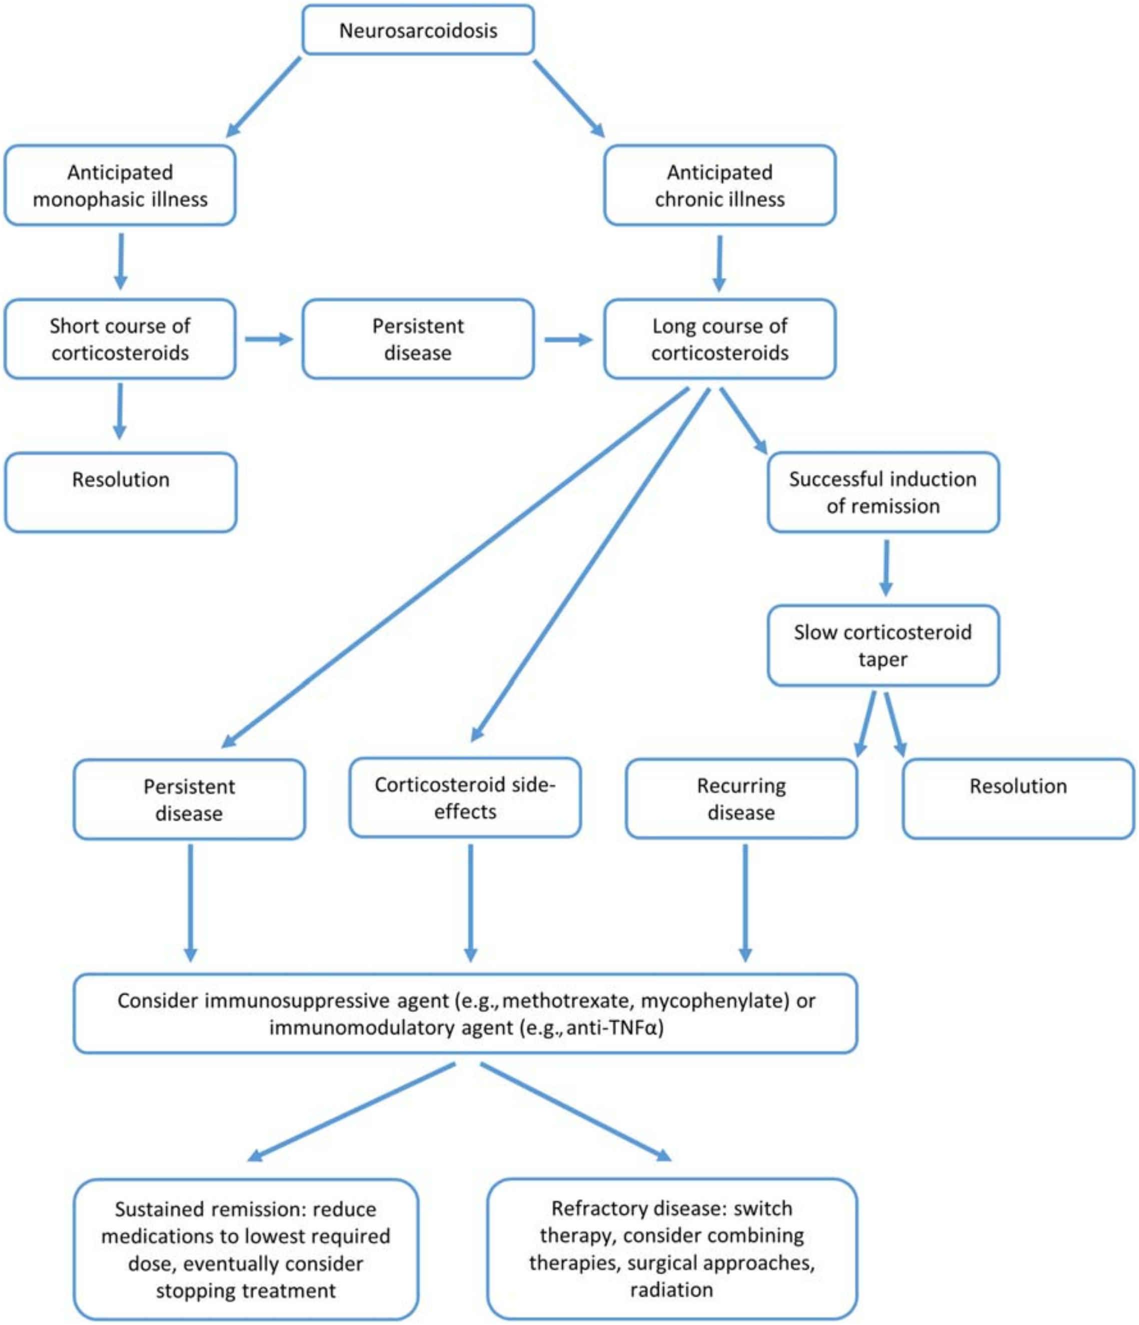
In some patients with a clinical syndrome suggestive of neurosarcoidosis along with supportive neuroimaging, CSF, or electrophysiologic findings, extensive investigation may reveal no evidence of underlying symptomatic or asymptomatic systemic sarcoidosis. This condition is termed "isolated neurosarcoidosis" and may occur in 4 to 10 percent of cases of neurosarcoidosis.[6] Nervous system biopsy in such patients may confirm the presence of granulomatous inflammation. However, in certain cases the risks of nervous system biopsy may be considered too high, for example with involvement of the spinal cord or brainstem structures. In these cases of suspected isolated neurosarcoidosis without biopsy confirmation, empiric treatment may be appropriate with close clinical monitoring and reassessment of the differential diagnosis according to clinical evolution and treatment response.

TREATMENT

No rigorous studies compare the various treatments for neurosarcoidosis. Although corticosteroid therapy is the mainstay of treatment, decisions regarding the optimal therapeutic dose and duration of therapy are made on an individual basis. A suggested treatment paradigm is shown in Fig. 49-14.

Treatment with corticosteroids is widely accepted and recommended for all forms of neurosarcoidosis. Many individual case reports and series provide evidence that it can produce impressive responses and alleviate symptoms, at least on a short-term basis. The theoretical goal of corticosteroid treatment in neurosarcoidosis is to reduce granulomatous inflammation, therefore diminishing the irreversible fibrosis and neuroaxonal damage that can develop, and to minimize tissue ischemia from perivascular inflammation. Corticosteroid treatment is often commenced at relatively high doses and tapered as the inflammatory process recedes. The decision to introduce other immunomodulating or immunosuppressive agents is frequently complex and should be based on individual factors.

Neurosarcoidosis can follow either a monophasic or chronic/recurrent course, and certain manifestations may be more likely to follow a monophasic course, such as isolated cranial neuropathy. Patients with multiple areas of neurologic involvement may be deemed more likely to require medium- to long-term immunotherapy. Parenchymal disease of the brain or spinal cord is often treated more aggressively than nonparenchymal disease due to higher risks of disability accumulation.[14]



Neurosarcoidosis
Anticipated monophasic illness
Anticipated chronic illness
Short course of corticosteroids
Persistent disease
Long course of corticosteroids
Resolution
Successful induction of remission
Slow corticosteroid taper
Persistent disease
Corticosteroid side-effects
Recurring disease
Resolution
Consider immunosuppressive agent (e.g., methotrexate, mycophenylate) or immunomodulatory agent (e.g., anti-TNFα)
Sustained remission: reduce medications to lowest required dose, eventually consider stopping treatment
Refractory disease: switch therapy, consider combining therapies, surgical approaches, radiation

FIGURE 49-14 ■ Treatment paradigm for patients with neurosarcoidosis.

Patient comorbidities such as cancer or obesity may impact therapeutic decision-making. Patients with active systemic sarcoidosis may have other areas of organ involvement influencing therapeutic choices.

Cranial Neuropathy

PERIPHERAL FACIAL PALSY

Facial weakness may improve without any specific treatment, and the long-term prognosis for patients seems favorable. A controlled trial of treatment has not been performed; however, it seems reasonable to give a short course (2 to 4 weeks) of prednisone in patients without other neurosarcoidosis manifestations. For the first week, the recommended dosing is in the range of 0.5 to 1.0 mg/kg daily or 40 to 60 mg daily. This initial dosing is followed by a gradual reduction leading to discontinuation of prednisone over the subsequent weeks. General supportive care including protection from corneal abrasions, as for any patient with a peripheral facial palsy, should be provided.

OTHER CRANIAL NERVE PALSIES

Patients with other cranial neuropathies may be managed with a corticosteroid protocol similar to that for peripheral facial palsy. However, often more than 4 weeks of therapy is needed. In particular, patients with optic neuropathy or dysfunction of the eighth cranial nerve may need more prolonged, aggressive therapy, which may not prevent irreversible nerve damage.

Aseptic Meningitis

Aseptic meningitis is typically initially treated with corticosteroids, often with a short course of high-dose intravenous methylprednisone followed by tapering oral prednisone. When planning the dose and duration of corticosteroid treatment, the chronicity and severity of the clinical manifestations should be considered, as well as the extent of meningeal enhancement seen on MRI. Patients with relatively mild, acute presentations may respond to a short (2- to 4-week) course of prednisone. In patients with chronic symptoms or associated other neurologic manifestations (such as hydrocephalus or cranial nerve palsies), a longer course of corticosteroid treatment with a slow taper over months may be required. In these patients, meningitis may recur during the corticosteroid taper, often prompting consideration of additional therapeutic options such as a corticosteroid-sparing agent. Response to treatment can be assessed by interval evaluations of meningeal enhancement on MRI or CSF pleocytosis in addition to clinical examination. However, the goal of therapy for chronic aseptic meningitis is not necessarily complete clearing of an asymptomatic CSF pleocytosis as attempts to completely normalize the CSF may expose patients to the adverse side effects of corticosteroids or other therapeutic agents without evidence of benefit in patients who are otherwise asymptomatic.

Hydrocephalus

Treatment of hydrocephalus in neurosarcoidosis varies depending on the cause and severity of the hydrocephalus. Mild, symptomatic hydrocephalus associated with meningeal disease may respond to corticosteroid treatment; prolonged therapy is often appropriate. Life-threatening, corticosteroid-resistant or acute obstructive hydrocephalus (e.g., secondary to a granulomatous mass lesion) requires external ventricular drainage or ventricular shunting. Unfortunately, mild hydrocephalus may evolve to severe, life-threatening disease quite rapidly; therefore, patients and care providers should be well educated as to the symptoms of acute progressive hydrocephalus and know to obtain prompt emergency care. High-dose intravenous corticosteroid therapy (methylprednisolone 20 mg/kg per day for 3 days) sometimes stabilizes a patient with life-threatening hydrocephalus, but urgent ventricular drainage is usually necessary. Shunt placement is not without risk in this patient population, which is the reason that prophylactic shunting in asymptomatic patients with hydrocephalus is not advocated. Shunt obstruction is quite common, and placement of a foreign object in the CNS of an immunosuppressed host predisposes to infection. As in all cases of hydrocephalus, a careful neuroimaging assessment should be completed before lumbar puncture is undertaken, to assess whether the procedure is safe.

Parenchymal Disease

Corticosteroid therapy may improve patients with a diffuse encephalopathy-vasculopathy syndrome or CNS mass lesion. Only rarely, however, does immunosuppressive treatment improve neuroendocrine dysfunction.[8]

Corticosteroid treatment of CNS parenchymal disease and other severe neurologic manifestations of sarcoidosis usually starts with prednisone, 1.0 to 1.5 mg/kg daily. Critically ill patients may require high-dose intravenous corticosteroid therapy. A short course of methylprednisolone, 20 mg/kg daily intravenously for 3 days, followed by prednisone, 1.0 to 1.5 mg/kg daily for 2 to 4 weeks, is a typical regimen. Patients with parenchymal disease often require prolonged therapy due to risks of progressive or recurrent disease, and prednisone should thus be tapered slowly, for example, by 5-mg decrements every 2 weeks as the clinical course is monitored.[14] Neurosarcoidosis often worsens at a prednisone dose of 10 mg or less daily.

Once a daily prednisone dose of approximately 10 mg is achieved, the patient should be evaluated for evidence of worsening or recurring disease. Clinical disease can be monitored by symptoms and examination, but surveillance of subclinical disease of the CNS involves neuroimaging. Intense enhancement of the meninges or parenchyma, for example, suggests that neurosarcoidosis is active, and further decreases in the corticosteroid dose may lead to a clinical exacerbation. Other manifestations of neurosarcoidosis can be evaluated for subclinical deterioration on an individualized basis (e.g., by evaluating NCS or serum creatine kinase level), but persistent mild CSF abnormalities are usually not an indication for continuing or escalating corticosteroid therapy. If neurosarcoidosis appears quiescent, a low daily prednisone dose of about 10 mg can be tapered further by 1 mg every 2 to 4 weeks. If a patient has a clinical relapse, the dose of prednisone should be doubled unless the dose is very modest, in which case a prednisone dose of 10 to 20 mg daily can be prescribed; the patient should then be observed for approximately 4 weeks before another taper is contemplated. Patients may require multiple cycles of higher and lower corticosteroid dosing during attempts to taper medications. Since the disease may become quiescent, patients may be needlessly exposed to the harmful side effects of long-term, high-dose corticosteroids if attempts are not made to withdraw medication. Additional treatments such as corticosteroid-sparing agents should be considered in patients with recurrent disease, chronically active disease, or persistently high corticosteroid requirements.

Seizures are generally not a major limiting problem and can usually be well controlled with antiseizure medications if the underlying CNS inflammatory reaction is treated effectively. Seizures are an indication of, or marker for, the presence of parenchymal involvement of the brain.

In patients with a CNS mass lesion that is unresponsive to high-dose corticosteroids, surgical resection may be considered, especially in life-threatening situations.

Peripheral Neuropathy and Myopathy

Patients with large-fiber peripheral neuropathy or myopathy may respond to a several-week course of corticosteroids, usually beginning with oral prednisone, 1 mg/kg per day (or approximately 60 mg/day). Here, too, prolonged treatment may be indicated, and corticosteroids should be tapered slowly, as discussed earlier. As small-fiber neuropathy is not thought to be directly caused by granulomatous inflammation of the nerves, it is unclear whether it should be considered as a target for treatment, or whether treatment in these patients should simply aim to control other manifestations of sarcoidosis. However, symptomatic improvements have been reported in patients with small-fiber neuropathy treated with intravenous immunoglobulins or anti-TNF-α agents, and with ARA290 (an erythropoietin derivative thought to have anti-inflammatory properties).[12] Symptomatic treatment, such as neuropathic pain medications, should also be considered in these patients.

IMMUNOSUPPRESSIVE AND IMMUNOMODULATORY TREATMENTS

Treatment alternatives to corticosteroids are increasingly considered for patients with neurosarcoidosis (Fig. 49-14). Indications for their use include contraindications to corticosteroids as initial therapy, chronic adverse effects of corticosteroids, an anticipated chronic course requiring high doses of corticosteroids, and progressive disease activity despite corticosteroid therapy. In general, exposing patients to high doses of corticosteroids over prolonged periods should be avoided. Medications that have been used as alternatives or adjuncts to corticosteroids include immunosuppressive agents such as mycophenolate mofetil, azathioprine, methotrexate, cyclophosphamide, chlorambucil, cladribine (2-chlorodeoxyadenosine), and monoclonal antibodies such as anti-TNF-α agents. While many of these agents are commonly used in clinical practice, the literature on their use in neurosarcoidosis is limited to case series or retrospective observational studies, rather than randomized-controlled trials.

The addition of other immunotherapy may allow a gradual decrease in corticosteroid dosage to prevent or minimize corticosteroid complications, often without deterioration in the patient's clinical status. However, in patients with a chronic or recurrent disease course, corticosteroids can rarely be eliminated completely, and low doses of corticosteroids may be required long-term to maintain disease control. In a small proportion of patients, neurosarcoidosis may be highly refractory to multiple treatments. The potential adverse effects of the therapy and extent of systemic disease should determine the choice of alternative treatment. It is wise to choose an agent whose adverse effects spare an organ or organ system that may already be compromised. In general, the side effects of these medications are limited, predictable, and respond to withdrawal of the offending agent. It may even be possible to restart the medication in some cases, without recurrent side effects.

Because TNF-α is implicated in the pathogenesis of granulomatous inflammation, TNF-α antagonists such as infliximab and biosimilar agents have been used with success for refractory neurosarcoidosis, with accruing evidence for the utility of these agents.[15] With retrospective studies suggesting favorable outcomes in patients treated with TNF-α antagonists, these medications are increasingly being employed in the initial treatment of neurosarcoidosis in conjunction with corticosteroids and mycophenolate or methotrexate to treat severe CNS disease. Rituximab, a monoclonal antibody directed against B cells, has also been beneficial in some case reports.

Another option for some patients with refractory CNS sarcoidosis is radiation therapy. The small number of reported patients treated in this manner precludes definitive conclusions about efficacy. Some case reports suggest a beneficial response, especially if total nodal and craniospinal irradiation is performed. A total dose of 19.5 Gy with daily fractionation of 1.5 Gy has been suggested. It appears that although radiation therapy is sometimes of benefit, continued immunosuppressive therapy is usually necessary.

Although it is not possible to predict with absolute certainty which patients with neurosarcoidosis will have disease refractory to conventional corticosteroid treatment, certain patients may have a particularly high-risk clinical profile. Patients with an optic neuropathy or CNS parenchymal disease (e.g., mass lesions, extensive encephalopathy-vasculopathy, or myelopathy) are at especially high risk. Such patients might benefit from the prompt use of adjunctive alternative treatments or if they either become refractory to corticosteroids or develop intolerable side effects. If a patient is stable for several months on low-dose prednisone and an alternative treatment, slow tapering of one of the drugs can be considered.

GENERAL SUPPORTIVE CARE

Patients with neurosarcoidosis, particularly those receiving treatment with potent immunosuppressive agents, require close attention to their general medical well-being, including monitoring for potential adverse effects of treatment. Formal, prescribed exercise and dietary advice may help patients avoid the weight gain and deconditioning associated with corticosteroid treatment. Rehabilitation services should be utilized as appropriate. Depression is not uncommon, and treatment is often helpful. Fatigue and cognitive symptoms are also common. Sleep disorders, especially sleep apnea, should be considered as a cause of fatigue or cognitive decline.

Therapy for endocrinologic disturbances is important. In particular, hypothyroidism, especially hypothalamic hypothyroidism, and hypogonadism are major problems in neurosarcoidosis that often require therapy. Patients receiving protracted, low-dose corticosteroid regimens may require supplemental doses of corticosteroids during periods of intercurrent illness or stress. Diabetes mellitus is a potential side effect of long-term, high-dose corticosteroid treatment but usually is not associated with ketoacidosis. Exercise and dietary programs are useful in managing hyperglycemia, but oral hypoglycemic agents or insulin therapy may be needed.

Patients with sarcoidosis are at risk for osteoporosis, especially from corticosteroid therapy. The treatment of osteoporosis in this context is a challenge because sarcoidosis may cause hypercalcemia and hypercalciuria. Management requires reduction of corticosteroid dosage when possible, cautious use of supplements of calcium and vitamin D, hormonal treatment, and use of other bone-building agents. Screening and serial measurements of bone density may be useful.

Patients with refractory neurosarcoidosis are at risk from both the sarcoidosis-associated inflammatory process and the complications of various therapies. If a patient is not doing well, not only should the original diagnosis of sarcoidosis be questioned, but the patient should also be evaluated for additional complications such as infection and malignancy.

PROGNOSIS

The clinical course and prognosis of neurosarcoidosis vary, but are somewhat predictable. One-third to two-thirds of patients will have a monophasic neurologic illness, and the remainder will have a chronically progressive or recurring course. Those with a monophasic illness typically have an isolated cranial neuropathy, most often involving the facial nerve, or an episode of aseptic meningitis. Those with a chronic course usually present with CNS parenchymal disease, hydrocephalus, multiple cranial neuropathies (especially involving the optic or vestibulocochlear nerve), peripheral neuropathy, or myopathy. Patients with CNS parenchymal disease or hydrocephalus are at highest risk of death, from either the inflammatory process itself or complications of therapy. Historically, mortality with neurosarcoidosis has been reported as approximately 5 to 10 percent, but more recent experience with new advances in treatment suggest that the mortality is in the lower range of that estimate.[5]

Because most patients with neurosarcoidosis are treated with immunosuppressive agents, it is impossible to determine the natural history of the untreated disorder. There is a lack of data demonstrating how treatment impacts the long-term profile of the disease, however it is thought that reducing inflammation-induced neuroaxonal or vasculopathic damage probably improves outcomes similar to other neuroinflammatory and neuroimmune disorders such as multiple sclerosis or autoimmune encephalitis. Even in severely ill or impaired patients, the inflammatory process may spontaneously subside over time, but other patients with recurrent or progressive disease can become severely incapacitated even with aggressive treatment.

In monitoring the response to treatment, a target measure, such as a specific clinical sign, symptom, functional assessment, or neurodiagnostic test, should be defined. For instance, a timed walk can be used for clinical assessment in some patients with gait disturbance from myelopathy or myopathy; in patients with meningeal or parenchymal disease, contrast-enhanced MRI is a helpful measure. This type of focused approach can be used to judge a response over a relatively short period of time.

The systemic inflammatory disorders discussed in this chapter can manifest with diverse neurologic syndromes due to central, peripheral, and autonomic nervous system involvement. These presentations can be in isolation or coincident, sequential or simultaneous. Patients can also develop neurologic syndromes secondary to the treatment of systemic inflammatory disease. Here, we discuss the connective tissue disorders and vasculitides that commonly have neurologic manifestations as well as differential diagnostic considerations.

CONNECTIVE TISSUE DISEASES

Systemic Lupus Erythematosus

SYSTEMIC DISEASE

Systemic lupus erythematosus (SLE) is a common systemic autoimmune disease with up to 150 cases per 100,000 population worldwide. SLE can manifest with a wide spectrum of systemic and neurologic findings and symptoms, each with varying severity. The 10-year mortality rate of SLE is about 30 percent. Proposed

diagnostic criteria have undergone multiple revisions to improve sensitivity and specificity. In 2019, the European League Against Rheumatism and the American College of Rheumatology (EULAR/ACJR) jointly released updated, validated classification criteria for SLE, incorporating weighted criteria (Table 50-1).[1] In the

TABLE 50-1 ■ 2019 European League Against Rheumatism and the American College of Rheumatology (EULAR/ACJR) Classification Criteria for Systemic Lupus Erythematosus (SLE)

Domain	Item	Definition	Weighted Points
Entry criterion	Positive ANA	$>$1:80 by Hep-2 Immunofluorescence	Mandatory
Constitutional	Fever	Temperature $\geq$38.3°C	2
Hematologic	Leukopenia	White blood cell count $<$4,000/mm^3	3
	Thrombocytopenia	Platelet count $<$100,000/mm^3	4
	Autoimmune hemolysis	Evidence of hemolysis (e.g., reticulocytosis) AND positive Coombs test	4
Neuropsychiatric	Delirium	(1) Change in consciousness or level of arousal with reduced ability to focus; (2) symptom development over hours to $<$2 days; (3) syndrome fluctuation throughout the day; and either (4a) acute/subacute change in cognition or (4b) change in behavior, mood, or affect	2
	Psychosis	(1) Delusions and/or hallucinations without insight; (2) absence of delirium	3
	Seizure	Primary general or focal seizure	5
Mucocutaneous	Alopecia		2
	Oral ulcers		2
	SCLE/DLE	Subacute cutaneous lupus erythematosus (SCLE): annular or papulosquamous cutaneous eruption which is usually photodistributed; skin biopsy with typical changes of perivascular lymphohistiocytic infiltrate often with dermal mucin noted. Discoid lupus erythematosus (DLE): erythematous-violaceous cutaneous lesions with secondary changes of atrophic scarring, dyspigmentation, often follicular hyperkeratosis/plugging leading to scarring alopecia on scalp; skin biopsy with typical changes of perivascular and/or periappendageal lymphohistiocytic infiltrate; follicular keratin plugs may be seen in scalp as well as mucin deposition	4
	ACLE	Acute cutaneous lupus (ACLE): malar rash or generalized maculopapular rash; skin biopsy with interface vacuolar dermatitis evidenced by perivascular lymphohistiocytic infiltrate, often with dermal mucin; may have perivascular neutrophilic infiltrate early in course	6
Serosal	Effusion	Imaging (e.g., ultrasound, x-ray, CT, MRI) evidence of pleural or pericardial effusion, or both	5
	Acute pericarditis	$\geq$2 of (1) pericardial chest pain, (2) pericardial rub, (3) EKG with new widespread ST elevation or PR depression, (4) new or worsened pericardial effusion on imaging	6
Musculoskeletal	Joint involvement	Either (1) synovitis involving $\geq$2 joints characterized by swelling or effusion OR (2) tenderness in $\geq$2 joints and $\geq$30 min of morning stiffness	6
Renal	Proteinuria	$>$0.5 g/24 h by 24-h urine or equivalent spot urine protein-to-creatinine ratio	4
	Class II/V	On renal biopsy according to International Society of Nephrology/Renal Pathology Society 2003 classification. II: Mesangial proliferative lupus nephritis; V: Membranous lupus nephritis	8
	Class III/IV	On renal biopsy according to International Society of Nephrology/Renal Pathology Society 2003 classification. III: Focal lupus nephritis; IV: Diffuse lupus nephritis	10
Complements	C3 or C4 low	C3 or C4 below the lower limit of normal	3
	C3 and C4 low	Both C3 and C4 below the lower limits of normal	4
SLE-specific antibodies	Anti-Sm	Anti-Sm antibodies	6
	Anti-dsDNA	Anti-dsDNA antibodies in immunoassay with demonstrated $\geq$90% specificity for SLE against relevant disease controls	6

EKG, electrocardiogram; MRI, magnetic resonance imaging; Anti-Sm, anti-Smith; Anti-dsDNA, anti–double stranded DNA.
Positive ANA is a mandatory criterion; score of $\geq$10 weight points on additive criteria have 96.1% sensitivity and 93.4% specificity for SLE. (Adapted from Aringer M, Costenbader K, Daikh D, et al: European League Against Rheumatism/American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus. Arthritis Rheumatol 71:1400, 2019.)

validation cohort, these criteria had a sensitivity of 96 percent and specificity of 93 percent for SLE, an improvement over previous classification schemes. Care should be exercised in applying such criteria clinically, particularly for those seronegative for antinuclear antibodies (ANAs).[1]

Patients with SLE present with systemic symptoms including fever, fatigue, and malaise. The most strongly suggestive findings are acute cutaneous (e.g., malar rash or generalized maculopapular rash), musculoskeletal (e.g., synovitis, joint tenderness, and morning stiffness), cardiac (e.g., acute pericarditis), and renal (e.g., nephritis; Table 50-1). Other systemic manifestations include hematologic (e.g., autoimmune hemolytic anemia, leukopenia, thrombocytopenia), neuropsychiatric (e.g., delirium, psychosis, seizure), and serosal. Inflammation can be evident in many tissues and organs, involving not only the heart and kidneys, but also the eyes, lungs, and gastrointestinal tract, among others.[1]

As a systemic autoimmune disease, SLE is characterized by the detection of a variety of autoantibodies. The detection of ANAs at a ratio of at least 1:80 are a mandatory criterion; the threshold is in place since approximately 10 percent of the general population are seropositive at low titers. A minority of SLE patients are seronegative for ANA. Low-level ANA seropositivity has been observed in other inflammatory diseases including connective tissue disorders described later in this chapter such as rheumatoid arthritis, Sjögren syndrome, and systemic sclerosis as well as neurologic diseases such as multiple sclerosis. Other, more specific autoantibodies can be detected in patients with SLE, including anti-Smith (anti-Sm) and antidouble-stranded DNA (anti-dsDNA), which are included in the 2019 EULR/ACR criteria.[1] More than 200 different autoantibodies have been described in SLE, although only a handful are routinely used in clinical practice. Some of these antibodies can occur in subclinical SLE or be predictive very early in the disease course [e.g., anti-Ro60/SSA, anti-Sm, anti-dsDNA, antinuclear ribonucleoprotein (anti-RNP), anti-histone, antiscleroderma 70 kDa antigen (anti-Scl70)], whereas others are pathogenic (e.g., ds-DNA). Of note, some of these antibodies are also detected in other connective tissue disorders (e.g., anti-Ro60/SSA and anti-La/SSB in Sjögren syndrome).

Antiphospholipid antibodies, most commonly those directed to anticardiolipin, are frequently detected in patients with SLE. These antibodies prolong the partial thromboplastin time for patients with SLE and are paradoxically associated with thrombosis more than hemorrhage. Care should be exercised in using anticardiolipin antibodies for diagnostic purposes as they can be detected in those without SLE or other autoimmune diseases, may be detectable only transiently, may be detected in the setting of other systemic illnesses, and may be found in the healthy general population. While 10 percent of healthy blood donors are seropositive for antiphospholipid antibodies, only 1 percent remain seropositive on follow-up testing at 1 year.[2]

Patients with SLE who are seropositive for antiphospholipid antibodies are more likely to develop stroke as well as other neurologic syndromes such as headache, chorea, and myelitis. These patients also are more likely to develop mild cognitive impairment compared to SLE patients who are seronegative for the antibodies. The development of ischemic stroke may be the consequence of the antiphospholipid antibody syndrome, which is characterized by clinical episodes of thrombosis (e.g., deep venous thrombosis, pulmonary embolism, nonbacterial endocarditis, ischemic stroke) or morbid events of pregnancy (e.g., miscarriages typically after 10 weeks gestation, fetal death, pre-eclampsia, eclampsia), especially in the setting of persistence of moderate or high levels of anticardiolipin antibodies. When evaluating patients for concern for antiphospholipid antibody syndrome, additional clinical events or findings should be considered, including a history of arthralgias, livedo reticularis, cardiac valve disease, hemolytic anemia, thrombocytopenia, pulmonary hypertension, acute or chronic renal vascular lesions, and Reynaud phenomenon.[2]

Along with these autoantibodies, complement protein levels are incorporated in the recent clinical criteria, and they play a role in monitoring disease activity. Patients with SLE commonly have levels of complement components C3 and C4 below normal limits, and complement protein levels are particularly low during inflammatory flares.[1] The lowering of circulating levels of these complement proteins is suggestive of immune-complex deposition.

NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

Neuropsychiatric systemic lupus erythematosus (NPSLE) refers to the syndromes of the central, peripheral, and autonomic nervous system as well as the psychiatric syndromes that have been observed in patients with SLE, excluding those syndromes attributable to other causes (Table 50-2).[3] These syndromes can present at any point in the course of SLE, including prior to other systemic manifestations and in those in clinical remission. The reported prevalence of NPSLE and respective syndromes varies widely by study, with estimated prevalence of over 50 percent.[4]

TABLE 50-2 ■ Neuropsychiatric Syndromes in Systemic Lupus Erythematosus

Syndromes	Estimated Prevalence (%)
Central Nervous System Syndromes	
Headache	28.3
Mood disorder	20.7
Cognitive dysfunction	19.7
Seizure	9.9
Cerebrovascular disease	8.0
Anxiety disorder	6.4
Psychosis	4.6
Acute confusional state	3.4
Aseptic meningitis, myelopathy, movement disorder, demyelinating syndromes	Rarely reported, unable to estimate
Peripheral Nervous System Syndromes	
Polyneuropathy	2.3
Cranial neuropathy	2.2
Mononeuropathy (single or multiple)	0.9
Myasthenia gravis, acute inflammatory demyelinating polyradiculopathy (AIDP), autonomic disorder, plexopathy	Rarely reported, unable to estimate

Syndromes as per American College of Rheumatology Ad Hoc Committee on Neuropsychiatric Lupus Syndromes, organized by neurologic category and pooled prevalence from meta-analysis of 17 studies reporting on a total of 5,507 patients with systemic lupus erythematosus.[3,4]

The central neurologic manifestations of NPSLE are widely varied in terms of presentation, severity, mechanisms, and treatment. Seizure, psychosis, and delirium feature in the 2019 EULR/ACR criteria; however, these capture only some of the neurologic syndromes SLE patients may develop as a consequence of SLE and its treatment. Headache, seizure, cognitive dysfunction, and cerebrovascular disease are common central nervous system (CNS) syndromes (Table 50-2).[4]

Headache, in the form of migraine and tension headaches, can occur in patients with SLE; however, it is not clear that these occur more commonly than in the general population. Patients with SLE can develop a new headache syndrome secondary to another etiology, such as posterior reversible encephalopathy syndrome (PRES) in the setting of severe hypertension and some immunosuppressive agents, infection in the setting of chronic immunosuppression, and stroke in the setting of SLE itself.

A minority of patients with SLE have a seizure at some point during the course of their illness, either accompanying one-time events such as metabolic derangements, drug toxicity, or PRES, or in the form of recurrent seizures in the setting of focal brain injury such as stroke.

Cognitive dysfunction is common among patients with SLE, affecting up to one-third of patients. Patients with SLE are nearly three times as likely as healthy individuals to develop cognitive impairment. Such dysfunction is typically mild and rarely severe. Concomitant neuropsychiatric conditions such as mood disorders and stroke can contribute to cognitive dysfunction in SLE.

Psychosis and delirium can develop in patients with SLE from a variety of etiologies, including direct parenchymal inflammation as well as secondary to other systemic processes such as hypertensive encephalopathy and PRES, metabolic derangements, and drug toxicity. Medications commonly used in the acute and chronic treatment of SLE are associated with encephalopathy (e.g., corticosteroid encephalopathy and psychosis), PRES (e.g., cyclosporine, tacrolimus), and opportunistic infections.

An estimated 8 percent of patients with SLE have cerebrovascular disease.[4] Patients with SLE are at increased risk for both ischemic and hemorrhagic stroke, with mechanisms including emboli and thrombosis (usually as a manifestation of antiphospholipid syndrome), atherosclerotic disease, and rarely secondary CNS vasculitis. Given this increased risk, patients with SLE should be treated to address common stroke risk factors for primary stroke prevention. In the event of a stroke, patients should not only undergo brain imaging as part of a secondary stroke prevention assessment, but also a thorough evaluation for vascular stenoses of the head and neck, cardiac evaluation for a cardioembolic source, and evaluation for the presence of antiphospholipid antibodies to characterize risk and individualize treatment.

Other CNS syndromes such as chorea, myelopathy, and aseptic meningitis rarely occur among patients with SLE. Chorea may be unilateral or bilateral, develop slowly at any point through the course of SLE, and resolve spontaneously. Patients often have increased levels of antiphospholipid antibodies. Patients with acute myelopathy as a manifestation of SLE typically present with a syndrome characterized by flaccid, hyporeflexic paraplegia and urinary retention, accompanied by nausea, vomiting, and evidence of active systemic lupus (Fig. 50-1). Their prognosis is poor for neurologic recovery. Patients may also develop a subacute spastic hyperreflexic paraparesis over the course

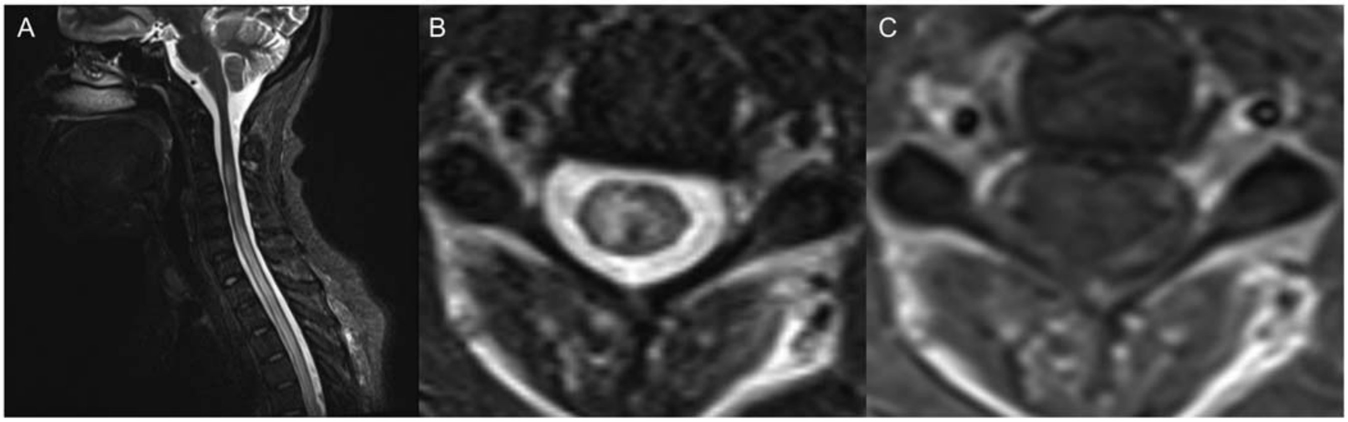

FIGURE 50-1 ■ A patient with systemic lupus erythematosus, seronegative for the aquaporin-4 antibody, presenting with a longitudinally extensive myelitis in the setting of hypocomplementemia. *A*, Magnetic resonance imaging (MRI) of the cervical spine, sagittal STIR sequence, demonstrating patchy T2 hyperintensities beginning at the level of C2–C3 and extending throughout the thoracic cord to the conus (not shown). *B*, Axial T2 sequence demonstrating hyperintensity of the right greater than left gray matter. *C*, Axial T1 postgadolinium imaging did not demonstrate associated enhancement.

of days, typically in the absence of fever or other signs of systemic lupus, which may have a relapsing, remitting course. Patients who present with episodes of myelopathy and optic neuropathy may have a neuromyelitis optica (NMO) spectrum disorder, a minority of whom are aquaporin-4 antibody seropositive.

PERIPHERAL NERVOUS SYSTEM DISEASE

The peripheral nervous system is frequently affected in a variety of connective tissue disorders, including SLE. A minority of SLE patients have evidence of peripheral neuropathies; however, many of these are due to other systemic or noninflammatory causes, such as diabetes or carpal tunnel syndrome, and are therefore not directly attributable to SLE. Sensory predominant or sensorimotor axonal polyneuropathies are the most common manifestations of a symptomatic inflammatory neuropathy due to SLE, affecting 2 to 8 percent of patients (Table 50-2).[4] Mononeuropathy and cranial neuropathy (most commonly of the facial nerve) are rare, while mononeuritis multiplex, acute inflammatory demyelinating polyradiculopathy, and chronic inflammatory polyneuropathy are even rarer (Table 50-2).[4] SLE patients may occasionally develop autonomic neuropathy, sometimes independent of sensory neuropathy, with impairment of sweating, cardiovascular reflexes, and gastrointestinal mobility. Polyneuropathy due to SLE is usually mild, rarely necessitates nerve biopsy, and does not require directed aggressive immunosuppression in addition to the treatment a patient with SLE is already receiving.

TREATMENT

There are a variety of treatments for SLE, with selection guided by the severity of the disease and its impact on affected organs. Aspirin was the first drug approved by the U.S. Food and Drug Administration (FDA) for treatment of SLE, followed by corticosteroids, and later the antimalarial drug hydroxychloroquine. In 2011, belimumab, a monoclonal antibody that blocks the B-lymphocyte stimulator protein, was the first medication specifically approved by the FDA for treatment of SLE. Immunosuppressive medications including cyclophosphamide, methotrexate, azathioprine, and mycophenolate mofetil are also commonly used in the treatment of SLE, particularly in the setting of severe renal or visceral disease.

Symptom-directed therapies play an important role in the treatment of SLE. Just as arthralgias may be treated with nonsteroidal anti-inflammatory drugs, many of the neurologic manifestations of SLE can be managed directly, including headache and mood disorders. Behavioral and cognitive therapy approaches also play an important role in addressing associated cognitive dysfunction.

In addition to symptomatic treatment, syndrome specific treatment is also appropriate in those with neurologic manifestations of SLE. Those with NPSLE presenting with psychosis may be managed with antipsychotic medications as well as steroids (assuming corticosteroid-induced psychosis has been excluded). Catatonia has also been observed in NPSLE and is typically treated with benzodiazepines and rarely with electroconvulsive therapy, in addition to immunosuppressive therapies. Intravenous immunoglobulin (IVIg) and plasmapheresis are mainstays of treating SLE-associated acute inflammatory demyelinating polyradiculopathy. Corticosteroids, plasmapheresis, and immunosuppressive medications such as cyclophosphamide are important considerations for the acute treatment of SLE patients presenting with optic neuritis, focal white matter lesions, and myelitis.

Primary stroke prevention strategies should be employed for patients given the prevalence of stroke among those with SLE. Warfarin is a consideration for those with cardioembolic strokes and the antiphospholipid antibody syndrome, but otherwise antiplatelet medications are the focus of secondary prevention in SLE.

Sjögren Syndrome

SYSTEMIC DISEASE

Sjögren syndrome is another common systemic autoimmune disease, affecting over 1 million American adults. It affects females more than males, with a peak incidence in midlife. It is characterized by an exocrinopathy, commonly manifesting with xerostomia and xerophthalmia, fatigue, and arthralgias, symptoms which are present in over 80 percent of patients. It may be primary, occurring in isolation or along with organ-specific autoimmune diseases such as thyroiditis or primary biliary cirrhosis or secondarily in association with other systemic autoimmune diseases (e.g., SLE, rheumatoid arthritis).[5]

In 2016, the ACR/EULAR jointly released validated classification criteria for Sjögren syndrome. The classification criteria are based on the weighted sums of five items, applied to those patients who have ocular or oral symptoms of dryness or have suspicion for Sjögren syndrome based on one of the domains of the EULAR Sjögren Syndrome Disease Activity Index (Table 50-3). Those patients who have a total score of at least four meet the criteria for Sjögren syndrome. Although designed for purposes of classification, these ACR/EULAR criteria may be useful clinically in the context of common symptoms.[6]

Sjögren syndrome most commonly presents with symptoms of oral and ocular dryness as well as fatigue, symptoms which in and of themselves are common within the general population and may be related to other syndromes including fibromyalgia, medication side effects, aging, and the use of contact lenses. Other constitutional symptoms such as myalgias, weight loss, and fever are reported commonly. Importantly, approximately 30 to 40 percent of patients may present with other systemic manifestations due to involvement of the exocrine glands of not only the eyes and mouth, but also of the skin, lungs, and vagina. Lymphocytic infiltration of epithelia of the kidneys, gall bladder, and lungs may lead to interstitial nephritis, primary biliary cholangitis, and obstructive bronchiolitis, respectively. B-lymphocyte hyperactivity may cause immune complex deposition, resulting in manifestations such as palpable purpura, glomerulonephritis, and interstitial pneumonitis. Thyroid syndromes (thyroiditis, hypothyroidism), gastrointestinal syndromes (atrophic gastritis), and liver disease (biliary cirrhosis) along with organomegaly (spleen and liver) and lymphadenopathy may be observed.[5]

TABLE 50-3 ■ 2016 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) Classification Criteria for Primary Sjögren Syndrome

Domain	Item	Definition	Weighted Points
Serologic assays	Anti-SSA (Ro)	Anti-SSA (Ro) antibody seropositivity	3
Oral tests	Labial salivary gland (LSG) biopsy	LSG biopsy with evidence of focal lymphocytic sialadenitis and focus score ≥ 1	3
	Unstimulated whole saliva (UWS) flow rate	UWS flow rate <0.1 mL/min	1
Ocular tests	Ocular staining score (OSS) or van Bijsterveld score (VBS)	OSS ≥ 5 or VBS ≥ 4 on at least one eye	1
	Schirmer test	Wetting of test strip of <5 mm/5 min by at least one eye	1

Oral and/or ocular symptoms or suspicion for Sjögren syndrome based on domains of the EULAR Disease Activity Index (ESSDAI) are preliminary requirements for application of these classification criteria; score of >4 weighted points on classification criteria with excellent sensitivity and specificity for primary Sjögren syndrome.[6]
Anti-SSA, anti-Sjögren-syndrome-related antigen A.

The pathogenesis of Sjögren syndrome is uncertain. Current models of disease implicate the activation of mucosal epithelial cells, potentially by viruses, leading to an innate and an adaptive immune response, complete with secretion of autoantibodies.[5] These autoantibodies contribute to the formation of immune complexes, leading to immune system activation against, and resultant damage to, affected tissues.[5] In support of this hypothesis, patients with Sjögren syndrome commonly have evidence of systemic autoimmunity, including ANA and anti-SSA/Ro and anti-SSB/La antibodies. The anti-SSA/Ro antibodies are the most specific for Sjögren syndrome.[5,6] Anti-SSB/La seropositivity in the absence of anti-SSA/Ro seropositivity is not specific and thus does not feature in the recent ACR/EULAR criteria.[6] Both anti-SSA/Ro and anti-SSB/La may be detected in patients with other autoimmune diseases, such as SLE. Antibodies not typically seen in Sjögren syndrome can be helpful in distinguishing it from other syndromes, such as anti-dsDNA antibodies, which are included in the classification criteria for SLE.[1] Tissue biopsy and measures of exocrine function are recommended for establishing the diagnosis of Sjögren syndrome.[5]

Providers should be mindful that patients with Sjögren syndrome have an approximate 10 percent lifetime risk for B-cell lymphoma attributed to chronic B-cell activation. These malignancies are primarily B-cell non-Hodgkin lymphomas, often developing in the organs where Sjögren syndrome is primarily active, such as the salivary glands. Thus, it is recommended that every 1 to 2 years, lymphocyte counts and protein electrophoresis along with biomarkers associated with development of lymphoma, namely rheumatoid factor, complement proteins C3 and C4, and cryoglobulins, are assessed.[5]

CENTRAL NERVOUS SYSTEM DISEASE

Approximately 2 percent of patients with Sjögren syndrome develop CNS syndromes. However, this figure is likely an underestimate as many symptoms, such as headache and cognitive dysfunction, may be mild or nonspecific. The most common focal CNS findings in Sjögren syndrome are lesions of the spinal cord. Patients may develop a myelopathy, with various presentations in terms of tempo (rapid vs. slowly evolving), extent of involvement (local vs. more generalized), and presentation (complete transverse myelopathy or Brown-Séquard syndrome). Importantly, as in the case of SLE, Sjögren syndrome patients may also present with longitudinally extensive myelopathies as part of NMO spectrum disorder, often in the setting of aquaporin-4 antibody seropositivity.

In addition to myelopathy, patients with Sjögren syndrome may have demyelinating lesions of the brain parenchyma and optic nerves, with associated clinical syndromes. These may have a relapsing-remitting course, placing Sjögren syndrome as a differential consideration in evaluating patients for possible multiple sclerosis. These radiographic findings are often consistent with those described in NMO, with patients frequently being seropositive for aquaporin 4 antibodies, arguing for their testing in patients presenting with lesions of the CNS.

Syndromes associated with the gray matter, such as seizures, and meningitis are less common. Patients may develop focal brain lesions with associated mononuclear infiltrates of the cerebrovascular system (venous and less commonly arterial) and typically microscopic infarcts of the surrounding brain tissue. Meningeal vessels are also often involved. Patients may present with an aseptic meningitis, with CSF analyses demonstrating a mild mononuclear pleocytosis and elevated protein level. There is rarely detection of unique intrathecal oligoclonal bands or increased immunoglobulin G synthesis relative to the serum in patients with Sjögren syndrome.

PERIPHERAL NERVOUS SYSTEM DISEASE

Peripheral nervous system disease is more common than CNS disease in Sjögren syndrome. Many patients develop neuropathy prior to the diagnosis of Sjögren syndrome, with sicca symptoms preceding or following neuropathic symptoms with equal frequency. The most common of these peripheral nervous system syndromes are sensory neuronopathy and small-fiber neuropathy. Patients less commonly develop trigeminal neuropathy, multiple mononeuropathies, multiple cranial neuropathies, polyradiculoneuropathies, and autonomic neuropathies.

Sensory neuronopathy accounts for nearly 40 percent of all Sjögren syndrome associated neuropathies. It is typically subacute in onset and tempo (occurring over the course of weeks to months) and characterized by multifocal, asymmetric dysfunction of both large and small sensory fibers, manifesting as impaired sensation to proprioception, vibration, temperature, and painful stimuli. Patients may present with pseudoathetosis, as well as symptoms of burning pain, hyperesthesia, and allodynia. Strength usually is preserved but reflexes are diffusely absent. On nerve conduction studies, most patients have absent or low-amplitude sensory nerve action potentials and somatosensory evoked potentials.

MRI of the spinal cord may demonstrate hyperintense signal within the dorsal columns. Important differential considerations for a patient presenting with sensory neuronopathy include other autoimmune syndromes such as SLE, medication or other toxicities (e.g., pyridoxine, cisplatin), infections [e.g., with human immunodeficiency virus (HIV) or varicella zoster virus], hereditary syndromes, and paraneoplastic neuronopathy (e.g., anti-Hu paraneoplastic subacute sensory neuronopathy in the setting of small cell lung cancer). Despite an exhaustive evaluation, half of cases of sensory neuronopathy are idiopathic.[7]

The clinical presentation of a Sjögren syndrome patient with a distal sensory polyneuropathy is typically with a chronic, painful, distal axonal neuropathy involving both small and large sensory fibers. Less commonly, patients present with evidence of distal motor fiber involvement. Autonomic symptoms also are often reported. Nerve biopsy typically demonstrates nonspecific axonal loss, though of variable degree. An idiopathic axonal neuropathy can occur in patients who meet diagnostic criteria for Sjögren syndrome. Conversely, an idiopathic axonal neuropathy, even in the setting of history of dry eyes or mouth, without other objective findings supportive of Sjögren syndrome, does not predict later manifestations of Sjögren syndrome. The key to diagnosis is subsequent serologic testing, ocular and salivary function evaluation, and pathologic tissue review to establish the diagnosis.[7]

Patients presenting with trigeminal neuralgia may present with either unilateral or bilateral numbness or paresthesia restricted to the trigeminal distribution without associated motor symptoms. The syndrome is typically indolent in progression and occasionally accompanied by sensory disturbances in the extremities. Patients may also present with autonomic symptoms including pupillary abnormalities, orthostatic hypotension, and hypohidrosis. Trigeminal involvement can be confirmed by blink reflex testing.[7]

In addition to trigeminal neuralgia, patients may present with other or multiple cranial neuropathies. Patients may present with bilateral nerve involvement including facial diplegia, involvement initially localizable to cranial structures (e.g., oculomotor and trochlear nerve involvement suggesting localization to the cavernous sinus rather than the cranial nerves themselves), and multiple cranial neuropathies which may be misinterpreted as evidence of a meningitis. Involvement of the limbs and trunk is not commonly observed in these syndromes.[7]

Patients may also present with a predominant and severe autonomic neuropathy, with associated symptoms and findings including Adie pupils, orthostatic hypotension, syncope, hypohidrosis or anhidrosis, constipation, and diarrhea.[7]

TREATMENT

Treatment of Sjögren syndrome is directed by the organs involved and the severity of involvement. For oral and ocular dryness, muscarinic agonists such as pilocarpine have shown benefit in randomized clinical trials. Topical cyclosporine eye-drops result in better tear production in comparison to placebo. Otherwise, dry eyes are treated with artificial tears. Regular dental examinations and good oral hygiene are crucial in reducing the risks for dental caries and periodontal disease. For pain management, randomized data are lacking and clinical experience suggests the use of first-line analgesics such as acetaminophen for generalized pain and nonsteroidal anti-inflammatory medications for joint pain. Neuropathic pain is typically treated with serotonin-norepinephrine reuptake inhibitors (e.g., duloxetine, venlafaxine), and antiepileptics (e.g., gabapentin or pregabalin) with use of tricyclic antidepressants typically limited by the associated side effect of mouth dryness.[5]

No systemic immunomodulatory therapies have been proven efficacious in Sjögren syndrome. In general, extraglandular involvement is treated with systemic immunosuppressive therapies. Commonly used medications are similar to those used for SLE, including azathioprine, cyclosporine, hydroxychloroquine, methotrexate, mycophenolate mofetil, and prednisone. Randomized, controlled trials of the biologic infliximab and etanercept have not demonstrated significant improvement in terms of joint pain, fatigue, and dryness. Small studies of rituximab have yielded mixed results, suggesting its potential utility in the treatment of some systemic manifestations of Sjögren syndrome.[5]

There are no specific treatments for some neurologic accompanying syndromes such as mild cognitive impairment, trigeminal neuropathy, and distal sensory neuropathy. Patients with CNS syndromes including transverse myelitis are typically treated with intravenous corticosteroids as first-line treatment, with plasmapheresis and cyclophosphamide used in refractory cases. Rituximab is indicated for the prevention of subsequent relapses in NMO spectrum disorders. Patients with sensorimotor neuropathy, sensory neuropathy, and small-fiber neuropathy may respond better to IVIg that those with sensory neuronopathy.[7] Patients with mononeuropathies and cranial neuropathies are typically treated with systemic corticosteroids.[7] Accompanying vasculitis or evidence of cryoglobulinemia may predict a response to rituximab. It is advised that treatment plans for neurologic manifestations of Sjögren syndrome be formulated in concert with the patient's rheumatologist.

Systemic Sclerosis

SYSTEMIC DISEASE

Systemic sclerosis (scleroderma) is a multisystem disease characterized by extensive fibrosis, small-vessel vasculopathy, and autoantibody production. Its affects up to 30 persons per 100,000 population, with women more commonly affected than men. Systemic sclerosis varies in presentation and prognosis, with recognized subsets including patients with limited cutaneous systemic sclerosis, diffuse cutaneous systemic sclerosis, and systemic sclerosis without skin involvement.[8] The majority of patients have skin thickening accompanied by involvement of internal organs, most commonly within the limited and diffuse cutaneous subsets. Limited cutaneous systemic sclerosis is mainly restricted to the hands, arms, and face, with Reynaud phenomenon present years before fibrosis is evident; it is typically accompanied by pulmonary hypertension. In contrast, diffuse systemic sclerosis is rapidly progressive, affecting large areas of skin and at least one internal organ. Patients may present with subcutaneous calcinosis, Raynaud phenomenon, esophageal dysfunction (often manifesting as dysphagia), sclerodactyly, and telangiectasia (i.e., CREST syndrome). While some patients may only have CREST, others may have systemic sclerosis manifesting with additional symptoms of pulmonary fibrosis, hypothyroidism, sicca syndrome, renal or cardiac involvement (particularly hypertension), arthralgias, and tenosynovitis. Of note, patients with systemic sclerosis may present with evidence of other concomitant autoimmune syndromes such as SLE, Sjögren syndrome, and rheumatoid arthritis.

The majority of patients have serologic evidence of autoimmunity, including an elevated ANA and antibodies directed against other antigens including centromeres, topoisomerase (Scl-70), RNA-polymerases (to anti-RNA polymerase II), and ribonuclear proteins (U1-RNP and U3-RNP) among other antigens.

In 2013, the ACR/EULAR classification criteria for systemic sclerosis were proposed. Patients may be classified as having systemic scleroderma if there is evidence of skin thickening proximal to the metacarpophalangeal joints. If not present, seven additional items can be used for classification, each of varied weights (Table 50-4). A score of at least 9 on these criteria is associated with good sensitivity and specificity for the diagnosis of systemic sclerosis. It is important to note that these criteria were developed for patient inclusion in studies of systemic sclerosis. These criteria are not applicable to those with finger-sparing skin thickening or a scleroderma-like disorder which may better explain their clinical findings.[8]

CENTRAL NERVOUS SYSTEM DISEASE

CNS involvement in systemic sclerosis is relatively uncommon and it is debatable whether associated neurologic syndromes are the direct result of neurologic injury due to the disease or sequelae of renal, cardiovascular, or pulmonary involvement. Descriptions are largely limited to case reports and series. The most commonly reported CNS syndromes are headache, seizures, and cognitive impairment. Stroke, transverse myelitis, and visual disturbances are described less commonly. Incidental radiographic findings have been reported, most commonly white matter lesions and irregular intracranial vessels, although it is unclear whether these finding represent true pathogenic associations.[9]

PERIPHERAL NERVOUS SYSTEM DISEASE

Peripheral nervous system disease is more common than CNS disease among patients with systemic sclerosis; however, it is difficult to attribute pathogenesis of these syndromes directly to systemic sclerosis. Of the reported peripheral syndromes, myopathy, trigeminal neuropathy, peripheral sensorimotor polyneuropathy, and carpal tunnel syndrome are the most common. Other mononeuropathies and cranial neuropathies have also been described.[9]

Autonomic dysfunction has similarly been reported, typically parasympathetic underactivity and sympathetic overdrive, with prevalence varying across reported case series. At times, autonomic dysfunction can develop prior to evidence of organ fibrosis. The most commonly reported findings include abnormalities of heart rate and blood pressure variability. Gastrointestinal symptoms, esophageal dysfunction, and motility disorders are correlated with autonomic involvement.[9]

TABLE 50-4 ■ 2013 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) Classification Criteria for Systemic Sclerosis (Scleroderma)

Domain	Item	Definition	Weighted Points
Skin and digit findings	Skin thickening of fingers of both hands (Sufficient criterion)	Extending proximal to metacarpophalangeal joints	9
	Skin thickening of fingers (only counting the highest score)	Sclerodactyly of the fingers	4
		Puffy fingers	2
	Fingertip lesions (only counting the highest score)	Fingertip pitting scars	3
		Fingertip ulcers	2
	Telangiectasia		2
	Abnormal nail fold capillaries		2
	Reynaud phenomenon		3
Pulmonary findings (max. 2 points)	Pulmonary arterial hypertensions	Pulmonary arterial hypertension	2
	and/or Interstitial lung disease	Interstitial lung disease	2
Serologic assays (max. 3 points)	Anticentromere		1
	Antitopoisomerase I		1
	Anti-RNA polymerase III		1

Designed for purposes of study inclusion, apply care in clinical application. These criteria are not applicable to those patients with skin thickening sparing the fingers nor to those with a scleroderma-like disorder which better explains their manifestations. The total score is determined by adding the maximum weight score in each item category. A score of >9 weighted points on classification criteria has good sensitivity and specificity for systemic sclerosis.[8]

TREATMENT

Treatment of systemic sclerosis centers on the management of related organ complications. Data on the treatment of neurologic syndromes in patients with systemic sclerosis are limited to case reports and series, with therapy largely focused on the neurologic disorder (e.g., antiepileptic medications for seizures, surgery for entrapment neuropathies). Many disorders are not treated specifically, such as mild neuropathies.

Rheumatoid Arthritis

SYSTEMIC DISEASE

Rheumatoid arthritis (RA) is multisystem disorder characterized by chronic destructive synovitis. It is the most common rheumatologic disease in adults, affecting over 1 million Americans, with increasing prevalence among those older than 65 years. The pathogenesis of rheumatoid arthritis is uncertain, although it is characterized by activation of endothelial cells leading to synovial membrane infiltration by B and T lymphocytes and monocytes, as well as neovascularization. The consequent expanded synovial membrane ("pannus") invades periarticular bone, leading to bony erosions and cartilage degradation. A variety of molecules have been identified which mediate the signs and symptoms of RA as well as the degradation of bone and cartilage; these molecules have emerged as targets of therapy, including tumor necrosis factor and interleukin-6. The majority of patients with RA have positive autoimmune serologies, most commonly rheumatoid factor which itself is nonspecific and detectable in a small percentage of the normal population. Anticitrullinated protein antibodies are more specific for the diagnosis of rheumatoid arthritis.

Early in the disease course, RA may manifest with involvement of only one or a few joints. Tenosynovitis may also develop at the same time or even earlier. Over time, patients develop the characteristic symmetric, polyarticular disease. Patients typically present with pain and synovitis of the joints of the hands and feet, accompanied by morning joint stiffness of at least 30 minutes to hours. If insufficiently treated, patients may develop extra-articular disease. Extra-articular disease occurs in over half of patients, manifesting as subcutaneous rheumatoid nodules (most common), sicca syndrome, Felty syndrome (RA, neutropenia, and hypersplenism), amyloidosis, scleritis or episcleritis, lung or heart involvement, anemia of chronic disease, eosinophilia, thrombocytosis, and rarely systemic vasculitis. RA vasculitis is necrotizing, involving small or medium-sized arteries, typically of the skin but occasionally of other organs, including those of the nervous system. Thus, patients with RA are at risk for other comorbidities due to chronic inflammation. Cardiovascular disease is common and the primary cause of death in RA; it is associated with RA disease activity. Patients may also develop interstitial lung disease, either as a manifestation of RA or as a complication of its treatment.

In 2010, the ACR and EULAR revised the 1987 ACR classification criteria to address concerns for sensitivity in the setting of early disease. The new criteria require the confirmed presence of synovitis in at least one joint, the absence of an alternative diagnosis for the synovitis, and a score of at least 6 of a possible 10 points across four domains: number and site of joints involved, serologies, evidence of an acute-phase response, and symptom duration (Table 50-5).[10]

Central Nervous System Disease

Syndromes involving the CNS are less frequent than those of the peripheral nervous system. The CNS manifestations can be nonfocal such as headache or focal including optic neuropathy and compressive myelopathy. Patients rarely develop focal cerebral disease. In chronic RA, stroke due to rheumatoid vasculitis is rare, as are meningitis and meningoencephalitis.

Cervical spine disease is a common late complication of RA and includes bony erosions and pannus compression, as well as atlanto-axial, subaxial, and vertical subluxation. In the setting of chronic inflammation, inflamed ligaments become lax and allow for subluxation, which is typically anterior but can occur in all directions. The subluxation is usually asymptomatic; however, risk for cord compression increases with increased subluxation. Over time, patients may develop progressive signs of compressive myelopathy such as quadriparesis, spasticity, and sphincter dysfunction that may evolve slowly or worsen suddenly. Patients with vertical atlanto-axial subluxation can develop signs not only of cervical myelopathy but also brainstem compression, including ophthalmoparesis, nystagmus, trigeminal or high cervical sensory loss, bulbar palsy, hydrocephalus, sleep apnea, and drop attacks. Rarely, patients with neck subluxation present with vertebral artery stroke.

Symptomatic management of atlanto-axial subluxation can entail cervical collars to decrease neck pain or headache, as well as halo devices and cervical traction for neck stabilization. Patients with compressive myelopathy with and without brainstem compression should undergo surgical stabilization as they are at risk for subluxation progression and further neurologic morbidity. Surgical stabilization does not tend to improve existing neurologic deficits, but rather halts their progression.

Patients with RA may develop neuropsychiatric syndromes including depression, anxiety, and cognitive impairment. When evaluating a patient with RA presenting with such syndromes, corticosteroid encephalopathy and associated mood disturbance is an important differential consideration in addition to infectious sequelae of chronic immunosuppression.

Rarely, patients may develop rheumatoid meningitis or meningoencephalitis. Clinical presentations vary, with nonspecific symptomatology including headache and cognitive dysfunction as well as focal neurologic deficits and seizures. MRI with gadolinium may demonstrate thickening and enhancement of the pachymeninges and leptomeninges as well as rheumatoid nodules that may be mistaken for malignancy. Cerebrospinal fluid analyses may be normal or demonstrate a monocytic pleocytosis with elevated protein. Given concern for malignancy as well as opportunistic infection in the setting of chronic immunosuppression, brain and meningeal biopsy may be pursued and demonstrates mononuclear cell infiltrates, necrosis, and occasionally granulomas. In addition, patients may develop a meningitis or meningoencephalitis in the setting of tumor necrosis factor-α inhibitor treatment itself. They may also develop normal-pressure hydrocephalus as a consequence of chronic meningeal inflammation.

Just as patients with RA are at increased risk for cardiovascular disease, they are similarly at risk for cerebrovascular disease. RA-associated cardiovascular syndromes, including congestive heart failure and valvular disease, place patients at increased risk of stroke, warranting careful primary stroke prevention evaluation. Rheumatoid vasculitis involving the cerebral arteries occurs rarely, but can manifest as stroke and stroke-like syndromes.[11]

Peripheral Nervous System Disease

Patients with RA may develop various compressive mononeuropathies, including at the ulnar groove, carpal tunnel, and tarsal tunnel. Patients may also develop neuropathies of the digits or of the fibular or posterior

TABLE 50-5 ■ 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis (RA)

Domain	Item	Definition	Score
Entry criterion	At least 1 joint with synovitis that is not better explained by another disease	Synovitis refers to swelling	
Joint involvement	1 large joint	"Large joints" includes shoulders, elbows, hips, knees	0
	2–10 large joints	Defined as per above	1
	1–3 small joints	"Small joints" include metacarpophalangeal, proximal interphalangeal, second through fifth metatarsophalangeal, thumb interphalangeal, and wrists; with or without large joint involvement	2
	4–10 small joints	Defined as per above; with or without large joint involvement	3
	>10 joints	Must include at least one small joint, all other joints may be any combination of large and small joints as defined above as well as other joints (e.g., temporomandibular, acromioclavicular, sternoclavicular)	5
Serologies (at least 1 test result is needed for classification)	Negative RF *and* negative ACPA	RF refers to rheumatoid factor; ACPA refers to anticitrullinated protein antibody; International Unit (IU) values are less than or equal to upper limited of normal (ULN) for respective laboratory or assay	0
	Low-positive RF *or* low-positive ACPA	Low-positive is defined as higher than ULN but ≤3 times the ULN for the respective laboratory or assay	2
	High-positive RF *or* high-positive ACPA	High-positive is defined as >3 times the ULN for the respective laboratory or assay	3
Acute-phase reactants (at least 1 test result is needed for classification)	Normal C-reactive protein (CRP) *and* normal erythrocyte sedimentation rate (ESR)	Normal as per local laboratory standards	0
	Abnormal CRP *or* abnormal ESR	CRP and ESR defined as per above; abnormal as per local laboratory standards	1
Duration of symptoms	<6 weeks	Duration of symptoms of less than 6 weeks per patient self-reported synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at time of assessment regardless of treatment status	0
	≥6 weeks	6 weeks or more of patient self-reported duration of symptoms in joints that are clinically involved at time of assessment regardless of treatment status	1

Classification criteria were developed for newly presenting patients, but are applicable to those patients with erosive disease typical of RA and a compatible history as well as those with longstanding disease. Criteria should be applied to those patients with at least one joint with definite clinical synovitis (swelling), with the synovitis not better explained by another disease (e.g., SLE, psoriatic arthritis, gout). Classification of definite RA is achieved with a total score of 6 or greater (of a possible 10) weighted points from individual scores in the four domains.[10]

tibial nerves. These mononeuropathies may be the result of compression by subcutaneous rheumatoid nodules, severe joint disease, a popliteal Baker cyst, or from synovial inflammation and thickening. The most common neurologic manifestation of RA is carpal tunnel syndrome. Successful treatment of RA together with carpal tunnel surgery (occasionally with tenosynovectomy) may improve carpal tunnel syndrome symptoms. Treatment of mononeuropathy is otherwise focused on management of RA and associated inflammation.

A length-dependent symmetric sensorimotor neuropathy is a potential late effect of RA, particularly in those with severe disease. The neuropathy is typically mild. When performed, nerve biopsy may demonstrate vasculitic changes; however, these changes are not an indication for systemic immunosuppressive therapy. Patients may also develop an autonomic neuropathy, manifesting with impaired sweating and abnormal postural and cardiovascular reflexes, which may develop in the absence of sensory neuropathy. Patients may also develop mononeuritis multiplex in the setting of rheumatoid vasculitis.[12]

Patients with RA may develop inflammatory myositis in a variety of forms including dermatomyositis (DM), polymyositis (PM), and vasculitic myositis. A noninflammatory myopathy sometimes arises in the setting of disuse as well as from chronic corticosteroid administration.

TREATMENT

RA is incurable, with recommended treatment goals being remission or low disease activity through the use of disease-modifying antirheumatic drugs (DMARDs). It is important to note that pain medications and nonsteroidal anti-inflammatory medications may improve symptoms, but they do not prevent the progression of disease toward irreversible disability. DMARD treatments include synthetic, small orally administered molecules (e.g., methotrexate, sulfasalazine, leflunomide, hydroxychloroquine, and the janus kinase inhibitors) as well as biologics (e.g., parenterally administered proteins such as etanercept, infliximab, adalimumab, and rituximab). A treat-to-target strategy is recommended, with the aim of reducing disease activity and achieving remission within 6 months. Methotrexate and corticosteroids feature in the initial management, together leading to low disease activity and remission in almost half of patients with early RA. In the setting of failure of response to initial therapy, additional synthetic DMARDs or biologics are introduced. In the setting of remission, dose reduction rather than cessation of all DMARDs is recommended.

Myopathies in Connective Tissue Disease

Inflammatory myopathies are a heterogeneous group of potentially treatable disorders, classified based on distinct clinical and pathologic features. The classic subtypes of inflammatory myopathies include DM, PM, inclusion-body myositis (IBM), and necrotizing autoimmune myositis (NAM). In addition, antisynthetase syndrome and overlap myositis syndromes are increasingly recognized.

Patients typically present with symmetric, subacute proximal weakness with difficulty in daily activities such as rising from seated to standing, ascending stairs, and lifting objects above the head. Ocular muscles are spared, and while facial and distal muscles may be involved early in IBM, distal muscle involvement typically occurs late in DM, PM, and NAM. Across these subtypes, serum creatine kinase is typically markedly elevated, up to 50 times the upper limit of normal in DM, PM, and NAM and up to 10 times normal in IBM. Electromyography (EMG) demonstrates myopathic changes including easily recruited, brief, low-amplitude motor unit action potentials (with mixed large-amplitude potentials in IBM) along with fibrillation potentials and positive sharp waves. Despite similarities, these syndromes can be distinguished based on distinct clinical, histopathologic, and pathophysiologic features.[13,14]

Myositis overlap syndromes are characterized by an autoimmune myopathy (typically DM or PM) occurring in the setting of a connective tissue disease such as SLE, Sjögren syndrome, systemic sclerosis, or rheumatoid arthritis. At the time of presentation with myositis, serologic evidence (but not necessarily clinical features) of connective tissue disease is present in up to 15 percent of patients. A minority of patients with SLE have evidence of inflammatory myopathy based on muscle enzyme elevation, but asymptomatic SLE patients may have evidence of muscle inflammation on biopsy.

DM can rarely occur in those with systemic sclerosis and mixed connective tissue disorder.[13] DM can affect children and adults, and typically manifests with both skin and muscle involvement. The proximal muscles are typically involved, accompanied by neck flexor, pharyngeal, or diaphragmatic weakness in those with more severe disease. Pathognomonic skin manifestations of DM include scaly, erythematous lesions of the extensor surfaces of the joints of the hand (Grotton nodules) and discoloration of the eyelids occasionally accompanied by periorbital edema (heliotrope rash). Patients may also have an erythematous rash of the upper arms and shoulders (shawl sign) as well as subcutaneous calcium nodules. In addition to skin and muscular manifestations, 20 to 30 percent of patients have interstitial lung disease, particularly in those seropositive for antibodies to aminoacyl-tRNA synthetases (anti-Jo) and melanoma differentiation-associated protein 5 (MDA5).[14] The hallmark histologic features of biopsied muscle include perifasicular atrophy of myocytes as well as perimysial and perivascular inflammation. DM may also occur as a paraneoplastic syndrome in association with hematologic and lymphatic cancers or various adenocarcinomas, breast cancer, and melanoma.[13,14]

PM is a rare myopathy, often misdiagnosed in those with other inflammatory muscle disorders (including IBM and NAM), and thus PM is a diagnosis of exclusion.[13,14] It is a myopathy of adults which is subacute in onset and progression, sparing extraocular and facial muscles, and occurring in the absence of rash, family history of neuromuscular disease, or toxic exposures.[13] EMG demonstrates active myopathic units while MRI may show areas of active muscle inflammation which may guide muscle biopsy.[13] Inflammatory infiltrates of muscle fibers, typically composed of $CD8^+$ lymphocytes, are seen histologically in biopsied muscle.[13,14]

Antisynthetase antibodies are detected in approximately one-quarter of patients with overlap myositis. This antisynthetase syndrome is characterized not only by myositis but also arthritis, fevers, hyperkeratotic lesions of the radial and palmar surfaces (mechanics hands), interstitial lung disease, and Raynaud phenomenon. Some patients may also have erythematous rashes similar to that of DM. Patients with antisynthetase syndrome were previously classified as having either DM or PM based on the presence or absence of such rash. However, histopathologic findings of perifascicular necrosis and sarcolemmal complement deposition suggest antisynthetase syndrome is distinct from DM and PM.[14]

When evaluating a patient with connective tissue disease for potential myopathy, it is important to be mindful of the potential myopathic side effects of immunosuppressant medications. Corticosteroids, particularly in the setting of chronic or high-dose courses, can induce a type-II muscle fiber atrophy, presenting with mild proximal weakness in the setting of normal serum creatine kinase and a noninformative EMG. Long-term, high-dose use of chloroquine can also cause a myopathy, characterized by weakness in the setting of a normal serum creatine kinase level. Cyclosporine and tacrolimus rarely cause a myopathy. Penicillamine can induce both PM and DM, both of which improve with its cessation.

VASCULITIS

The vasculitides are disorders characterized by blood vessel inflammation. They can be categorized by type and size of inflamed blood vessels, location in the body, and pathologic features. The majority are systemic, with isolated neurologic involvement rarely occurring. Primary CNS vasculitis (PCNSV) and nonsystemic vasculitic neuropathy (NSVN) are the classic primary vasculitides of the nervous system.

Primary Vasculitides of the Nervous System

PRIMARY VASCULITIS OF THE CENTRAL NERVOUS SYSTEM

PCNSV is an uncommon, poorly understood varied group of disorders collectively characterized by idiopathic, predominantly monocytic, transmural inflammation of the vascular wall of small and medium-sized vessels of the brain parenchyma, spinal parenchyma, and leptomeninges. Historically, PCNSV has been referred to as granulomatous angiitis or primary angiitis of the nervous system. The pathogenesis of PCNSV is uncertain, with one hypothesis that it is a secondary inflammatory syndrome following a primary infection, such as varicella zoster virus. A rare and potentially treatable disease, PCNSV affects both children and adults; however, it most frequently presents in men at a median of 50 years of age.[11]

Clinically, patients present with an insidious and slowly progressive course, although some presentations may be acute. Syndromes vary, with nonspecific manifestations being most common, such as headache and subacute encephalopathy. In contrast to systemic vasculitis, fever and other systemic symptoms are uncommon. Patients frequently present with persistent motor, sensory, and language deficits, often in the setting of seizures. Ischemic, and less commonly hemorrhagic, stroke is common.

Serum blood tests are typically normal in patients with PCNSV, with occasional nonspecific elevations in the acute-phase reactants erythrocyte sedimentation rate (ESR) and C-reactive peptide (CRP), and detection of ANA and antiphospholipid antibodies. Levels of the von Wildenbrand factor antigen are often elevated in children with PCNSV, particularly those with small-vessel involvement.

The neurologic evaluation can be suggestive but not diagnostic of PCNSV. CSF analyses commonly demonstrate a mild pleocytosis and elevated total protein concentration. Electroencephalogram is most often nonspecific, with generalized or focal slowing commonly reported. MRI with gadolinium can show evidence of both cortical and subcortical infarction (most commonly multiple and bilateral), intracranial hemorrhage, parenchymal and leptomeningeal enhancement, and possibly mass-like lesions. MR angiography, however, is of limited utility, particularly for the evaluation of vessels of the posterior circulation as well as small, distal blood vessels. This emphasizes the importance of CT-based or conventional angiography in demonstrating findings suggestive of vasculitis, including alternating segments of vascular stenosis and dilatation, arterial occlusions, and rarely microaneurysms in multiple, bilateral, large and small blood vessels.[11]

The gold standard for diagnosis remains neurosurgical biopsy of the dura, leptomeninges, cortex, and white matter, ideally with radiographic guidance targeting involved areas rather than random sampling. When performed by a skilled neurosurgeon, the risk for neurologic complication is as low as 1 percent. Importantly, biopsy allows for the demonstration of vasculitis as well as the evaluation for mimics. Long-term immunosuppressive treatment can decrease the sensitivity of biopsy, emphasizing the importance of aggressively pursuing diagnosis in suspected cases.[11]

There are three main types of PCNSV, each with distinct pathologic features without evolution, suggesting that these are distinct types rather than different stages of the same disease. The most common is granulomatous, characterized by angiocentric mononuclear inflammation, granulomas, and multinucleated giant cells. β-Amyloid deposition in vessel walls is demonstrated in half of patients with granulomatous PCNSV. Lymphocytic PCNSV occurs in approximately one-quarter of patients, more commonly in children with angiography-negative PCNSV, and it is characterized by a predominant lymphocytic inflammation with occasional plasma cells and vessel wall destruction. The third and least common is necrotizing PCNSV, which is characterized by transmural fibrinoid necrosis; it is associated with intracranial hemorrhage. Occasionally, necrotizing and granulomatous findings are noted together.[11]

Several clinical criteria and subsequent refinements have been proposed for the diagnosis of PCNSV. The most widely used clinical criteria require a history and findings of an acquired neurologic deficit of unknown etiology; characteristic angiography findings (e.g., alternating areas of smooth-wall narrowing and dilation of arteries, occlusions of cerebral blood vessels, absence of proximal vessel involvement, and absence of findings suggestive of alternative etiologies); biopsy demonstrating histopathologic evidence of vasculitis; and no evidence of systemic vasculitis or other attributable etiology. Some reserve a definitive diagnosis of definite vasculitis for those patients with vasculitis proven by biopsy review, while those with angiographic evidence of a primary cerebral vasculitis and supportive brain MRI and CSF findings without available biopsy tissue are classified as having probable PCNSV.[11]

It is important to be mindful of the syndromes that may mimic PCNSV. CNS vasculitis can be secondary to systemic infections (e.g., varicella, HIV, syphilis, aspergillosis, cystercercosis, bacterial endocarditis, bacterial meningitis), systemic vasculitides [e.g., antineutrophil cytoplasmic antibodies (ANCA)–associated vasculitides, Behçet disease], connective tissue diseases (e.g., SLE, RA, Sjögren syndrome), antiphospholipid syndrome, lymphoma, neurosarcoidosis, and drugs such as stimulants. It is important to distinguish patients with PCNSV from those with reversible vasoconstrictive syndrome (RCVS) and other noninflammatory vasculopathies. RCVS typically affects women in the postpartum period or after exposure to vasoconstrictive agents. In contrast to PCNSV, subarachnoid hemorrhage is a common presentation while ischemic and hemorrhagic stroke are less commonly observed in RCVS.[11]

With no randomized controlled treatment trials, treatment of PCNSV is guided by the experience of reported cases, cohort studies, and expert opinion. Treatment typically entails an induction phase with corticosteroids alone or along with cyclophosphamide, and maintenance therapy with mycophenolate mofetil, azathioprine, or methotrexate. The vast majority of patients have a favorable response to various combinations of induction therapy, but up to one-third of treated patients experience relapse.

Nonsystemic Vasculitic Neuropathy

NSVN presents most commonly as a slowly progressive, asymmetric, multifocal neuropathy. Also referred to as primary vasculitis of the peripheral nervous system, it usually affects patients in their seventh decade of life, more commonly women. It rarely presents acutely. The clinical course is typically insidious with a long duration of symptoms prior to diagnosis. In contrast to neuropathies associated with the systemic vasculitides discussed later in this chapter, symptoms are confined to the peripheral nervous system. Weight loss is reported in roughly one-third of patients, while fever is reported in a minority of patients. The most common neurologic presentations are of either multiple mononeuropathy, asymmetric polyneuropathy, or distal symmetric polyneuropathy affecting both motor and sensory nerves. Pain is a frequent symptom. NSVN has a low rate of morbidity and even lower rate of mortality. Patients commonly experience chronic pain; however, they are typically independent in mobility and activities of daily living. Patients with NSVN should be followed longitudinally as approximately 10 percent of patients will later be found to have a systemic vasculitis.[12]

As NSVN is a diagnosis of exclusion, the diagnostic approach to a patient presenting with a painful, asymmetric, multifocal neuropathy is to assure it is not due to a systemic vasculitis. Blood tests including complete blood cell counts, chemistry panels, glucose levels and glycated hemoglobin, acute-phase reactants, serum protein electrophoresis, complement levels, cryoglobulins with hepatitis serologies, and serologic testing for systemic vasculitides are performed to evaluate for not only systemic vasculitis, but also infections, hematologic malignancy, and metabolic mimics. Patients with NSVN may have nonspecific abnormalities on testing, such as elevated ESR, peripheral leukocytosis, thrombocytosis, and elevated ANA. Serologies for connective tissue disorders such as SLE, infections such as with HIV and spirochetes, and radioimaging such as plain chest radiograph or CT (for sarcoid) may be performed based on the clinical history and examination.[12]

EMG and nerve conduction studies are central to the diagnosis. They frequently demonstrate evidence of acute to subacute patchy, multifocal, nonlength-dependent axonal sensorimotor neuropathy, either mononeuropathy or, more commonly, polyneuropathy. Additionally, there may be evidence of conduction block at the nidus of nerve infarction.[12]

Electrodiagnostic testing is also important in guiding muscle and nerve biopsy. Inflammatory infiltration and occasionally necrosis of the epineurial and perineurial large arterioles are seen in NSVN. Inflammation of the small arterioles, capillaries, and venules may also be seen in the setting of microvasculitis. The inflammatory infiltrates are typically associated with immune complex, complement, and fibrinogen deposition in the epineurial blood vessel walls; neovascularization; and multifocal fiber loss with perineurial thickening and Wallerian degeneration of nerve fibers. Although patients may have no clinical evidence of myopathy, muscle biopsy may demonstrate vasculitis within muscle tissue, particularly of the perimesial arterioles.[12]

Corticosteroids are the cornerstone of treatment of NSVN. Patients with a history of clinical progression and histopathologic evidence of active NSVN should be treated with high-dose oral prednisone or prednisolone (typically 1 mg/kg per day) followed by a long slow taper over the course of months. Less often, patients may have evidence of active vasculitis on biopsy but be clinically improving; treatment or observation with close clinical follow-up may be considered. In severe cases, high-dose intravenous methylprednisolone followed by a slow oral corticosteroid taper may be pursued. If patients demonstrate progression despite corticosteroids, cyclophosphamide can be used as second-line therapy, preferably intravenously in severe cases. After stabilization, some patients may be transitioned to azathioprine or methotrexate for maintenance therapy.[12]

Systemic Vasculitis

SYSTEMIC DISEASE

The noninfectious, systemic vasculitides can be broadly categorized by the size of the affected vessels, which differ in their structure and function. Large-vessel vasculitides (i.e., giant-cell arteritis and Takayasu arteritis) will be discussed separately later in this chapter. Vasculitides of the medium vessels (medium arteries to arterioles) and small vessels (small arteries, arterioles, capillaries, venules, and small veins) can also affect both the central and peripheral nervous system and are discussed here. These conditions include the medium-vessel arteritis polyarteritis nodosa (PAN) and the ANCA-associated small-vessel vasculitides granulomatosis with polyangiitis (GPA, formerly Wegener granulomatosis), eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg—Strauss syndrome), and microscopic polyangiitis (MPA). Kawasaki disease, a medium-vessel vasculitis, primarily occurs in children and rarely manifests with neurologic syndromes.[15]

PAN is a rare systemic vasculitis, affecting the main medium-sized visceral arteries as well as their small artery and arteriole branches. It can be a sequela of chronic hepatitis B virus infection, with increased incidence in areas where hepatitis B is endemic. It most commonly affects men, typically between 40 and 50 years of age. PAN presents with constitutional symptoms including fever, malaise, fatigue, and weight loss, with the majority of patients demonstrating skin involvement (e.g., livedo reticularis, cutaneous nodules, skin ulcerations, ischemia of the digits), Patients also commonly have joint and kidney involvement, including hypertension, renal artery aneurysms, and renal infarction. Less commonly, patients manifest with testicular involvement, cardiac involvement (e.g., tachycardia, patchy myocardial ischemia and infarction, heart failure), and rarely pulmonary or otolaryngologic involvement. Gastrointestinal manifestations are common, with patients often presenting with abdominal pain, frequently in the setting of microaneuryms of the mesentery. The most common neurologic manifestation of PAN is neuropathy, affecting the majority of patients and most commonly in the form of multiple mononeuropathies. Cranial nerve and CNS involvement rarely occur.[12]

Through the course of diagnostic evaluation, patients with PAN are found to be seronegative for ANCA and are often found to have evidence of systemic inflammation including elevated ESR, leukocytosis, thrombocytosis, and anemia.[12] Renal function may be impaired, as evidenced by elevated blood urea nitrogen and creatinine, with proteinuria and hematuria found on urine analysis. Biopsies of affected organs demonstrate necrotizing arteritis of small and medium arteries; no involvement of the arterioles, capillaries, or venules; and no evidence of glomerulonephritis on renal biopsy.[15]

GPA is an ANCA-associated vasculitis of the small and medium vessels, which initially manifests with involvement of the respiratory tract before involving other organs over the course of months. It is characterized by necrotizing granulomatous inflammation of small arteries, arterioles, capillaries, venules, and small veins.[15] It most commonly manifests with involvement of the upper airway with ulcerations of pharynx and ears; lower airway including ulcerations of lungs, transient infiltrates, or even pulmonary hemorrhage; and kidney with glomerulonephritis.[12] Less commonly it affects the muscles and joints, eyes, skin, and rarely the heart (e.g., pericarditis) and gastrointestinal tract (up to 10%).[12] Up to 25 percent of patients have involvement of the peripheral nervous system, while up to 10 percent show involvement of the CNS, and 15 percent have cranial neuropathies.[12]

On laboratory testing, up to 90 percent of GPA patients are seropositive for ANCAs [more often with antiproteinase 3 (PR3) than antimyeloperoxidase (MPO) antibodies], while 25 percent are ANA seropositive.[12] Patients commonly demonstrate evidence of systemic inflammation, with elevated ESR, leukocytosis, thrombocytosis, and anemia commonly noted.[12] Classification of GPA by the ACR is based on the presence of at least two of the following: nasal or oral inflammation, abnormal chest radiograph, microhematuria or red cell casts in the urine, or pathologic demonstration of granulomatous inflammation involving organ arteries or arterioles.

EGPA is less common than GPA and MPA. It is characterized by necrotizing granulomatous inflammation rich in eosinophils affecting small and medium blood vessels.[15] In contrast to PAN, patients with EGPA have eosinophilia in the setting of pulmonary involvement, primarily asthma and pulmonary infiltrates, which are evident in up to 75 percent of patients.[12] Patients also commonly present with rhinosinusitis and involvement of the skin, gastrointestinal tract, joints, heart, and kidney.[12] Up to 70 percent of patients develop neuropathy, with CNS (10 to 15%) and cranial neuropathies (less than 5%) being less common.[12] Patients initially develop asthma and allergic rhinosinusitis followed by eosinophilia in the peripheral blood and eosinophilic pneumonia, followed years later by evidence of systemic vasculitis.[12] The ACR classification of EGPA is based on the presence of four of the following: asthma, eosinophilia, mononeuropathy or polyneuropathy, transient pulmonary infiltrates, abnormal paranasal sinuses, and nasal polyps.

On laboratory assessment, all EGPA patients have eosinophilia, with ESR commonly elevated. Patients may have elevated immunoglobulin E levels. Only 30 to 40 percent are ANCA seropositive, more commonly anti-MPO than anti-PR3. ANCA seropositivity is associated with renal disease, particularly in those with necrotizing glomerulonephritis, which otherwise is not common in EGPA.[12]

MPA is another common ANCA-associated vasculitis. It is characterized by a nongranulomatous necrotizing vasculitis with a paucity of immune deposits involving small vessels; inflammation is isolated to these vessels.[12] In contrast to PAN, necrotizing glomerulonephritis and pulmonary capillaritis are common.[15] Patients are predominantly male, with an average age between 60 and 70 years. The majority present with constitutional symptoms. The most common systemic manifestations involve the kidney, joints, skin, lungs, gastrointestinal tract, and less commonly the ears, nose, throat, and heart.[12] Peripheral neuropathies are observed in 45 percent of patients, while the CNS is involved in 10 to 15 percent.[12] On laboratory testing, patients are frequently seropositive for ANCA (75 to 85%), more commonly anti-MPO than anti-PR3, and have an elevated ESR.[12] In contrast to PAN, patients with MPA do not have evidence of hepatitis infection.[12] Patients with MPA do not meet criteria for either GPA or EGPA.[12]

Importantly, vasculitis can be a manifestation of a variety of diseases, including connective tissue disorders and infections. Rheumatoid vasculitis affects medium-sized vessels, and is typically a late manifestation of severe RA. Patients may develop neuropathy along with other evidence of systemic vasculitis. Sjögren syndrome is associated with a microvasculitis, typically of epineurial vessels, without other systemic involvement. Vasculitis can also occur in SLE and sarcoidosis. Infectious vasculitides are an important consideration. While hepatitis B is associated with PAN, chronic hepatitis C with cryoglobulinemia causes a medium-vessel vasculitis itself, leading to a vasculitic neuropathy. Similarly, HIV is associated with a medium-vessel vasculitis, thought to be due to immune complex deposition.[18] HIV vasculitis occurs in less than 1 percent of infected individuals, typically in the setting of CD4 counts less than 500 cells/µL. Vasculitides can also occur due to viral (e.g., cytomegalovirus, varicella zoster virus), bacterial (e.g., borrelia, syphilis, ricketsial, mycobacterial), and fungal (e.g., histoplasma, cryptococcal) infections. Medium-vessel vasculitides can rarely be paraneoplastic, presenting as a painful sensorimotor neuropathy or mononeuritis. The most commonly associated cancers are small cell lung cancer and lymphoma, and the most commonly reported associated antibody is to antineuronal antigen–1 (anti-Hu).[12]

CENTRAL NERVOUS SYSTEM DISEASE

CNS vasculitis in the context of systemic vasculitis can present as a variety of syndromes in patients of all ages. In the setting of constitutional symptoms, patients may develop syndromes ranging from the seemingly benign (e.g., headache) or nonspecific (e.g., concentration problems, encephalopathy) to focal and localizable (e.g., seizures, stroke, meningitis). Of note, ischemic strokes can occur in single or multiple locations, typically in small-vessel areas. As noted earlier, the frequency of CNS involvement varies across the small- and medium-vessel systemic vasculitides, most frequently in ANCA-associated vasculitides.[12]

PERIPHERAL NERVOUS SYSTEM DISEASE

Vasculitis of the medium and small vessels can manifest as a systemic vasculitic neuropathy, which typically presents with an acute-to-subacute, painful, sensory or sensorimotor neuropathic syndrome in the setting of constitutional symptoms such as fever, fatigue, weight loss, night sweats, and, in some instances, a skin rash. Classically, patients present with an ischemic mononeuropathy or mononeuritis multiplex characterized initially by deep, aching pain of the proximal limb, followed in short order by burning dyasthesias or parathesias and focal weakness in the distribution of a single nerve, followed subsequently by involvement of additional discrete nerves over the course of weeks. In time, the overlap of mononeuropathies can present clinically as an asymmetric or even symmetric polyneuropathy. Approximately one-third of patients present with a slowly progressive, distal, symmetric sensorimotor neuropathy. The majority of patients with EGPA and PAN present with a peripheral neuropathy, while those with GPA and MPA are less likely to have neuropathy as a presenting symptom. Cranial nerves may be involved (potentially multiple, particularly in GPA). Rarely, patients present with a syndrome of acute ascending paralysis, with electrodiagnostic studies demonstrating an axonal rather than demyelinating polyradiculopathy and evidence of vasculitis on nerve biopsy. The pathologic findings of systemic vasculitic neuropathy on muscle and nerve biopsy are similar to those described previously for NSVN. MPA may manifest with inflammation of small blood vessels, while GPA may lead to epineurial granulomas and EGPA with granulomas accompanied by eosinophilic infiltration.[12]

TREATMENT

The treatment of systemic vasculitis is two part: induction therapy followed by maintenance therapy over the course of months to years. Corticosteroids (prednisone or methylprednisolone) and cyclophosphamide (either intravenous or oral) are standard induction therapies commonly given in combination for moderate to severe PAN, GPA, EGPA, and MPA. Remission is typically achieved over the course of months of corticosteroid tapering and cyclophosphamide therapy, and patients may be transitioned to azathioprine or methotrexate as maintenance therapy. Cyclosporine, leflunomide, and mycophenolate mofetil are common second-line maintenance therapies.[12]

Polymyalgia Rheumatica and Giant-Cell Arteritis

SYSTEMIC DISEASE

GCA, also referred to as "temporal arteritis," is the most common primary large-vessel arteritis, affecting adults 50 years or older and often associated with polymyalgia rheumatica (PMR).[16] PMR is the more common syndrome, affecting up to 10 times the number of patients as GCA.[16] Both typically affect the elderly, with peak incidence in the eighth decade and a female predominance.[16] GCA is characterized pathologically by granulomatous arteritis with giant cells involving the aorta and its major branches.[15] The carotid branches, vertebral arteries, and temporal arteries are commonly affected.

PMR is a chronic, idiopathic systemic inflammatory illness characterized by aching pain and stiffness, particularly upon waking in the morning. The aching pain is distributed symmetrically and involves the proximal joints, particularly the shoulders more so than the neck or pelvis. Imaging studies of patients with PMR demonstrate inflammation of the joints, including bursas and periarticular structures. Muscle weakness does not feature in the syndrome; however, myalgias are a key feature and are accompanied by elevated acute serum phase reactants. Patients commonly manifest systemic symptoms of fever, malaise, fatigue, anorexia, and weight loss.[16]

Approximately half of patients with GCA initially present with PMR.[16] Systemic symptoms such as fever, fatigue, and weight loss are characteristically accompanied in GCA by headache and jaw claudication. Patients may report or be demonstrated on examination to have scalp pain and enlarged, nodular arteries of the scalp, particularly the temporal arteries. Having a high index of suspicion for GCA is particularly important given the risk of luminal occlusion and associated ischemic complications such as ischemic optic neuropathy and stroke.[16] Among those with GCA, approximately 20 percent have aortitis and are at risk for aortic dissection, aortic aneurysms, and associated syndromes such as aortic valve insufficiency, myocardial infarction, and intestinal ischemia.[16] Less than 10 percent of patients have inflammation of the subclavian-axillary and brachial arteries, and approximately 5 percent demonstrate inflammation of the superficial femoral and popliteal arteritis.[12] Involvement of these vessels leads to asymmetric pulses, Raynaud phenomenon, and symptoms of claudication in the extremities. Glomerulonephritis occurs in approximately 10 percent of patients.[12] The most common neurologic syndromes are otologic (60 to 90% of patients) or involve the optic nerve (15 to 20%).[12] Rarely, the peripheral and central nervous systems are involved.[12]

The most common laboratory abnormalities of both PMR and GCA are an elevated ESR and CRP. Patients are also commonly anemic and demonstrate thrombocytosis and leukocytosis. Approximately 30 percent of patients have abnormal liver function studies. ANCAs are rarely detected, and their detection is suggestive of an ANCA-associated vasculitis rather than GCA.[16]

When GCA is suspected, biopsy of the temporal artery should be pursued to confirm the diagnosis. GCA is characterized by patchy vascular inflammation, and therefore biopsy should be ideally performed on vessels that are abnormal on palpation. Biopsy is diagnostic in 85 to 95 percent of cases; however, if a first biopsy is histologically normal, biopsy of the contralateral temporal artery should be pursued. Importantly, treatment with corticosteroids should not be deferred out of concern for affecting biopsy yield. Following tissue confirmation of GCA, magnetic resonance angiography or computed tomographic angiography can be used to evaluate the aorta and its major branches to assess the extent of GCA involvement.[16]

Central Nervous System Disease

Headache is a common presenting symptom and typical of GCA. New-onset headache in a patient older than 50 years of age should raise concern for GCA, particularly in the setting of other typical symptoms such as PMR, fever, jaw claudication, and unexplained weight loss.[16]

Arteritic ischemic optic neuropathy occurs in up to 20 percent of patients with GCA.[12] It can lead to irreversible vision loss. Patients typically experience sudden, painless, monocular vision loss that progresses over the course of days. The vision loss may occasionally be of the entire visual field in the affected eye, the consequence of central retinal artery occlusion. It may be proceeded by amaurosis fugax, a syndrome of brief, transient episodes of painless vision loss. Patients less commonly report retrobulbar pain. On examination, there is typically loss of light perception and an afferent pupillary defect once infarction has occurred. Funduscopic examination at 24 to 48 hours after symptom onset demonstrates optic disc swelling and pallor as well as occasional flame-shaped hemorrhages or cotton wool spots. High-dose intravenous corticosteroids should be initiated promptly in suspected cases while the confirmatory diagnostic evaluation, including temporal artery biopsy, is pursued.[16]

Other CNS syndromes, such as stroke and transient ischemic attack (TIA), rarely occur in patients with GCA. When they do occur, strokes are typically embolic, with a predilection for the posterior cerebrovascular circulation (since the vertebral arteries are commonly inflamed) more than the anterior circulation. Intracranial arteries are rarely involved.

Peripheral Nervous System Disease

Otologic syndromes due to cranial nerve ischemia are common in GCA. Approximately 90 percent of patients are affected by vestibular dysfunction and 60 percent experience hearing loss. Patients may also have other ischemic cranial neuropathies, including the oculomotor nerve, or ischemia of the extraocular muscles themselves. Peripheral neuropathies, both focal and multifocal, rarely occur. The cervical nerve roots, upper brachial plexus, and distal median nerve (often due to carpal tunnel syndrome) are most commonly affected.[12]

Treatment

Corticosteroids are the standard treatment for both GCA and PMR. The initial treatment of GCA is prednisone at a dose of 1 mg/kg per day for 2 to 4 weeks followed by a slow taper. Monitoring of ESR and CRP allows for assessment of response to therapy and guides the prednisone taper. New-onset symptoms, such as arteritic ischemic optic neuropathy, are treated with intravenous methylprednisolone, typically at a dose of 1,000 mg daily for 3 days followed by a slow oral prednisone taper. Aspirin should be considered in patients with GCA given the associated stroke risk.[16]

In contrast, PMR is treated with lower doses of prednisone (typically 15 to 20 mg daily initially) over the course of several months, with monitoring for remission of symptoms. Prednisone taper is typically at a rate of 20 percent or less each month, and is again guided by acute-phase reactant levels and clinical monitoring.[16] Unfortunately, corticosteroid-sparing agents such as methotrexate are of either marginal or no benefit in GCA.[16]

Takayasu Arteritis

SYSTEMIC DISEASE

Originally described in Japan, Takayasu arteritis is the most common arteritis among those of Asian ancestry. Commonly referred to as "pulseless disease," it is an idiopathic vasculitis of the large vessels, including the aorta, major arterial branches, and the pulmonary artery. Histopathologically, it is characterized by granulomatous inflammation of the large arteries. Similar to GCA both clinically and histopathologically, age of onset in patients less than 50 years of age is a key distinguishing feature of Takayasu arteritis.[15]

Clinically, patients initially present with systemic symptoms of fever, malaise, weight loss, anorexia, nausea, and vomiting. On examination, patients frequently demonstrate findings of erythema nodusum and synovitis. Systemic inflammatory symptoms and signs precede vascular involvement. In time, patients develop vascular stenoses and occlusions, impairing blood flow in the large vessels, particularly of the extremities; this leads to difficult in palpating peripheral pulses and to limb claudication and arterial bruits. Patients may have hypertension secondary to renal artery stenosis, and additional findings including Reynaud phenomenon, tenderness of the involved arteries, or aortic valve insufficiency as a consequence of aortic root inflammation.

Paraclinical findings include elevated levels of acute-phase reactants such as ESR and CRP, as well as other signs of inflammation including peripheral leukocytosis and anemia.[12] These laboratory findings and systemic symptoms may resolve spontaneously, leaving only arterial stenoses and occlusions as the findings characteristic of Takayasu arteritis. In this setting, arteriography can be used to assess the extent of disease involvement of the aorta and its major vessels, including the carotid and vertebral arteries. Takayasu arteritis usually does not affect the peripheral nervous system.

CENTRAL NERVOUS SYSTEM DISEASE

Inflammation of the carotid and vertebral arteries puts patients at risk for ischemic stroke as well as TIA. Patients are also at risk for embolic stroke in the setting of myocardial infarction from coronary artery inflammation. Takayasu arteritis does not involve the intracranial arteries. Ischemic stroke risk is driven by carotid and vertebral artery stenoses and hypertension. This hypertension, which is a risk factor for intracranial hemorrhage, is often caused by renal artery stenosis.

TREATMENT

As with GCA, corticosteroids are the standard treatment of Takayasu arteritis. Despite corticosteroid therapy, many do not improve and relapses are common. Vascular complications occur in the majority of patients. Patients may require vascular surgical bypass, stenting, or angioplasty of arterial stenoses; however, these stenoses often recur despite intervention.

Behçet Disease

SYSTEMIC DISEASE

Behçet disease is an idiopathic vasculitis with variable involvement of vessels of all sizes.[15] Patients present with a history of acute episodes of recurrent oral aphthous ulcers, recurrent genital aphthous ulcers, eye lesions (uveitis, retinal vasculitis, or both), and a variety of cutaneous lesions including erythema nodosum, pseudofolliculitis, papulopustular lesions, and acneiform nodules in postadolescent patients.[17] These features along with a positive pathergy test feature in the diagnostic criteria.[17] Less frequently, patients experience episodes of arthritis, epididymitis, gastrointestinal inflammation and ulceration, vascular complications (e.g., arterial occlusions, aneurysms, thrombophlebitis), and inflammatory lesions of the CNS.[17]

Behçet disease varies in prevalence between populations, although cases cluster along the ancient Silk Road from Japan to the eastern Mediterranean. Globally, the prevalence is approximately 10 per 100,000 population, with the highest prevalence in Turkey. Behçet disease is more common among males than females; however the ratio of male-to-female patients varies across studied cohorts. Patients typically develop symptoms when 20 to 30 years of age.[17]

There are no specific paraclinical findings for Behçet disease. Patients often have elevated markers of systemic inflammation. Sensitivity and specificity of the skin pathergy test vary across populations.[17]

CENTRAL NERVOUS SYSTEM DISEASE

Approximately 10 to 15 percent of patients with Behçet disease develop neurologic syndromes, though this varies across populations. Patients develop neurologic symptoms between 20 and 40 years of age, and men are more frequently affected neurologically than women.

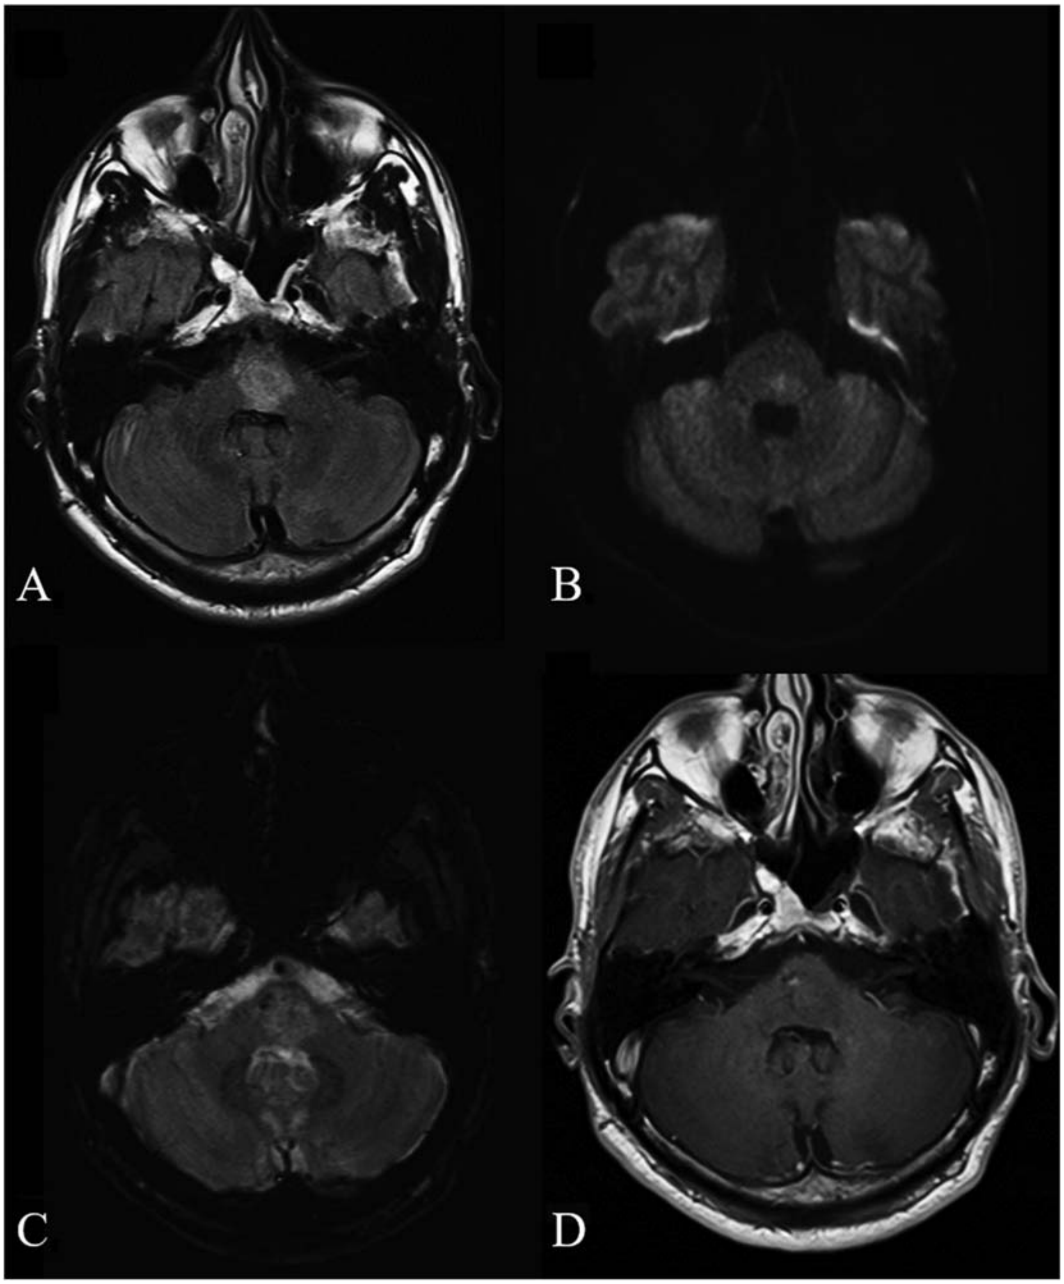

FIGURE 50-2 ■ Parenchymal neuro-Behçet disease. *A*, MRI brain fluid-attenuated inversion recovery sequence demonstrates a heterogeneous T2 hyperintensity within the pons extending to the left cerebellar peduncle. *B*, Diffusion-weighted sequence demonstrates mild diffusion restriction within the lesion. *C*, Susceptibility-weighted sequence demonstrates hypointensities in the right pons compatible with hemosiderin deposition. *D*, Postgadolinium T1 sequence demonstrates mild enhancement within the pons near the areas of hemosiderin deposition.

Neurologic manifestations typically arise 3 to 6 years after the onset of other systemic features of Behçet, primarily involving the CNS.[17]

Neurologic Behçet disease is divided into two groups: a parenchymal group with meningoencephalitis predominantly affecting the brainstem, and a nonparenchymal group with thrombosis within the dural venous sinuses. In the acute phase, parenchymal disease is characterized by a small-vessel perivascular inflammatory infiltrates composed of neutrophils, eosinophils, basophils, lymphocytes, and monocytes with areas of apoptotic neuronal loss and necrosis. This inflammation can involve the brainstem, subcortical gray matter, and white matter (Fig. 50-2). Parenchymal involvement is the most common manifestation of neurologic Behçet disease. Of those with parenchymal disease, approximately 75 percent present with a subacute meningoencephalitis, with fever, malaise, and headache occurring both before and during an attack. The symptoms of meningoencephalitis develop over the course of days and persist for weeks. Patients with parenchymal involvement can also develop a variety of syndromes based on areas of inflammation, including cranial neuropathies (e.g., optic neuropathy), ophthalmoparesis, cerebellar dysfunction, extrapyramidal and pyramidal dysfunction, stroke-like syndromes, seizures, cognitive syndromes, psychosis, and spinal cord involvement (e.g., transverse myelitis). Rarely, imaging studies may demonstrate lesions that mimic tumors.[17]

Nonparenchymal Behçet disease is less common, accounting for 20 percent of cases of neurologic disease. Stroke is rare in neurologic Behçet disease in general, and is typically caused by nonparenchymal disease. Central venous sinus thrombosis (CVST) is a common nonparenchymal syndrome, and is typically subacute to chronic in onset. Patients may develop intracranial hypertension in the presence as well as in the absence of CVST. Patients with CVST may also rarely develop seizures. Intracranial aneurysms have been occasionally reported in the setting of Behçet disease, but these are likely coincidental rather than the consequence of the syndrome.[17]

Disease activity has been associated with elevations in ESR, and thrombocytosis may be noted, particularly in those with CVST. Up to 80 percent of patients with parenchymal disease have abnormal CSF profiles, typically featuring a modest elevation in CSF protein in the setting of a neutrophilic-predominant pleocytosis which transitions to a lymphocytic-predominant pleocytosis in the chronic phase of disease. MRI may demonstrate T2 hyperintensities of the involved parenchyma, and these abnormalities typically enhance and are associated with edema (Fig. 50-2). Atrophy may be evident in the setting of chronic disease. MRI of the spinal cord in patients with a transverse myelitis typically demonstrates lesions that mimic demyelinating plaques, some of which are longitudinally extensive. Venography (either MR or CT) readily demonstrate thromboses.[17]

PERIPHERAL NERVOUS SYSTEM DISEASE

Cases of peripheral neuropathy, mononeuritis multiplex, myopathy, and myositis have been reported in patients with Behçet disease; however, the relation of these reported syndromes to Behçet disease is uncertain.[17]

TREATMENT

There are no controlled or comparative treatment trials for Behçet disease, with choice of therapy directed by individual clinical manifestations. For parenchymal disease, a course of high-dose intravenous methylprednisolone followed by a slow oral prednisone taper is used; abrupt cessation is avoided given concern for early relapse. The role of other forms of immunosuppression in neurologic Behçet disease is uncertain. CVST may be treated by anticoagulation with heparin or low-molecular-weight heparin as well as corticosteroid therapy.[17]

Patients with acute parenchymal lesions recover well after steroid treatment; however, some patients recover without treatment. Approximately one-third of patients have a progressive disease course, with accrual of neurologic deficits in the setting of recurrent episodes.[17]

ACKNOWLEDGMENT

A previous version of this chapter was authored by Richard Rosenbaum, MD, in earlier editions of this book.

Sleep disorders commonly occur in patients who present to neurologists. At times, symptoms are obvious, such as insomnia or excessive daytime sleepiness (EDS). However, some patients have serious sleep disorders, such as sleep apnea, that are often not readily apparent to the patient or physician and can exacerbate a neurologic disorder. Established links exist between sleep apnea and stroke, epilepsy, and migraine, between certain sleep behavior disorders and neurodegenerative diseases, and between circadian rhythm disorders and dementia. In light of these links, it is important that neurologists become familiar with sleep disorders and incorporate sleep diagnosis and treatment into daily practice, and that sleep specialists and internists gain wider appreciation of the impact of sleep disorders on neurologic function and disease. This chapter reviews key aspects of sleep medicine and their association with clinical neurology.

SLEEP PHYSIOLOGY

Sleep is defined by behavioral and physiologic changes that include postural recumbence, behavioral quiescence, eye closure, and specific physiologic parameters based on electroencephalography (EEG), electro-oculography (EOG), and electromyography (EMG). Sleep is further subdivided into non—rapid eye movement (NREM) and rapid eye movement (REM) sleep.

The normal adult brain enters sleep first through NREM stages followed by REM sleep approximately 90 minutes later. NREM and REM sleep then alternate through four to six cycles lasting 90 to 110 minutes each. The first third of sleep is dominated by NREM sleep and the last third of the night is dominated by REM sleep. NREM sleep is further divided into three stages (N1, N2, N3).

Sleep Stages

The staging of sleep is based on the recordings of the EEG, chin EMG, and EOG made during polysomnography (PSG). The PSG is scored by assigning a sleep stage to each 30-second epoch recorded. The characteristics of the various sleep stages are summarized in Fig. 51-1.

STAGE WAKE

Stage wake can occur when the subject is alert with eyes open or relaxed with eyes closed. When the eyes are open, the EEG shows low-amplitude, fast mixed-frequency activity. The EOG tracing consists of eye movements and eye blinks, and the EMG chin activity is increased. Once the eyes are closed, alpha rhythms (8 to 13 Hz) predominate on the EEG and are most prominent in the occipital leads. This alpha activity attenuates with concentration or with eye opening. Stage W is scored when 50 percent of the epoch shows alpha activity in the occipital region. The normal adult spends less than 5 percent of the night in this stage.

STAGE N1

Stage N1 sleep is characterized by light sleep or drowsiness. It is identified by less than 50 percent of the epoch being occupied by alpha activity on the EEG. The EEG also shows low-voltage, mixed-frequency activity predominantly in the theta frequency (4 to 7 Hz). The EOG channel often shows slow rolling eye movements, and EMG activity is diminished. Vertex sharp waves may appear in the central EEG leads in the later part of stage N1. In the normal adult, stage N1 should occupy 2 to 5 percent of sleep, but patients with excessive sleep fragmentation such as those with sleep apnea often have a larger percentage of stage N1 sleep.

STAGE N2

Stage N2 sleep is defined by the presence of K-complexes or sleep spindles on the EEG. The background EEG shows low-amplitude, mixed-frequency activity. The EOG typically shows no eye movements, but slow rolling eye movements may persist from stage N1. EMG activity is reduced from stage N1 and wake. Stage N2 generally constitutes 45 to 55 percent of sleep in adults.

STAGE N3

Stage N3 sleep, also referred to as slow-wave sleep, represents the deepest sleep stage. Slow-wave sleep was initially divided into stages 3 and 4; however, because of the physiologic similarities between these stages, they have been combined into a single stage. Stage N3 is defined by the presence of high-amplitude slow waves with a frequency of 0.5 to 2 Hz and an amplitude of 75 μV. Slow-wave activity must occupy at least 20 percent of the epoch to meet criteria for stage N3. The EMG is active but diminished compared to stages W and N1, and there are no eye movements. Stage N3 occupies 15 to 25 percent of sleep in healthy adults.

STAGE REM

REM sleep is characterized by a highly active brain with loss of muscle tone. The EEG shows a low-voltage, mixed-frequency pattern with sawtooth waves. The chin EMG

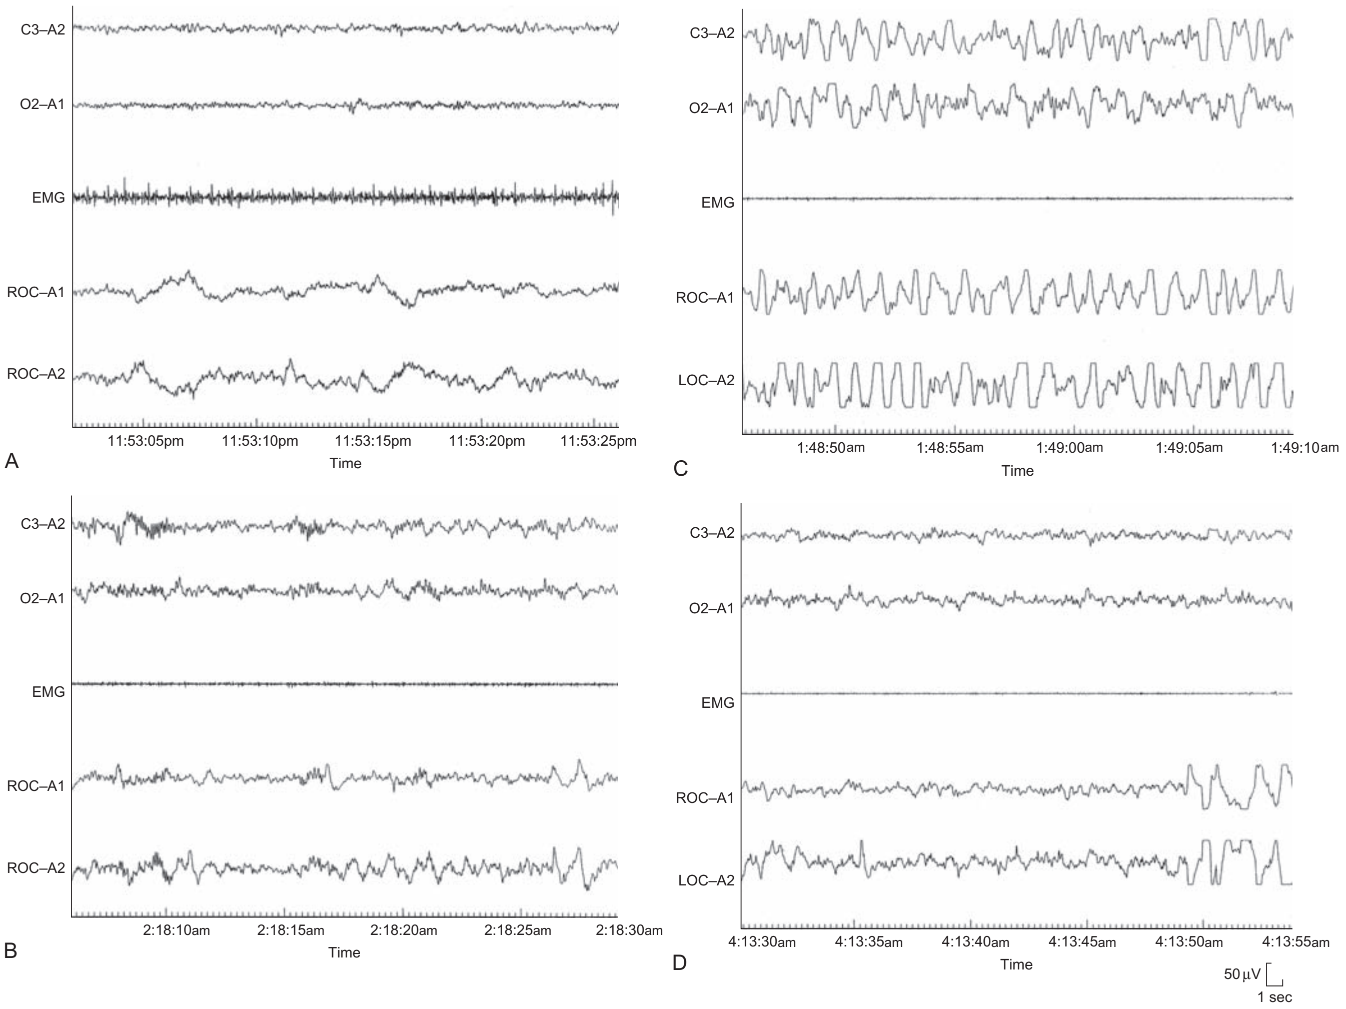

FIGURE 51-1 ■ The stages of sleep. *A*, Stage N1. There is low-voltage mixed-frequency electrocerebral activity with ongoing muscle activity and slow, rolling eye movements. *B*, Stage N2 sleep showing sleep spindles. K-complexes are also classically present but are not clearly shown in this epoch. *C*, Stage N3 sleep, with high-amplitude, low-frequency delta activity in the electroencephalogram (EEG). The eye-movement channels reflect the EEG. *D*, Stage REM. The EEG is of low amplitude and mixed frequency and is accompanied by muscle atonia and rapid eye movements. (Adapted from Abad VC, Guilleminault C: Polysomnographic evaluation of sleep disorders. p. 727. In Aminoff MJ (ed): Aminoff's Electrodiagnosis in Clinical Neurology. 6th Ed. Elsevier Saunders, Oxford, 2012.)

tone is markedly diminished, and the EOG shows rapid eye movements. There is a cessation of K complexes, sleep spindles, and high-amplitude waves. REM sleep accounts for 20 to 25 percent of total sleep time in healthy adults.

Sleep Patterns Across the Human Lifespan

Sleep patterns change markedly throughout the human lifespan. The most pronounced changes occur during the first year of life. Newborns enter sleep through REM sleep (called "active sleep" in the newborn), and then sleep alternates between REM and NREM in 50- to 60-minute intervals rather than the 90-minute cycles of adults. During the first year of life, EEG patterns develop to allow distinction between different stages of NREM sleep.

Stage N3 sleep is most prominent in childhood and decreases by almost 40 percent in the second decade of life. It further declines with age and is almost absent by the age of 60, especially in men, perhaps due to a decline in the amplitude of EEG waves from reduced synaptic activity.

REM sleep occupies 50 percent of sleep in the first year of life. By 6 years of age, REM sleep time is reduced to 20 to 25 percent of sleep and is maintained at this percentage into old age. REM sleep markedly declines with organic brain dysfunction.

Arousals and episodes of awakening from sleep increase dramatically with age and may correlate with an underlying sleep disorder, medical condition, or neurologic disease. The percentage of stage N1 sleep also increases with age, signifying more transitions between wake and sleep.

Sleep requirements change with age. A newborn sleeps about 16 hours per day. This falls to about 11 hours in children 3 to 5 years of age. Adolescents between 9 and 10 years of age require approximately 10 hours of sleep. Adults average 7.5 to 8 hours of sleep; although this duration remains steady into healthy old age, the ability to consolidate sleep into a single continuous sleep period declines. Elderly individuals may revert to a biphasic sleep pattern with increased daytime napping.

CIRCADIAN NEUROBIOLOGY

The sleep–wake cycle is regulated by two opposing processes, the circadian rhythm and the homeostatic drive for sleep. The circadian rhythm is set by the suprachiasmatic nucleus of the hypothalamus, which regulates the sleep–wake cycle. The suprachiasmatic nucleus projects to the pineal gland to release melatonin, which promotes sleep. The nucleus is synchronized by external cues known as *zeitgebers*, of which the strongest is light. Light inhibits the release of melatonin from the pineal gland and in this way sleep is influenced by the day–night cycle.

The homeostatic process refers to an increased propensity for sleepiness with longer periods of being awake. Adenosine is a byproduct of the waking brain, and levels rise with prolonged periods of wake, increasing the tendency for sleep. Caffeine is an adenosine antagonist and is used to promote wakefulness.

In the morning, the suprachiasmatic nucleus output is low. The homeostatic drive increases over the day and is opposed by increased output from the suprachiasmatic nucleus. By the end of the day, suprachiasmatic nucleus output is decreased through inhibition by melatonin, and the homeostatic drive is increased, resulting in the onset of sleep.

The circadian rhythm of sleep becomes clinically relevant when the sleep–wake cycle is changed such as in shift work or jet lag. Adaptation becomes difficult both because of sleep loss and increased homeostatic drive for sleep and because the circadian rhythm continues on its own established schedule. Elderly individuals who have difficulty consolidating sleep and those with neurodegenerative diseases often have disruption of the normal cycling of sleep consistent with circadian rhythm disorders. Light therapy can be a useful tool to help reset the circadian rhythm and establish a normal sleep–wake cycle.

NEUROANATOMY OF SLEEP

Changes between wake, NREM, and REM sleep are produced through modulation of neurotransmitters and neuromodulators interconnecting the neuronal system that regulates sleep.

The ascending arousal system is important in maintaining wakefulness. It is composed of a cholinergic branch and a monoaminergic branch. The cholinergic branch includes the pedunculopontine and laterodorsal tegmental nuclei, which project to the thalamic reticular nucleus in order to activate the cerebral cortex. Acetylcholine excites the thalamic and cortical neurons maximally during wake and REM sleep.

The monoaminergic branch includes the locus coeruleus, dorsal and median raphe nuclei, tuberomammillary nuclei, and ventral periaqueductal gray matter. Histamine (H_3), norepinephrine, and serotonin are released from these various nuclei, which are also maximally active during wakefulness in order to activate the cerebral cortex. The monoaminergic system is quiet in NREM sleep and turned off in REM sleep. Hypocretin neurons in the lateral hypothalamus augment this activation of the cortex during wakefulness.

Dopamine is elevated during periods of wakefulness, and dopaminergic neurons modulate cortical activation indirectly through regulatory activity of the globus pallidus and the thalamus.

Sleep onset is associated with a rapid deactivation of both the monoaminergic and cholinergic branches of the arousal system. GABAergic neurons in the preoptic hypothalamus promote sleep onset. The ventrolateral preoptic nucleus sends descending inhibitory projections to multiple arousal systems during sleep.

The homeostatic process and the circadian clock determine the activity of the ventrolateral preoptic nucleus. In NREM sleep, this nucleus inhibits both the cholinergic and monoaminergic branches of the ascending arousal system to induce sleep. In REM sleep, only the monoaminergic nuclei are inhibited, but the cholinergic nuclei are active.

REM sleep is driven by cholinergic neurons in the pons. Descending cholinergic projections produce muscle atonia by activating neurons in the pontine reticular formation and ventral reticular formation that then project to the spinal cord. Glycine is the essential neurotransmitter in these pathways.

The monoaminergic nuclei also inhibit the ascending arousal system during wakefulness, resulting in a system of reciprocal inhibition. This has been termed the "sleep switch." Both sides of the switch strongly inhibit each other, resulting in a feedback loop with only two possible states: sleep and wakefulness.

Hypocretin is the stabilizer of this switch. In wakefulness, hypocretin reinforces the arousal system to avert unwanted switches into sleep. Narcolepsy with cataplexy is a disorder of low levels of hypocretin, causing a lack of stability in the "sleep switch," resulting in frequent and unwanted transitions between sleep and wakefulness.

APPROACH TO THE PATIENT WITH SLEEP DISORDERS

Clinical Evaluation

Complaints related to sleep and wakefulness are pervasive in the general population. Approximately 30 percent of adults report one or more symptoms of insomnia including difficulty falling asleep, staying asleep, awakening too early, or nonrestorative sleep. It is estimated that 4 to 21 percent experience EDS at least 3 days per week.[1] Only 6 percent of patients with sleep complaints see a physician specifically for a sleep problem, and many others resort to over-the-counter medications or self-remedies.

Sleep disorders are associated with significant morbidity and mortality. Insomnia, for example, is associated with impairment of all aspects of quality of life including physical functioning, bodily pain, social functioning, and mental health. Obstructive sleep apnea (OSA) increases the risk of cardiovascular and cerebrovascular disease as well as causing motor vehicle accidents.

Individuals with sleep disturbances present with any of four main complaints. The first is insomnia, which may be described as difficulty in falling asleep or staying asleep, having an insufficient amount of sleep, or poor quality of sleep. The second is EDS, which may manifest as feelings of lack of energy or tiredness associated with naps, falling asleep at inappropriate times, or difficulty with concentration or memory. The most common cause of EDS is insufficient time for sleep. The third complaint is of abnormal sleep behavior, usually described by a bed partner. The fourth is of an inability to sleep at the desired time. A single sleep disorder may be associated with multiple complaints.

It is important to understand the motivation of patients in seeking treatment. For example, insomnia may impact job performance and cause a concern for loss of employment. A complaint of snoring may present only after a person is forced to sleep in a separate room to prevent disturbing a bed partner. The International Classification of Sleep Disorders (ICSD) has helped unify the approach to sleep complaints by classifying over 60 sleep disorders.

Patients should fill out a sleep questionnaire and a 1- to 2-week sleep diary. The questionnaire should address the patients' usual sleep hours, nocturnal awakenings, daytime napping, work hours, snoring, daytime functioning, sleep environment, movements in sleep (e.g., leg movements), abnormal behaviors in sleep (e.g., sleepwalking), lifestyle factors (e.g., caffeine intake), weight changes, past medical history, social history, medications, family history of sleep disorders, and other sleep symptoms (e.g., cataplexy or sleep paralysis). A sleep diary should record the time of getting in and out of bed, sleep onset time, awakenings, naps, exercise, sleep medication, and caffeine intake. There are several scales used to assess the degree of daytime sleepiness in a person, such as the Epworth Sleepiness Scale, that can help with diagnosis.

In addition to general medical and neurologic examinations, the physical examination should include the patients' weight, height, body mass index (BMI), blood pressure, and neck circumference. The upper airway should be inspected for pharyngeal narrowing, tonsillar enlargement, uvula enlargement or edema, a large tongue, low-lying palate, and micrognathia, all of which are risk factors for sleep apnea.

Laboratory Testing

POLYSOMNOGRAPHY

The PSG is the most useful diagnostic tool in sleep medicine. Several physiologic variables are recorded during the PSG, including EEG, EMG of the chin and legs, EOG, electrocardiogram, airflow through the nose and mouth, respiratory effort, and oxygen saturation.

The EEG is usually performed using six channels: two frontal leads, two central leads, and two occipital leads. Various stages of sleep are better identified using particular leads, such as identifying delta waves primarily in the frontal leads. A full EEG montage is sometimes used to differentiate parasomnias from epileptiform activity. The EMG of the chin is important in identifying the reduction in muscle tone seen during REM sleep. The EMG of both legs helps capture periodic limb movements (PLMs) in sleep. The EOG is used to identify characteristic eye movements, such as occur during REM sleep. A thermistor or nasal cannula records airflow by monitoring temperature changes. The nasal cannula is attached to a pressure transducer and is more accurate in detecting respiratory changes such as hypopneas. Respiratory effort is recorded using piezoelectric belts around the chest and abdomen in order to differentiate obstructive from central apneas, which are characterized by a complete lack of respiratory effort. A pulse oximeter is usually worn on the finger to monitor oxygen saturation.

The PSG should also include videography to record behavioral changes in sleep, a body position monitor, and snore recording. Sleep is recorded in 30-second intervals termed epochs.

PSG is useful for the diagnosis of sleep-related breathing disorders, narcolepsy, PLM disorder, and REM sleep behavior disorder. When a patient is diagnosed with sleep apnea, the PSG is also used to determine the optimal positive airway pressure (PAP) for treatment; titration can be performed on two separate nights or, alternatively, a split-night study can be performed. During the split-night study, the patient is observed for the first 2 to 3 hours for signs of sleep apnea and, if it is detected, the technician will interrupt the study and begin titration. Certain sleep disorders do not require PSG, such as insomnia, restless legs syndrome (RLS), and circadian rhythm disorders, unless a concomitant breathing disorder is suspected.

MULTIPLE SLEEP LATENCY TEST

The multiple sleep latency test (MSLT) is used to document pathologic daytime sleepiness and to make a diagnosis of narcolepsy or idiopathic hypersomnia. It consists of five nap opportunities each 2 hours apart beginning 2 hours after the termination of the nocturnal PSG. The recording montage consists of the EEG, chin EMG, EOG, and electrocardiogram. Each nap is terminated either 20 minutes after starting (if the patient does not fall asleep) or 15 minutes after the first 30-second epoch of sleep.

The average latency to sleep onset across all five naps is calculated. A mean sleep latency of 8 minutes or less with at least two sleep-onset REM periods strongly suggests a diagnosis of narcolepsy. It is important that the MSLT is performed after at least 6 hours of total sleep time because sleep deprivation can mimic narcolepsy.

MAINTENANCE OF WAKEFULNESS TEST

The maintenance of wakefulness test, a variation of the MSLT, measures a person's ability to stay awake in the daytime. It is useful in determining the effects of treatment on daytime sleepiness and consists of four trials of remaining awake while sedentary every 2 hours, beginning 2 hours after the patient has awakened from nighttime sleep. Each trial is terminated after 40 minutes if the patient remains awake or after the first three consecutive epochs of stage N1 sleep or the first epoch of any other stage of sleep. The mean sleep latency across all four naps is calculated. This test is often used to assess the ability of commercial drivers to remain awake at work.

ACTIGRAPHY

Actigraphy is used to objectively assess the patient's sleep–wake schedule in the normal environment for a 1- to 2-week period. The actigraph is worn on the nondominant wrist and detects small movements to establish periods of rest and activity which equate with wake and sleep. It is most useful in patients with circadian rhythm disorders or insomnia.

HOME SLEEP STUDIES

A home sleep study is a simplified version of a PSG that usually focuses exclusively on respiratory parameters, without measurement of sleep stages. There are various versions, but all should include nasal airflow, respiratory effort, and an oximeter. Home sleep studies can be used in patients with a high pretest probability of having OSA but have a reduced sensitivity for capturing mild cases. In practice, they are used in patients with suspected severe uncomplicated OSA to confirm the diagnosis. The home sleep study is not clinically useful for patients with suspected insomnia, narcolepsy, circadian rhythm disorders, parasomnias, or nocturnal movement disorders.

INSOMNIA

Standardized Definitions

Insomnia is one of the most prevalent health complaints, with 30 to 50 percent of the population reporting transient insomnia. When even more specific diagnostic criteria are utilized, the rates still range between 5 and 20 percent.[2]

Criteria for insomnia differ somewhat between the three main classification systems: International Classification of Diseases, 11th edition (ICD); Diagnostic and Statistical Manual, Treatment Revision, 5th edition

(DSM-V-TR); and International Classification of Sleep Disorders, 3rd edition (ICSD-3). The ICSD-3 classifies insomnia based on duration of symptoms whereas the DSM-V focuses on medical or psychologic comorbidities presenting with insomnia symptoms.

For many years, insomnia was thought of as a symptom of another underlying condition. Classification symptoms all distinguish between forms of "primary" (insomnia occurring without any comorbidities) and "secondary" insomnia (insomnia due to another disorder). Clinical practice has traditionally been to treat the "cause" first, with the belief that insomnia would remit after the underlying condition was addressed. A major shift in this line of thought has taken place in recent years, with a significant amount of research negating the view of primary and secondary insomnia. The relationship between sleep and psychiatric disorders appears to be bidirectional, and causative factors can be extremely difficult to separate from the insomnia itself. The symptom of "nonrestorative" sleep has also been called into question as it is typically related to another sleep disorder that impairs sleep quality.

Risk Factors and Common Comorbidities

Insomnia is most commonly seen in women, older adults, populations with lower socioeconomic status, those with divorce or marital separation, and in those with comorbid psychiatric or medical disorders. Insomnia is commonly observed in neurologic disorders, particularly Parkinson disease, Alzheimer disease, epilepsy, stroke, multiple sclerosis, and traumatic brain injury. Patients with medical conditions such as pain disorders and heart disease are all at increased risk of insomnia.

Consequences

Insomnia is a risk factor for the development of anxiety, depression, substance use, and suicidality. It is also associated with poor attention and concentration, increased work absenteeism, higher medical costs, increased rates of motor vehicle accidents, more falls in the elderly, and reduced overall quality of life.

Clinical Assessment and Diagnosis

The history should focus on symptoms, chronology, exacerbating and alleviating factors, social, medical, and psychiatric precipitants and comorbidities, as well as previous therapies and their success. Symptoms of insomnia range from difficulty in falling or staying asleep to early morning awakenings, or a combination of these symptoms.

TABLE 51-1 ■ Medications and Substances Commonly Associated With Insomnia

- Alcohol
- Caffeine
- Nicotine
- Antidepressants
- Decongestants
- Corticosteroids
- Bronchodilators
- β-Adrenergic antagonists
- Stimulants
- Statins

Understanding a patient's typical sleep—wake periods (on weekdays and weekends) and what the patient does both during the day (including work schedule, napping, and exercise) and in the hours leading up to bedtime and throughout the night is important. A detailed analysis of the patient's thoughts and attitudes about sleep and maladaptive behavioral strategies is crucial to design effective treatment. Symptoms of any other sleep disorders that might impact sleep quality should be assessed, such as snoring, restless legs, apnea, pain, and parasomnias. A medication (prescription and over-the-counter) and substance use history (including time of day taken) is important and should include any caffeine, alcohol, or tobacco use. Table 51-1 lists medications and substances commonly associated with insomnia and Table 51-2 summarizes common comorbid medical conditions.

The most common assessment tools for insomnia include a sleep diary and questionnaires such as the

TABLE 51-2 ■ Medical Conditions Commonly Comorbid With Insomnia

Neurologic: stroke, Parkinson disease, neuropathy, traumatic brain injury

Pulmonary: chronic obstructive pulmonary disease, asthma

Endocrine: diabetes, hypertension

Renal: chronic renal failure

Rheumatologic: rheumatoid arthritis, fibromyalgia, osteoarthritis

Cardiovascular: congestive heart failure, coronary artery disease

Gastrointestinal: gastroesophageal reflux

Insomnia Severity Index and the Pittsburgh Sleep Quality Index. Overnight PSG may be warranted in cases in which a comorbid additional sleep disorder is considered or when treatment for insomnia has been unsuccessful. Actigraphy can be useful for establishing circadian disturbances that may be contributory as well as for tracking sleep–wake times and treatment response.

Pathophysiology

Insomnia is considered a disorder of hyperarousal, with patients demonstrating higher levels of cortisol, increased basal metabolic rates, and the presence of excessive beta or gamma activity on EEG.

The 3P (predisposing, precipitating, and perpetuating) model describes the development and maintenance of chronic insomnia. This model suggests that individuals may be vulnerable to developing insomnia based on predisposing factors that may be biologic (e.g., a diagnosis of chronic pain), psychologic (e.g., a family history of anxiety), or social (e.g., working shifts). Precipitating factors (e.g., a divorce or cancer diagnosis) may start an acute insomnia episode that is followed by behaviors that perpetuate a chronic insomnia, including worrying about sleep or consequences of poor sleep, spending more time in bed in an attempt to catch up on sleep, napping, and using more caffeine, alcohol, or over-the-counter medications.

Treatment

Treatment for insomnia generally involves nonpharmacologic and pharmacologic approaches. Unless a main, obvious underlying cause is found, treatment should focus on insomnia as a separate diagnosis to any other medical or psychiatric issues that may present simultaneously. Nonpharmacologic treatment is always preferred as a first-line intervention, though for many patients a combination of both behavioral and pharmacologic methods may be most beneficial.

Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) is regarded as a highly effective first-line treatment for insomnia. CBT is as effective as the newer benzodiazepine receptor agonists and appears to be more effective in the long term than pharmacologic methods. CBT is as effective in patients with or without comorbid pain, cancer, depression, and anxiety. It improves sleep onset latency, sleep quality, number of awakenings, and total sleep time. It has also been used to help taper off hypnotics; CBT and pharmacotherapy may be started together acutely and then CBT alone may be used chronically following initial gains.

CBT treatments can vary from as few as two 30- to 60-minute sessions to as many as 12 sessions. The core treatment interventions include stimulus control, sleep restriction and sleep hygiene, relaxation training, light therapy, and cognitive therapy.

Stimulus control instructs the patient to use the bed only for sleep and sex, therefore allowing the bed to become conditioned only for those two behaviors. Patients are told to go to bed only when sleepy and to get out of bed if unable to sleep and only return to bed when sleepy again. When out of bed, patients should engage in behaviors that are calm, quiet, and relaxing—all done in dim light without any screen time (e.g., television, cell phones, computers).

Sleep restriction is aimed at minimizing the gap between the amount of time the patient spends in bed and the actual amount of time they are asleep. Patients are advised to select the same awakening time daily (using an alarm) and to allow for a sleep window that approximates the average total sleep time over the past week, but never limiting this to less than 4.5 hours. Sleep hygiene aims to eliminate sleep-incompatible behaviors as described in Table 51-3.

Cognitive therapy teaches patients to challenge maladaptive thoughts and beliefs about sleep, including minimizing worry regarding sleep time and its consequences, and to think realistically about their concerns. Relaxation therapy is helpful for some patients and may include deep breathing or muscle relaxation. Though not routinely used as a part of CBT, strategic use of bright light in the morning or before bedtime may help with some patients who may have a circadian component to their insomnia.

TABLE 51-3 ■ Common Sleep Hygiene Recommendations

1. Keep the same bedtime and wake time every day.
2. Limit liquids, heavy meals, tobacco, and alcohol within 3 hours of bedtime.
3. Limit caffeine at least 8 hours before bedtime.
4. Exercise regularly, but not within 3 hours of bedtime.
5. Wind down for at least 1 hour before bed in dim lights. Engage in something quiet, calm, and relaxing.
6. Keep the bedroom quiet, cool, and dark.
7. Take a hot shower or bath 1.5–2 hours before bedtime, not right before bed.
8. Limit any screen time (TV, tablets, phone, computer) within an hour of bedtime and during the nighttime hours.

PHARMACOLOGIC INTERVENTIONS

Benzodiazepine Receptor Agonists

The medications for insomnia (Table 51-4) approved by the U.S. Food and Drug Administration (FDA) include the benzodiazepines (e.g., temazepam, flurazepam, estazolam, quazepam, triazolam) and nonbenzodiazepine hypnotics (e.g., zaleplon, zolpidem, and eszopiclone). All of the benzodiazepine receptor agonists have been shown to be efficacious and reduce sleep latency with an increase in overall sleep time. There is no single medication that is preferable to any other FDA-approved medication; the pros and cons of each (half-life, cost, past response to treatment) need to be considered with each patient.

These medications are all absorbed rapidly but vary in their half-life. Medications with a longer half-life may be more beneficial for a patient with sleep maintenance and early morning awakening insomnia, whereas a shorter half-life may be preferred for a patient with prolonged sleep-onset latency. Long-acting medications also have a greater risk of daytime somnolence and impaired cognitive functioning, especially in older adults. Newer medications such as zaleplon, zolpidem, and eszopiclone have fewer daytime side effects.

Longer-term efficacy and safety trials with newer nonbenzodiazepines in patients with insomnia have shown continued efficacy with increasing total sleep time and decreasing sleep latency, with overall improvement in daytime functioning and no development of physiologic tolerance. Zaleplon has a short half-life (1 hour) and is best for sleep-onset problems. Zolpidem can increase total sleep time, but the extended-release form also reduces wake time following sleep onset. A newer form of zolpidem (zolpidem tartrate) is fast-acting and aimed at middle of the night awakenings when the patient has at least 4 hours remaining before awakening; taken sublingually, it rapidly dissolves and helps the patient return to sleep. Dosages of this formulation differ based on sex (1.75 mg for women, 3.5 mg for men). Eszopiclone has been found to be effective for both sleep onset and maintenance issues.

Common side effects of benzodiazepines include residual sedation, impaired psychomotor performance, falls, and an increased risk of motor vehicle accidents. Tolerance, abuse, and dependence (especially with benzodiazepines), rebound insomnia, and anterograde amnesia are also concerns. Since these medications can reduce ventilatory drive, caution should also be used in patients with chronic obstructive pulmonary disease or untreated sleep-related breathing disorders.

The newer nonbenzodiazepines do not tend to have physiologic dependence as a concern, though psychologic dependence can develop. These medications most commonly have drowsiness, dizziness, and headaches as reported side effects. Though less commonly reported, amnesia and complex sleep-related behaviors such as sleepwalking or sleep eating have been reported.

TABLE 51-4 ■ Medications Commonly Used for Treatment of Insomnia

FDA-Approved Pharmacologic Treatments

Drug	Dose (mg)	Half-Life (h)	Insomnia Type
Zolpidem	5–10	1.5–2.4	Sleep onset/ maintenance
Zolpidem CR	6.25–12.5	1.6–4.5	Sleep onset/ maintenance
Zolpidem tartrate	1.75–3.5	1.4–3.6	Sleep maintenance
Eszopiclone	1–3	6	Sleep onset/ maintenance
Zaleplon	5–20	1	Sleep onset
Ramelteon	8	1–2.6	Sleep onset
Suvorexant	10–20	12	Sleep onset
Lemborexant	5–10	17–19	Sleep onset/ maintenance
Doxepin	3–6	10–30	Sleep onset
Temazepam	7.5–30	8–15	Sleep maintenance
Estazolam	1–2	10–24	Sleep maintenance
Flurazepam	15–30	48–120	Sleep maintenance
Quazepam	7.5–15	39–73	Sleep maintenance
Triazolam	0.125–0.25	2–6	Sleep onset

Common Off-Label Pharmacologic Treatments

Drug	Half-Life (h)	Side Effects
Amitriptyline	12–24	Dry mouth, dizziness, weight gain
Trazodone	3–14	Dizziness, daytime sedation, constipation
Mirtazipine	13–40	Weight gain, constipation
Quetiapine	6	Elevated liver enzymes, agitation
Olanzapine	20–54	Weight gain, orthostasis
Gabapentin	5–7	Dizziness, ataxia, nausea

Melatonin Receptor Agonists

Ramelteon is an FDA-approved nonbenzodiazepine receptor agonist medication to treat sleep-onset insomnia. It is not a scheduled substance and does not act on the GABA receptors. Rather, it is a selective melatonin agonist that binds to the melatonin receptors MT1 and MT2 in the suprachiasmatic nucleus. Particularly helpful in older adult populations, ramelteon has been shown to help increase total sleep time and reduce sleep latency. Potential side effects include drowsiness, fatigue, nausea, dizziness, and headache. It has also been studied in patients with mild-to-moderate OSA, with no increase in apneic episodes.

Suvorexant is an FDA-approved orexin antagonist used to treat sleep onset and sleep maintenance insomnia. It is the first in a new class of insomnia medications targeted at orexin antagonism. Specifically, suvorexant blocks the binding of wake-promoting neuropeptides orexin A and orexin B to receptors OX1R and OX2R, which is thought to suppress wake drive. Suvorexant is effective at decreasing sleep latency and increasing total sleep time. Orexin antagonism may also cause potential side effects such as somnolence and mild cataplexy. Other potential side effects include headache, dizziness, and abnormal thinking or behavioral changes. Rebound insomnia may occur upon stopping suvorexant.

Lemborexant, a newer orexin receptor antagonist, was recently approved by the FDA for treating sleep onset and sleep maintenance insomnia. It reduces sleep latency and decreases wake periods after sleep onset, and is not associated with rebound insomnia or withdrawal effects upon discontinuation. Its most common side effects are daytime somnolence and nightmares; complex sleep behaviors, such as sleep walking and sleep driving, also have been reported.

Antidepressant Medications

Low-dose doxepin (3 to 6 mg) has been FDA approved as a treatment for sleep-maintenance insomnia. It is particularly useful for increasing total sleep time and sleep efficiency in patients with primary insomnia. Given their sedating properties, other antidepressants are commonly used (in much lower dosages than for depression treatment). Although limited evidence exists demonstrating efficacy in the treatment of insomnia, practitioners commonly prescribe trazodone, mirtazapine, and amitriptyline because they are perceived as safer than benzodiazepines with a lower potential for dependence. Many patients also have co-existing depression, anxiety, or both, and prescribing physicians feel that these medications may help with both mood and sleep disturbance. Side effects include drowsiness, weight gain, increased suicidal ideation in young adults, dizziness, cardiac arrhythmias, and priapism (with trazodone in particular).

Alternative Medications

Although many patients resort to over-the-counter medications as sleep aids (particularly those that contain diphenhydramine), these medications are not advised in the treatment of chronic insomnia. Atypical antipsychotics (especially quetiapine and olanzapine) are often used off-label to treat both primary insomnia and insomnia comorbid with psychiatric conditions. Case studies have reported effectiveness, particularly with older adults. However, there is a black-box warning regarding the use of antipsychotics in the elderly due to an increased risk of death. Other side effects commonly include weight gain, orthostasis, daytime sedation, agitation, and elevated liver enzymes.

Antiepileptic medications, particularly gabapentin, have also been used to treat insomnia, particularly in patients with comorbid conditions (especially with generalized anxiety disorder, epilepsy, and chronic pain). Side effects include daytime sedation, dizziness, mood changes, and cognitive impairment.

The effects of melatonin taken before bedtime have not been routinely demonstrated, although some reports have suggested decreases in sleep-onset latency. Generally well tolerated by patients, melatonin is not regulated by the FDA and over-the-counter preparations can vary greatly. It is not considered a standard treatment for insomnia and appears to be better suited for treatment of circadian rhythm disorders.

HYPERSOMNIAS

EDS has many implications, including an increased risk of injury at work or home, impaired alertness, increased risk of motor vehicle accidents, and lower overall productivity. EDS can also cause psychologic stress with family, friends, and co-workers.

Narcolepsy

Narcolepsy is a disorder of EDS that is usually associated with cataplexy and other REM phenomena such as sleep paralysis and hypnagogic hallucinations. Sleep regulation and wakefulness are disrupted with rapid transitions between wakefulness and REM sleep, thereby resulting in fragmented sleep and EDS.

Although onset can occur at any age, narcolepsy most commonly begins in the second decade of life, with a second peak seen around 35 years of age. There is a prolonged latency of about 10 years from the time of symptom onset to diagnosis, although improved awareness is shortening this interval. Narcolepsy is usually a sporadic disease with only 1 to 4 percent of cases being autosomal-dominantly inherited.

CLINICAL FEATURES

Excessive Daytime Sleepiness

EDS is the hallmark symptom seen in all patients with narcolepsy and is characterized by a constant baseline sleepiness, along with lapses into sleep throughout the day. Short naps are refreshing, but sleepiness returns within a few hours. Sleep attacks (sudden onset of sleep or the irresistible urge to sleep) can occur throughout the day. Activities that are passive increase the likelihood that sleep will occur, but in severe cases sleep attacks can occur during activities such as talking, standing, eating, or driving. Automatic behaviors (activities where the patient is functionally capable but without recall of the events) are also seen in some patients. For example, a patient can drive to a location without remembering the process of getting there.

Cataplexy

Cataplexy is defined as a sudden loss of muscle tone associated with emotion. It is pathognomonic for narcolepsy, although some patients with narcolepsy do not have cataplexy. Patients often describe knee buckling, head dropping, facial twitching, jaw dropping, or weakness of the arms. Emotions that elicit cataplexy are usually positive, such as laughter, excitement, or joy; they can also be negative, such as anger or frustration. If all striated muscles are involved, patients may fall. However, several seconds of build-up often precede a full attack, so most patients are able to sit down to prevent a fall. Patients may avoid emotional situations, such as social events where cataplexy may occur, affecting quality of life.

Sleep Paralysis

Sleep paralysis is a temporary state of involuntary immobility occurring in transitions between REM sleep and wakefulness. Patients are unable to make gross body movements or speak, but they can open their eyes and are aware of their surroundings. Episodes may last a few minutes and abate either spontaneously or when interrupted by noise or other external stimuli. Sleep paralysis can be frightening, especially when first experienced. Often sleep paralysis is accompanied by hypnagogic hallucinations. About 20 to 50 percent of patients with narcolepsy experience sleep paralysis, but sleep paralysis is also common in the general population.

Hypnagogic Hallucinations

Hypnagogic hallucinations are vivid visual, auditory, tactile, or even kinetic perceptions that, like sleep paralysis, occur during the transitions between wakefulness and REM sleep. Examples include a sensation of impending threat, feelings of suffocation, and sensations of floating, spinning, or falling. Hypnagogic hallucinations occur in 40 to 80 percent of patients with narcolepsy and cataplexy. They are easy to distinguish from the hallucinations occurring in psychiatric disease because patients with narcolepsy usually recognize the events as not real. Psychiatric hallucinations also occur at any time of day, whereas hypnagogic hallucinations surround the sleep period.

Disturbed Nocturnal Sleep

Because narcolepsy is a disorder of EDS, disturbed nocturnal sleep is often overlooked. Patients with narcolepsy typically fall asleep quickly, but have difficulty in maintaining sleep. Frequent arousals are often reported along with difficulty in falling back to sleep. The total amount of sleep in a 24-hour period is the same as in normal individuals; however, it is distributed throughout the day and night, causing daytime sleep attacks and fragmented nocturnal sleep.

Associated Symptoms

Disturbances in memory, concentration, and attention are common in narcolepsy, probably secondary to EDS. REM sleep behavior disorder and PLMs may occur as well. Patients with narcolepsy also report more depressive ideation.

Patients with narcolepsy with cataplexy often have a high BMI or obesity, attributed to metabolic changes resulting from hypocretin loss. A high BMI may also predispose patients to developing OSA; at least 25 percent of patients with narcolepsy have both conditions, which together can worsen EDS, mood, and cognition.

DIAGNOSIS

The differential diagnosis of EDS is shown in Table 51-5. The diagnosis of narcolepsy with cataplexy can be made based on a clear history of EDS and cataplexy. The diagnosis should be confirmed by nocturnal PSG followed by

TABLE 51-5 ■ Differential Diagnosis of Excessive Daytime Sleepiness

Sleep apnea
Behaviorally induced insufficient sleep time
Idiopathic hypersomnia
Recurrent hypersomnia (Kleine–Levin syndrome)
Circadian rhythm disorder, shift work disorder
Metabolic encephalopathy
Drug intoxication or withdrawal
Depression
Epilepsy
Malingering

an MSLT. The diagnosis of narcolepsy without cataplexy can be more difficult and requires a PSG and MSLT.

Nocturnal PSG shows a shortened REM latency in 50 percent of patients. Sleep efficiency is often reduced, with multiple awakenings and an increased percentage of stage N1 sleep. The MSLT should show a mean sleep latency of 8 minutes or less along with two or more sleep-onset REM periods in the setting of sufficient nocturnal sleep.

A less commonly used, but very specific and sensitive method to make the diagnosis is through measurement of cerebrospinal fluid (CSF) hypocretin-1 level, which is less than 110 pg/mL in 90 percent of patients with narcolepsy with cataplexy. Hypocretin loss is now recognized to be the cause of human narcolepsy with cataplexy, and symptoms begin when the majority of hypocretin cells have degenerated.

Narcolepsy is now classified into different types. In type 1, EDS is accompanied either by cataplexy or by low CSF hypocretin levels; in type 2, less severe EDS occurs without cataplexy and with normal CSF hypocretin levels.

PHARMACOLOGIC TREATMENTS

There is no cure for narcolepsy. Treatment goals are to improve quality of life, EDS, and cataplexy as well as other bothersome REM phenomena. A variety of medications can be used to treat these symptoms (Table 51-6).

Excessive Daytime Sleepiness

Modafinil and armodafinil are often used to treat EDS. Sodium oxybate, discussed later, is also effective in treating EDS as well as cataplexy. The various forms of modafinil are effective wake-promoting agents with good safety and tolerability measures and a low abuse potential. Women of childbearing age taking oral contraceptives should use alternative contraception when taking modafinil or armodafinil, as the metabolism of ethinylestradiol may be increased. In the past, amphetamines were the main treatment for EDS; dextroamphetamine, methamphetamine, and combinations of amphetamine salts are helpful with improving daytime alertness, but side effects limit their use.

Solriamfetol is a selective dopamine and norepinephrine reuptake inhibitor now approved by the FDA for the treatment of excessive sleepiness in adult patients with narcolepsy or OSA. Solriamfetol is dosed as a once-daily medication to be taken upon awakening to minimize interference with sleep schedule. Common

TABLE 51-6 ■ Medications Typically Prescribed for Narcolepsy

Drug Name	Dose	Clinical Use	Side Effects
Modafinil (Provigil)	200–400 mg daily in divided dose	EDS	Headache, nausea
Armodafinil (Nuvigil)	150–250 mg daily	EDS	Same as modafinil
Sodium oxybate (Xyrem)	4.5–9 g daily in divided doses	Cataplexy, EDS, broken nighttime sleep	Nausea, vomiting, dizziness
Solriamfetol (Sunosi)	75–150 mg daily	EDS	Headache, anxiety, insomnia
Dextroamphetamine (Dexedrine)	15–60 mg daily	EDS	Irritability, sweating, headaches, tremors
Methylphenidate (Ritalin)	20–60 mg daily in divided doses	EDS	Same as dextroamphetamine
Venlafaxine	75–225 mg daily	Cataplexy	Insomnia, irritability
Pitolisant (Wakix)	17.8–35.6 mg daily	EDS	Headache, nausea, anxiety

EDS, excessive daytime sleepiness.

side effects include headache, nausea, decreased appetite, insomnia, and anxiety.

Pitolisant is a selective H_3 receptor antagonist that increases the synthesis and release of histamine, a wake promoting neurotransmitter. It has recently been approved to treat narcolepsy and is not scheduled as a controlled substance. It significantly decreases EDS. Common side effects include headache, nausea, and anxiety. Pitolisant prolongs the QTc interval, especially in patients with renal or hepatic disease, and should be avoided in patients with known QTc prolongation or cardiac arrhythmias.

Cataplexy

Sodium oxybate is effective in reducing cataplexy as well as EDS. It also reduces other REM phenomena such as sleep paralysis and hypnagogic hallucinations. Due to its sedative properties, it is commonly given in divided doses at sleep onset and then 2 to 4 hours later. Once nightly and low-sodium sodium oxybate are being studied as alternatives to the current formulation of sodium oxybate. Common side effects of sodium oxybate include nausea, vomiting, dizziness, and nocturnal enuresis. If used as recommended, sodium oxybate is safe and has a low risk of dependence or tolerance.

Tricyclic antidepressants were initially the treatment of choice for cataplexy. Medications such as protriptyline and clomipramine are effective, but side effects can be limiting. Newer norepinephrine reuptake inhibitors, such as venlafaxine and atomoxetine, may be more effective and have a more favorable side-effect profile. Selective serotonin reuptake inhibitors (SSRIs) and monoamine-oxidase inhibitors can also be used for cataplexy but are generally less effective.

Disturbed Nocturnal Sleep

Sodium oxybate increases slow-wave sleep and allows patients to sleep more continuously through the night. Newer nonbenzodiazepines such as zolpidem have also been used to consolidate nighttime sleep, but few studies have tested this approach.

NONPHARMACOLOGIC TREATMENTS

Scheduling naps, shifting work periods to times of alertness, avoiding sugar, calculated caffeine use, and following basic sleep hygiene can all benefit patients with narcolepsy. The patient should be advised against driving, bathing, swimming, and using any heavy machinery or household appliances during times of sleepiness. Psychotherapeutic strategies for the management of stressful situations, depression, and anxiety are recommended.

Idiopathic Hypersomnia

Idiopathic hypersomnia is generally less common than narcolepsy, with symptoms beginning in teenagers or young adults. It is typically under-recognized and often a diagnosis made by excluding other causes of EDS.

The primary symptom of idiopathic hypersomnia is EDS despite a full night of sleep and normal sleep architecture; idiopathic hypersomnia includes forms with and without a long sleep time. Patients with long sleep times have at least 10 hours of sleep at night, rarely awaken during nocturnal sleep, have significant difficulty in getting up in the morning, and, unlike patients with narcolepsy, do not find naps to be refreshing. Patients usually report "sleep drunkenness"—difficulty in achieving full alertness upon awakening after a full night of sleep. Patients without long sleep times have less than 10 hours of sleep at night and are less likely to report sleep drunkenness with their EDS. The differential diagnosis of idiopathic hypersomnia is similar to that of narcolepsy.

Nocturnal PSG is routinely performed to exclude other causes of daytime sleepiness and to determine the length of sleep time. An MSLT is also performed, demonstrating EDS with a mean sleep latency of less than 8 minutes and fewer than two sleep-onset REM periods (to rule out possible narcolepsy).

Treatment of idiopathic hypersomnia is similar to that of EDS in patients with narcolepsy, focusing on stimulants and wake-promoting agents, especially modafinil and armodafinil. Positive pharmacologic responses are difficult to achieve. Sleep hygiene, proper diet, and strategic use of caffeine should be utilized. Planned naps and increasing time in bed have not been found to be helpful.

Kleine–Levin Syndrome

Kleine–Levin syndrome is a rare disorder with an estimated prevalence of 1 to 2 cases per million people. Patients are mostly adolescent boys; mean age of onset is 15 years, with some rare cases beginning as early as age 9.[3] Rare familial cases have been reported, with Ashkenazi Jews in the United States and Israel particularly affected. In a majority of cases, the first episode is triggered by a high fever or infection. Disease course typically lasts 8 to 14 years with spontaneous remission in adulthood.

The hallmark symptom of Kleine–Levin syndrome is episodic hypersomnia, with sleep time increasing to over 12 hours per day. Cognitive impairment, apathy, confusion, slowness, derealization, and amnesia are typically seen. Though not reported by all patients, hypersexuality, depressed mood, and hyperphagia may occur. Between episodes, functioning returns to normal with regard to sleep needs, cognitive functioning, and appetite.

Medically based differential diagnoses include alcohol and drug use, multiple sclerosis, temporal lobe seizures, stroke, tumor, Lyme disease, and encephalitis. Typical psychiatric differential diagnoses include depression, bipolar disease, and psychotic disorders. Many patients with Kleine–Levin syndrome first present for psychiatric evaluation.

No standard treatment has been adopted for Kleine–Levin syndrome. When given at the beginning of an episode, amantadine may help to shorten or stop an event. Lithium, lamotrigine, and valproic acid may also be beneficial. Stimulants have shown limited efficacy and may worsen behavioral and cognitive symptoms. Risperidone may help with severe cognitive changes. Family supervision is paramount during episodes. Between episodes, the patient should keep a regular sleep–wake schedule and alcohol and nicotine should be avoided.

SLEEP-RELATED BREATHING DISORDERS

Epidemiology

The estimated prevalence of sleep apnea in the general population ranges between 9 and 85 percent depending on how OSA is defined.[4] Sleep apnea increases in prevalence with increasing age, male sex, and obesity. It is most common in men over the age of 40 years; the incidence in women increases after menopause. Obesity is present in approximately 70 percent of OSA patients. Many nonobese patients have apnea because of the anatomy of their airway, however, and this is underdiagnosed.

Definitions

OSA occurs when there are repetitive episodes of complete or near-complete cessation of airflow during sleep, with continued respiratory effort against a closed airway. These events may cause either a decline in oxygen saturation or a cortical arousal from sleep. Partial reduction in airflow with preserved respiratory effort is defined as a hypopnea.

Obstructive events can occur in any stage of sleep but are most severe during REM sleep, when muscle atonia is present. The pathophysiologies of obstructive apneas and hypopneas are similar and result in the same physiologic consequences. Thus, by PSG they are combined in a single measure known as the apnea-hypopnea index (AHI).

The diagnosis of OSA in adults is made when the AHI is 5 or greater. An index of 5 to 14 is considered to indicate mild OSA; between 15 and 29, moderate OSA; and 30 and above is severe OSA. Generally, the magnitude of the AHI reflects symptom severity; however, some patients may have minimal symptoms but severe sleep apnea on PSG.

Symptoms

Symptoms of OSA are present during both the night and day. Nocturnal symptoms include snoring, gasping or choking, cessation of breathing, frequent arousals, nocturia, excessive movement in sleep, and hyperhidrosis. However, snoring can be the only symptom, and patients are often unaware of any symptoms; it is therefore helpful to interview the bed partner or a family member. Upon awakening, patients often report having a dry mouth, nasal congestion, headaches, or heartburn.

In the daytime, EDS is usually present as a result of respiratory events causing disturbed nighttime sleep. Patients report dozing off when sedentary and have difficulty with concentration and attention, which puts them at increased risk of motor vehicle accidents. Individuals with sleep apnea have a motor vehicle accident rate that is approximately threefold higher than the general population. OSA is particularly concerning in commercial drivers and pilots.

Predisposing Factors

It has been shown in many studies that obesity, particularly truncal obesity, increases the likelihood of sleep apnea. An increase of BMI by 1 standard deviation is associated with a fourfold increase in OSA prevalence.

The prevalence of sleep apnea increases with age, with the steepest increase during the transition from middle to older age. In those older than 65, the prevalence of a sleep-related disorder of breathing ranges from 49 to 90 percent.[4] The ratio of sleep apnea in men and women is about 2 to 1; however, disease prevalence triples in postmenopausal women, even when corrected for BMI.

There may be a genetic predisposition to sleep apnea. The relative risk is between 3 and 5 when parents have OSA and is independent of lifestyle habits. This risk may be due to craniofacial size and shape as well as soft-tissue structures and may explain the higher prevalence found in certain ethnic groups, including Asians and African-Americans. Other structural factors that predispose to OSA include chronic nasal congestion, allergies, deviated nasal septum, tonsillar or adenoid hyperplasia or both, retrognathia or micrognathia, dental mandibular crowding, macroglossia, high-arched palate, enlarged uvula, vocal cord paralysis, increased pharyngeal length, and hereditary craniofacial syndromes such as Pierre Robin syndrome or Treacher Collins syndrome. Additional factors include smoking, alcohol intake, chronic nasal congestion, Down syndrome, acromegaly, hypothyroidism, polycystic ovary syndrome, and neuromuscular diseases.

Physiologic Consequences

During an obstructive apnea or hypopnea, tidal volume and oxygen saturation decline, and carbon dioxide levels rise. Sympathetic tone increases with each event, causing vasoconstriction and often tachycardia that results in increased blood pressure. Other physiologic responses include increased release of inflammatory mediators, elevation of leptin levels, increases in platelet adhesiveness, and raised fibrinogen levels. Generalized endothelial damage also likely occurs.

Pathophysiologic effects of OSA contribute to increases in morbidity and mortality. Several large studies have shown a dose-dependent relationship between sleep apnea and hypertension. Refractory hypertension is a known comorbidity of sleep apnea, and treatment of OSA may lower blood pressure in these patients.

Sleep apnea is also a risk factor for atrial fibrillation[5] and results in a 50 percent reduction in postcardioversion maintenance of normal sinus rhythm after ablation. Studies have shown that untreated sleep apnea increases the risk of coronary artery disease, myocardial infarction, heart failure, cardiovascular mortality, and pulmonary hypertension.[6]

The risk of stroke increases in patients with sleep apnea.[7] This association is most robust in those with moderate or severe sleep apnea. OSA also worsens damage caused by a stroke and increases the risk for subsequent stroke. Sleep apnea after stroke has been shown to worsen cognitive and motor ability.

Clinical Evaluation

PSG should be performed if sleep apnea is suspected. Obstructive apneas are defined as a 90 percent reduction in air flow lasting for at least 10 seconds, with continued inspiratory effort in thoracic and abdominal muscles (Fig. 51-2). This is in contrast to a central apnea, in which there is complete absence of inspiratory effort. An apnea can also be mixed, characterized by initial cessation of both flow and effort, followed by the appearance of effort without flow.

A hypopnea is defined as a reduction of 30 percent or more in flow for at least 10 seconds, associated with a 3 percent oxygen desaturation (Fig. 51-3). Apneas and hypopneas are combined to calculate the AHI.

A respiratory effort-related arousal is characterized by a series of breaths lasting for at least 10 seconds, with flattening of the nasal pressure waveform leading to an arousal from sleep. If esophageal pressure is measured by manometry, it will show progressively more negative

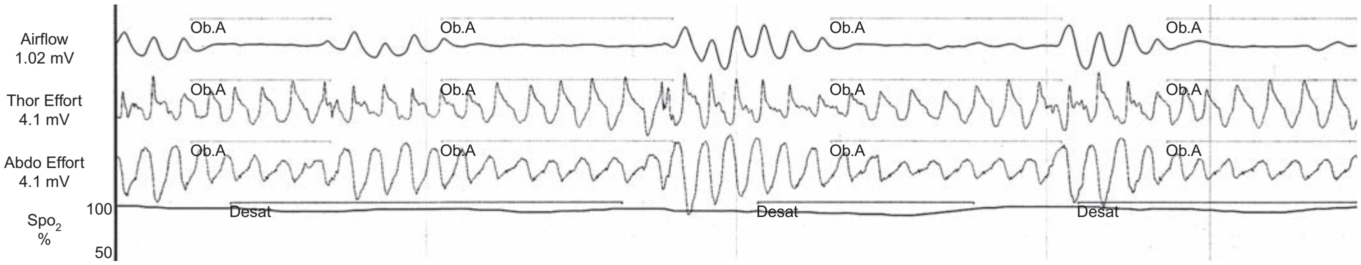

FIGURE 51-2 ■ Obstructive apnea. This 2-min screen shows complete cessation of airflow for at least 10 seconds, accompanied by persisting respiratory efforts of the thoracic (Thor Effort) and abdominal muscles (Abdo Effort). The associated oxygen desaturation (Desat) is not essential for the events to be scored as obstructive apnea (Ob.A). (From Avidan A, Barkoukis T: Review of Sleep Medicine. 3rd Ed. Elsevier, Philadelphia, 2012.)

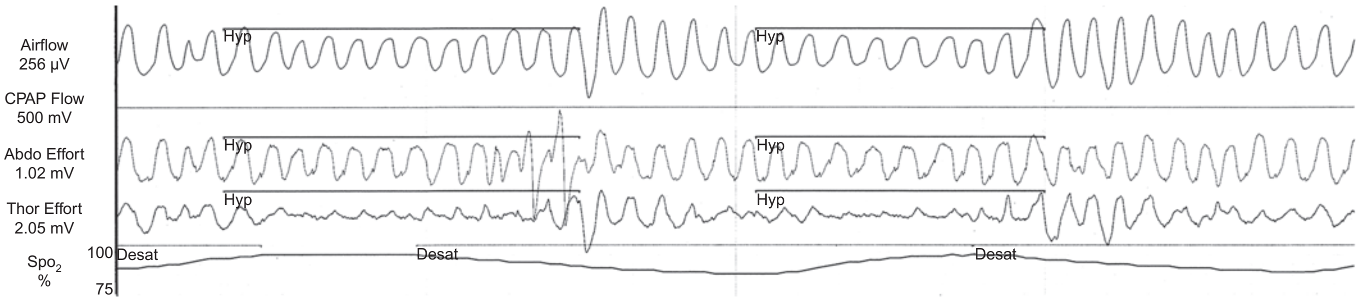

FIGURE 51-3 ■ Obstructive hypopnea (Hyp). This 2-min screen shows airflow reduced by about 50 percent from baseline. There are persisting respiratory efforts of the thoracic (Thor Effort) and abdominal muscles (Abdo Effort), and a decline of more than 3 percent in oxygen saturation. CPAP, continuous positive airway pressure; Desat, desaturation. (From Avidan A, Barkoukis T: Review of Sleep Medicine. 3rd Ed. Elsevier, Philadelphia, 2012.)

pressures preceding the arousal. On PSG the respiratory disturbance index is calculated by combining the total number of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep. Respiratory effort-related arousals are used to identify patients with upper airway resistance syndrome in whom recurrent arousals from sleep occur without clear apneas or hypopneas on PSG. Patients with this syndrome respond to the same treatments as those with OSA.

Treatment

POSITIVE AIRWAY PRESSURE THERAPY

Continuous positive airway pressure (CPAP) is the treatment of choice for OSA. CPAP acts as a pneumatic splint to keep the airway open, thereby preventing obstruction during sleep. It is effective in ameliorating daytime sleepiness, reducing respiratory events, and normalizing oxygen saturation.

Ideally, an in-laboratory CPAP titration should be performed to determine the optimal pressure. CPAP pressures may need to be increased in REM sleep, when the patient is in the supine position, or after ingestion of sedative medications or alcohol. When high pressures are required, bilevel PAP is often used so that patients can exhale against a lower pressure. It is also used in patients who are unable to tolerate CPAP or in those with an element of central hypoventilation. Adaptive servo-ventilation is a noninvasive ventilatory treatment option developed for the treatment of central or complex sleep apnea.

Auto-CPAP devices have been developed to select the optimal PAP without in-laboratory titration. Additionally, auto-CPAP devices can deliver the lowest pressure needed regardless of changes in body position, sleep stage, or weight. Different auto-CPAP algorithms are used depending on the manufacturer. Limitations of these devices include erroneously increased pressure due to leakage and the limited ability to differentiate between central and obstructive respiratory events. Studies to date have shown similar outcomes with CPAP and auto-CPAP therapy.[8]

SURGERY

Young patients with enlarged tonsils, adenoids, or both respond well to surgical intervention. Uvulopalatopharyngoplasty is the most common surgery performed for OSA and includes resection of the uvula, any redundant retroglossal soft tissue, and palatine tonsillar lymphoid tissue. Unfortunately, success—defined as normalization of AHI to less than 10—only occurs in about 33 percent of patients.[9] Approximately 50 percent of patients have a reduction in apneas by more than 50 percent; however, patients with severe sleep apnea are often left with mild to moderate sleep apnea. The most common side effect of the surgery is nasopharyngeal regurgitation of fluid.

Other surgeries that are performed for sleep apnea include septoplasty, rhinoplasty, nasal turbinate reduction, nasal polypectomy, tongue reduction, palatal implants (Pillar procedure), genioglossal advancement or shortening, and maxillomandibular advancement. Relative contraindications to upper airway surgery include morbid obesity and decompensated respiratory or cardiac conditions. In practice, surgery is recommended when patients are unable to tolerate PAP therapy. Surgery is most successful in patients with a low BMI and low AHI.

Upper Airway Stimulation

The hypoglossal nerve stimulator is an implanted device that stimulates the hypoglossal nerve to reduce apneas. The painless stimulation activates the muscles of the tongue, increasing the tone and moving it forward, away from the back of the airway to open the lower pharyngeal airway. The pacemaker-like device monitors breathing pattern and is activated when airflow limitation is detected. Currently the FDA has approved the hypoglossal nerve stimulator for patients older than 22 years with moderate or severe OSA and predominantly obstructive events who have failed or are intolerant to CPAP.[10] Eligible patients should not have complete concentric velopharyngeal collapse on screening sleep endoscopy or any other anatomic findings that would compromise performance of the device. It is not recommended for patients with a BMI exceeding 32 kg/m^2. The most common risks are associated with surgical placement of the device, as well as risk of battery stimulator dysfunction.

Oral Appliances

Oral appliances are dental devices made to maintain patency of the upper airway during sleep. Mandibular advancement devices protrude the mandible forward to increase the luminal area of the airway. Tongue-retaining devices, in contrast, keep the tongue in place, preventing occlusion of the upper airway. Some devices combine these two mechanisms.

Most studies have shown that oral appliances reduce snoring and decrease the number of respiratory events, but do not necessarily normalize them to an AHI less than 5. The most common adverse effects reported with oral appliances include dental discomfort, temporomandibular joint pain, bruxism, gingival irritation, and hypersalivation. These effects are usually mild and self-limited. Contraindications to oral appliances include an inadequate number of teeth (at least 6 to 10 per arch are needed), severe temporomandibular joint problems, inadequate mandibular protrusive ability, and significant bruxism.

Oral appliances are most effective in mild to moderate OSA, in patients with a BMI less than 30, and in patients with supine-dependent OSA.[11]

Behavioral Modifications

The most effective behavioral modification for OSA is weight loss. Lifestyle and dietary modifications, pharmacologic therapy, and bariatric surgery can all be effective in achieving this goal. Studies have shown a 50 percent reduction in AHI with a mean weight loss of 9 percent. Other behavioral interventions include smoking cessation, alcohol avoidance, and increasing time of sleep. Positional therapy (avoiding a supine position during sleep) can be used for patients with supine-dependent OSA. Pharmacologic treatment has not been effective for treating the respiratory events in OSA, but modafinil, armodafinil, and solriamfetol are approved to treat the EDS associated with sleep apnea.

CIRCADIAN RHYTHM DISORDERS

Circadian rhythm disorders develop when there is a persistent or recurrent pattern of sleep disturbance because of alterations in the circadian clock or a misalignment between the endogenous circadian rhythm and the external environment imposed by social or work cycles. The sleep disturbances that arise include insomnia, EDS, or both, and lead to impairments in occupational, social, or other aspects of daily functioning.

Various tools are used to make a diagnosis of a circadian rhythm disorder including the history of sleep and wake patterns, a sleep diary, and actigraphy. Other diagnostic tools that are used more in research than clinical practice include assessment of core body temperature and melatonin levels, the latter increasing approximately 2 to 2.5 hours before sleep onset. The nadir of the core body temperature occurs about 2 hours before habitual wake time.

Delayed Sleep Phase Disorder

Delayed sleep phase disorder is characterized by an inability to fall asleep at the appropriate time at night and an inability to awaken in the morning. This results in a delay of the major sleep period relative to the required sleep—wake time (Fig. 51-4). The patient reports symptoms of sleep-onset insomnia and EDS. If the patient is allowed to sleep at the preferred time, sleep quality and duration are normal and stable.

The prevalence of delayed sleep phase disorder is 0.17 percent in the general population. It occurs most often in adolescence, with a prevalence of 7 to 16 percent. It is estimated that 5 to 10 percent of patients with chronic insomnia in a sleep clinic have delayed sleep phase disorder.

Polymorphisms in the clock genes *hPer3* and *hCLOCK* have been associated with delayed sleep phase disorder.

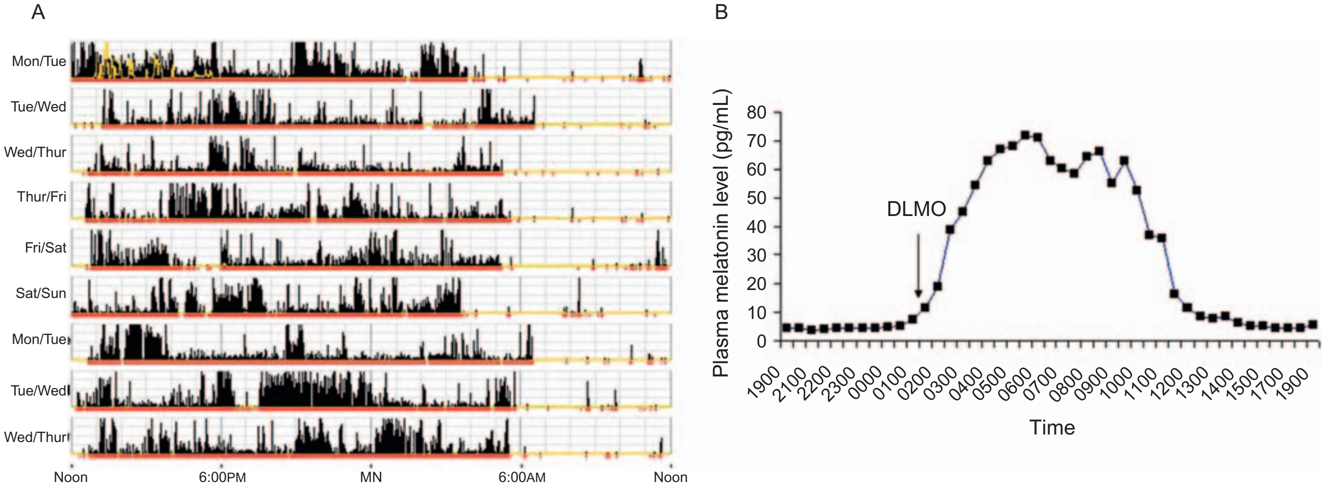

FIGURE 51-4 ■ Actogram of a patient with severe delayed sleep phase disorder (DSPD). *A*, Actogram derived from actigraphy data obtained over 9 days. The yellow lines depict light exposure. The high-amplitude dense bars are representative of wakefulness, and time with little or no activity represents sleep. The average sleep onset is at 5–6 A.M. and wake time is from noon to 1 P.M. Note the stable delay of the sleep–wake rhythm in relation to the conventional sleep time and wake-up time. *B*, The 24-h rhythm of plasma melatonin levels in this patient. The dim-light melatonin onset (DLMO) was defined as an absolute threshold at 10 pg/mL. The DLMO of this patient is delayed, at 1:23 A.M. (which is approximately 5 h later than expected in nondelayed persons).

Additionally, a polymorphism of arylalkylamine *N*-acetyltransferase and an increased frequency of HLA-DR1 are significantly more prevalent in these patients, which may explain the positive family history of such disorder in 40 percent of patients. More recently a mutation in the human clock gene *CRY-1* has been discovered as a cause of familial delayed sleep phase.[12] Environmental factors, such as exposure to bright lights in the evening and lack of light in the morning, can intensify the delayed sleep phase.

Treatment often requires a combination of behavioral techniques, light therapy, chronotherapy, and possibly pharmacologic treatments. Behavioral therapy includes maintaining a regular sleep–wake schedule and proper sleep hygiene. Bright light of 2,000 to 2,500 lux for 2 hours in the biologic morning along with avoidance of bright light in the biologic evening can help achieve earlier sleep and wake times.

Chronotherapy is a technique that involves progressively changing the sleep time by several hours each night until the desired sleep time is reached. It is a highly effective treatment for delayed sleep phase disorder. Compliance is often difficult, however, because it requires individuals to have a flexible schedule. Vacation time is often the best time to try this approach.

Melatonin taken in the early evening decreases sleep latency, increases sleep duration, and improves daytime functioning in patients with delayed sleep phase disorder. Individuals are advised to take 0.3 to 3 mg about 6 hours before their sleep time. Rarely, hypnotics are used to treat delayed sleep phase disorder.

Advanced Sleep Phase Disorder

Advanced sleep phase disorder is a stable advance in the sleep–wake period relative to the desired time. Patients tend to fall asleep early in the night, typically between 6 and 9 P.M., and awaken early in the morning, between 2 and 5 A.M. (Fig. 51-5). Individuals with advanced sleep phase disorder report sleepiness in the early evening, making it difficult to participate in activities at that time. Additionally, early morning insomnia can result in EDS. If patients are allowed to sleep at their endogenous circadian period, their sleep time and quality are normal for age.

Advanced sleep phase disorder is more common in middle-aged and older adults, with an estimated prevalence of about 1 percent. Familial forms of advanced sleep phase disorder exist and should be suspected in younger patients. Mutations in the clock genes *hPer2* and *CSK1D* have been identified.

Treatment recommendations include a combination of bright light exposure in the evening, adhering to a

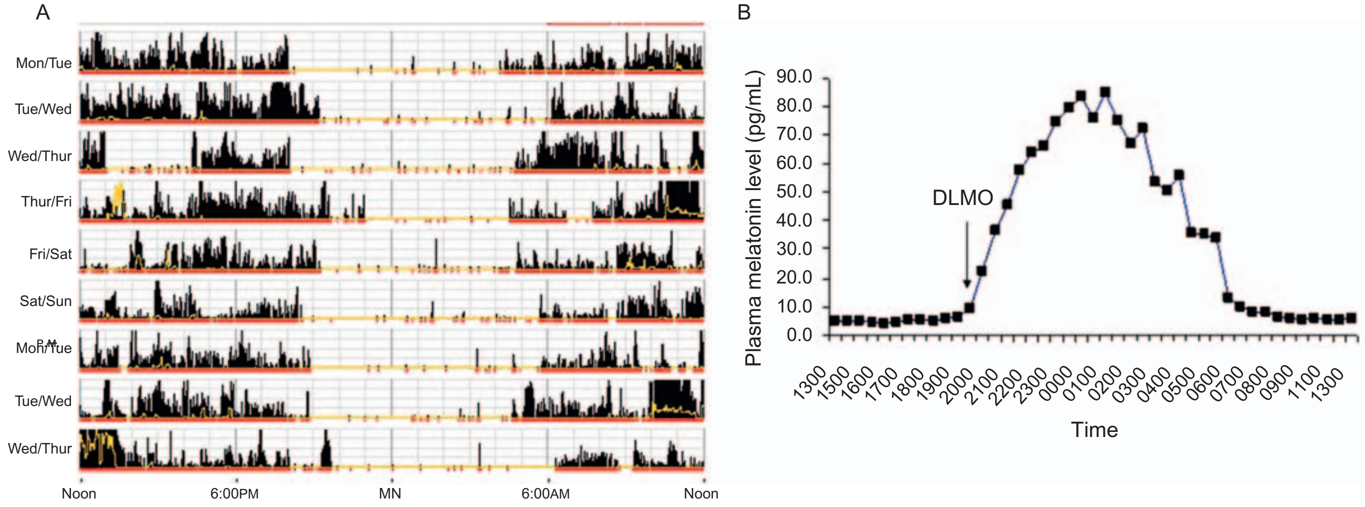

FIGURE 51-5 ■ Actogram of a patient with severe advanced sleep phase disorder. *A*, Actogram derived from actigraphy data obtained over 9 days. The yellow lines depict light exposure. The high-amplitude dense bars are representative of wakefulness, and time with little or no activity time represents sleep. The average sleep onset is 8–9 P.M. and wake time is from 4–5 A.M. Note the stable advance of the sleep–wake rhythm in relation to the conventional sleep and wake-up times. *B*, The 24-h plasma melatonin level rhythm of this patient. The DLMO was defined as an absolute threshold at 10 pg/mL. The DLMO of this patient is advanced, at 7:30 P.M. (which is approximately 2–3 h earlier than expected in nonadvanced persons).

planned sleep–wake schedule, and good sleep hygiene. Studies have shown that bright lights between 7 and 9 P.M. can phase-delay the circadian clock and improve sleep efficiency. Early morning melatonin can theoretically delay the circadian rhythm, but there are no published studies on its efficacy for advanced sleep phase disorder.

Shift Work Disorder

Shift work disorder is a common condition that remains under-recognized and undertreated. It is estimated that 10 percent of shift workers have the disorder. As about 20 percent of the workforce in industrialized countries is employed in some kind of shift work, the prevalence must be high.

Shift work disorder develops when the work schedule occurs during the normal sleep period, resulting in either EDS, insomnia, or both. Difficulty in sleeping occurs when the circadian alerting signal is high, and EDS results from being awake when the circadian alerting signal is low. Additionally, shift workers are often chronically sleep deprived. Night workers sleep between 1 and 4 hours less per night than day workers. Night work and early morning (before 6 A.M.) start times are associated with the most sleep deprivation and greatest wake-time impairments.

Shift work disorder is associated with impairments in performance at work that can have safety consequences, for example, in bus drivers, machine operators, and train conductors. Additional symptoms include chronic fatigue, mood disorders, gastrointestinal problems, as well as disruptions of social and family life. The risks of alcohol or drug abuse, weight gain, hypertension, cardiovascular disease, and breast and endometrial cancer are increased in shift work disorder.

The goals of treatment include realigning the endogenous circadian rhythm with the work schedule and alleviating the insomnia or daytime sleepiness. To achieve circadian realignment, various behavioral interventions can be utilized. The first step includes bright light exposure during the first half of the shift followed by avoidance of bright light about 2 hours before the end of the shift. In addition, wearing dark sunglasses in the morning on the way home from work can improve adaptation. It is important that the room for sleeping is dark and quiet, with a comfortable temperature setting, and that no disturbances occur to interrupt sleep.

To help improve alertness on the job, a short 1- to 2-hour nap about 2 to 3 hours before work can decrease sleepiness. Modafinil and armodafinil are FDA approved for treatment of excessive sleepiness in shift work disorder and significantly improve performance; caffeine is another alerting agent that is frequently used.

Melatonin before bedtime in night shift-workers has been shown to improve sleep duration, but it does not significantly improve alertness. Short-acting hypnotics can also improve symptoms of insomnia associated with shift work disorder.

Jet Lag Disorder

Jet lag develops when there is temporary desynchronization between the internal circadian rhythm and external time cues, resulting in insomnia, daytime sleepiness, and general malaise. Factors that increase the severity of symptoms include the number of time zones traveled and the direction of travel. It is generally more difficult to travel eastward than westward. Symptoms usually resolve within 7 days. Frequent flyers can develop functional impairment requiring treatment.

The goal of treatment is to accelerate realignment of the circadian clock to the new time zone. Circadian adaptation to eastward travel necessitates advancing the circadian rhythm, whereas westward travel requires phase delay. Timed light exposure and exogenous melatonin are recommended (Fig. 51-6). Other behavioral interventions include attempted adjustment to the new time zone before leaving the existing one; avoidance of alcohol, caffeine, and dehydration during travel; and timed naps. Hypnotic agents, such as ramelteon and zolpidem, and agents promoting wakefulness, such as modafinil and armodafinil, improve symptoms of insomnia and EDS, respectively, in jet lag.

Irregular Sleep–Wake Disorder

Irregular sleep–wake disorder is characterized by multiple short sleep and wake periods without a single distinct sleep period. Diagnostic criteria require at least three sleep periods of varying duration in a 24-hour period; however, total sleep time per 24-hour period is normal for age. This results in symptoms of insomnia, excessive EDS, or both. Voluntary maintenance of an irregular sleep–wake schedule must be distinguished from irregular sleep–wake disorder.

This disorder is most commonly seen among institutionalized residents such as those with dementia, mental retardation, and traumatic brain injury. These individuals often lack exposure to external synchronizing cues such as light, activity, and a social schedule. Additionally, neurodegeneration or injury to the central circadian clock system can result in this temporally disorganized sleep–wake schedule.

FIGURE 51-6 ■ Strategies to accelerate circadian adaption to jet lag. *A*, An example of a treatment strategy for jet lag associated with an eastward flight over six time zones (from Chicago to London). Adjustment requires an equal number of hours of phase advance. On arrival, the traveler should avoid bright light in the early-morning hours (before 9 A.M.) for the first 2 days so that light does not decrease before nadir of the core body temperature (T_{cmin}), which will induce a phase delay, and exposure to bright light after 9 A.M. to induce phase advances. In addition, melatonin, 1–5 mg taken at 6 P.M. local time on the departure day and at local bedtime (10–11 P.M.) on arrival for 4 days is helpful. *B*, Treatment strategy for jet lag associated with a westward flight over five time zones (from Chicago to Hawaii). The subject should be exposed to as much as light as possible in the late afternoon and early evening at the destination, which will result in the required phase delay.

The goal of treatment for irregular sleep–wake disorder is consolidation of the sleep period, which is best achieved with combination therapy consisting of bright light exposure in the daytime, increased structured activities during the day, avoidance of daytime naps, exogenous melatonin in the evening, reduction of noise and light at night, and institution of a bedtime routine. Melatonin alone has not been shown to help nursing home residents; however, it is effective in children with cognitive problems and irregular sleep–wake disorder.

Non–24-Hour Sleep–Wake Rhythm Disorder

Non–24-hour sleep–wake rhythm disorder (N24SWD) is characterized by a sleep–wake pattern that is not entrained to the 24-hour environmental cycle, usually leading to a delay, over time, of sleep onset and wake times. A lack of synchronization between the endogenous circadian clock and the 24-hour light–dark cycle is the cause. Individuals report complaints of insomnia, EDS, and inability to meet social and occupational obligations.

N24SWD is seen in 50 percent of blind people and is relatively rare in sighted people. Blind individuals with absence of light perception do not receive photic input to the circadian pacemaker, leading to N24SWD. The etiology in sighted people is unclear, but predisposing risk factors include a long circadian period that is beyond the range of entrainment to a 24-hour cycle, psychiatric disorders, and neurodegenerative diseases such as dementia.

Treatment is aimed at establishing stable entrainment of the sleep–wake pattern to the 24-hour external cycle. For patients without light perception, combination therapy is helpful and involves creation of structured social and occupational schedules, maintenance of good sleep hygiene, and low-dose melatonin 1 hour before the preferred sleep time. For sighted patients or those with visual impairment but preserved light perception, timed bright light and melatonin along with the above behavioral interventions are effective.

Tasimelteon was approved in 2014 for the treatment of N24SWD in blind people. It is a selective dual melatonin receptor agonist (MT1 and MT2). By activating melatonin receptors in the suprachiasmatic nucleus, tasimelteon has been shown to improve sleep by resynchronizing the circadian rhythm. Reported side effects include headache, abnormal dreams, urinary and upper respiratory tract infections, and elevated serum alanine aminotransferase.

SLEEP-RELATED MOVEMENT DISORDERS

Sleep-related movement disorders are a category of conditions that involve simple, usually stereotyped, movements that affect sleep. The primary disorders that present to the clinician include RLS and PLM disorder.

Restless Legs Syndrome

RLS is characterized by a compelling urge to move the limbs that is worse during rest, relieved by movement, and is most prominent in the evening or night. The urge to move is associated with distressing sensations in the limbs that are described as creeping, crawling, tingling, burning, or aching. The symptoms most often occur in the legs, but may involve the arms or other parts of the body as well. Approximately 80 to 90 percent of patients with RLS also have PLMs. The condition often has a profound impact on quality of life because of sleep disruptions, including difficulty in initiating and maintaining sleep. The pathophysiology of RLS is not fully understood, but iron-deficiency and central dopaminergic system dysfunction have been implicated.

The estimated prevalence of RLS ranges from 3 to 15 percent; however, the prevalence of clinically significant RLS requiring treatment is 1.6 to 2.8 percent.[13] The female to male ratio is roughly 2:1. Prevalence increases with age, and treatment is often not sought until after age 40. Familial aggregation is common in primary RLS, with a three- to sixfold greater risk for first-degree relatives of patients with RLS. There is also a high concordance rate (83%) in monozygotic twins. At least five different chromosomes (12q, 2p, 14q, 9p, 22p) have been linked to RLS. Secondary RLS is associated with many different medical and neurologic conditions (Table 51-7).

Treatment should begin with behavioral modifications such as improving sleep hygiene with regular sleep–wake times, avoiding caffeine and alcohol, and moderate daily exercise. Iron-deficiency is a common cause of RLS; therefore, serum iron and ferritin levels should be checked before any medication is initiated. Iron replacement should occur when serum ferritin is below 20 ng/mL. Dopamine agonist or alpha$_2$ delta calcium-channel ligands are considered first-line pharmacologic therapy for patients who do not respond to behavioral management or iron supplementation (Table 51-8).

Dopamine agonists alleviate the symptoms of RLS in 70 to 90 percent of patients with low doses and have less risk of augmentation than levodopa. Pramipexole is a nonergot-derived D3 and D2 receptor agonist that has proven efficacy for RLS at daily doses of 0.25 to 1 mg. Ropinirole is another nonergot-derived D3 and D2 receptor agonist that is effective for RLS at a mean dose of 2 mg daily. Plasma concentrations of ropinirole and pramipexole peak almost 2 hours after ingestion; therefore, it is important to dose them several hours before symptom onset. Ergot-derived dopamine agonists are not considered first-line treatment because of the risk of pulmonary fibrosis and valvular heart disease.

TABLE 51-7 ■ Secondary Causes of Restless Legs Syndrome

Medical

- Iron-deficiency anemia
- End-stage renal disease
- Rheumatologic disorders
- Diabetes
- Obstructive sleep apnea
- Liver disease
- Chronic obstructive pulmonary disease
- Celiac disease
- Gastric bypass surgery
- Crohn disease

Neurologic

- Neuropathy
- Parkinson disease
- Spinocerebellar ataxia types 1, 2, 3
- Multiple sclerosis
- Migraines
- Myelopathies

Medications

- Antihistamines
- Neuroleptics
- Metoclopramide
- Proton pump inhibitors
- Selective serotonin reuptake inhibitors (SSRIs)
- Serotonin-norepinephrine reuptake inhibitors (SNRIs)
- Lithium
- Mirtazapine

Lifestyle

- Sleep restriction
- Smoking
- Alcohol
- Caffeine
- Too little or too much physical activity

TABLE 51-8 ■ Pharmacologic Therapy for Restless Legs Syndrome

Drug	Dose (mg)	Cautions
Dopaminergic Agents		
Levodopa	100–200	Augmentation, rebound, tolerance
Pramipexole	0.25–1	Sleepiness, impulse control impairment
Ropinirole	0.25–2	Sleepiness, impulse control impairment
Rotigotine patch	0.5	Augmentation, skin reaction
Alpha$_2$ Delta Calcium-Channel Ligands		
Gabapentin	600–2,400	Somnolence, renal impairment
Pregabalin	75–300	Angioedema, renal impairment
Gabapentin enacarbil	600	Somnolence, renal impairment
Other		
Oxycodone	5–20	Abuse potential, dependence
Tramadol	50–200	Augmentation, withdrawal
Clonazepam	0.25–1	Withdrawal, dependence
Zolpidem	5–10	Complex sleep-related behaviors

Adverse effects associated with dopamine agonists include nausea, headache, somnolence, and dizziness.

Transdermal dopamine agonists have been approved as an alternative treatment of RLS. Rotigotine, in patch form, has good long-term safety and efficacy data. The rationale for continuous drug administration is to maintain a more steady plasma level, thus benefiting patients with daytime symptoms of RLS.

Alpha$_2$ ligands, such as gabapentin, pregabalin, and gabapentin enacarbil, are also effective treatments for RLS and PLMs. Alpha$_2$ ligands can be particularly helpful in patients with painful RLS or those with concomitant neuropathic pain, insomnia, impulse control disorders, or addiction associated with the use of dopamine agonists. However, dopamine agonists are preferable in patients with severe RLS, depression, obesity, or metabolic syndrome.

The mean effective daily dose of gabapentin is around 1,800 mg/day, divided into two daily doses; however, doses up to 2,400 mg/day may be necessary. Pregabalin has been shown to be effective for RLS as well at a mean effective dose of around 125 mg/day. Gabapentin enacarbil, at a single dose of 600 mg/day, has been shown to have superior absorption and longer duration of action when compared to gabapentin.

Other medications that have shown some efficacy in relieving symptoms of RLS include oxycodone, tramadol, clonazepam, levodopa, and zolpidem. The side-effect profiles of these medications limit usage; however, they should be considered when first-line therapy fails or as adjunct therapy. Levodopa was initially used for RLS; however, its use is limited by rebound, tolerance, and augmentation (the occurrence of more severe RLS symptoms that develop earlier in the evening).

Periodic Limb Movements

PLMs are repetitive stereotyped limb movements occurring during sleep. PLMs usually occur in the lower extremities but can involve the arms. The stereotyped movements frequently consist of extension of the big toe with partial flexion of the knee and ankle. Movements may cause an autonomic or cortical arousal or an awakening.

Patients are often asymptomatic, with only the bed partner reporting the abnormal movements. PLMs can be present in many sleep disorders, such as RLS and narcolepsy. Often they are an asymptomatic finding during a sleep study.

PLM disorder is characterized by the presence of PLMs along with sleep disruption not otherwise caused by another sleep disorder. Sleep disruption from PLMs can present as daytime sleepiness or insomnia.

If PLMs are found to be part of another sleep disorder, such as RLS, then the primary sleep disorder should be treated. PLMs must be differentiated from PLM disorder in order to discern whether treatment is needed. The same medications that are used for RLS have been shown to alleviate PLMs.

PARASOMNIAS

Parasomnias are disorders characterized by abnormal behavioral or physiologic events, or both, that accompany sleep-specific sleep stages, or sleep–wake transitions. These events typically occur because of inappropriate timing of the sleep cycles. Physiologic and behavioral manifestations include activation of the central nervous system, with skeletal muscle activity and associated autonomic changes, resulting in undesirable or unwanted motor or verbal phenomena during sleep. Parasomnias can lead to disrupted sleep, poor health outcomes, psychosocial problems, and even cause physical harm in more severe cases. They are typically classified based on the state in which they occur—REM sleep, NREM sleep, or both sleep states.

NREM Parasomnias

Disorders of arousal during NREM sleep include sleepwalking, sleep terrors, and confusional arousals. Thought to occur due to the instability of slow-wave sleep, arousal disorders are built on the premise that the arousals are not an all-or-none phenomenon, but rather a continuum of reestablishment of full alertness, orientation, judgment, and control over behavior; a rapid alteration of sleep and waking states; or both.

Sleepwalking (Somnambulism)

Sleepwalking refers to a series of multifaceted motor behaviors that are initiated during slow-wave sleep and result in walking during a state of altered consciousness within the first third of the sleep period. Most prevalent in children between 5 and 10 years old and less common in older groups, sleepwalking episodes range from subdued to sophisticated, including unlocking doors, texting, dressing, and driving. They range in duration from 15 seconds to 30 minutes, and recall may be limited or absent. The walker's eyes are open and behaviors may be clumsy. When awakened, the walkers typically respond with simple responses ("had to take a shower"). Sleepwalking in adults can be dangerous as it can be associated with violent or dangerous activity. Sleepwalking patients are generally neurologically normal, but other sleep disorders should be excluded.

Confusional Arousals

Confusional arousals are brief, impaired, and incomplete arousals that typically begin during slow-wave sleep. The individual typically looks confused, especially in the early part of the night. Confusional arousals differ from sleepwalking in that the affected patient does not leave the bed. Most commonly seen during the first third of the night in slow-wave sleep, such arousals can also occur in other NREM sleep stages or the later part of the night. Common examples include sitting up in bed with simple vocalization or picking at bedclothes.

Anxiety, sleep deprivation, fever, and endocrine factors (e.g., pregnancy) may increase the frequency of episodes. Other precipitating factors include alcohol or hypnotic consumption, antihistamines, and lithium. Primary sleep disorders (e.g., apnea or periodic leg movements) may also exacerbate confusional arousals.

Sleep Terrors

Sleep terrors (night terrors, pavor nocturnus) are less common than sleepwalking, beginning with an incomplete arousal from slow-wave sleep. Often associated with a frightening image and autonomic activation, a typical event might terrify the patient, who often emits an abrupt piercing scream and has autonomic and behavioral manifestations of intense fear. Usually associated with agitation, sweating, tachycardia, and hyperpnea, sleep terrors are more common in children than adults. Episodes occur in the first third of the night, with the patient having no or very little recall of the event the next morning. Witnesses tend to be more distressed by the events than patients. Children who present with sleep terrors often grow out of them, but events may continue to be precipitated by alcohol use, stress, sleep deprivation, and shift work. Adults presenting with sleep terrors should be assessed for psychiatric disorders.

TREATMENT OF AROUSAL DISORDERS

Management of arousal disorders should involve reassurance and education, especially in children. Symptoms generally do not require intervention and events will usually minimize with time (in children). Although stress or psychiatric issues may be a factor, it should not be the clinician's first assumption as to etiology. Proper clinical management involves the recommendation of sleep hygiene including avoidance of alcohol and drugs, maintenance of a consistent sleep—wake schedule, and reduction of bedroom light and noise. Sleep deprivation should be avoided. The environment should be kept safe to avoid injuries from arousals.

It is often difficult to arouse individuals from slow-wave sleep episodes. When aroused, patients may be confused or even aggressive, with subsequent amnesia for the episode. Scheduled awakenings (awakening the patient 15 minutes before each usual arousal on a regular basis) have been effective.

Stress-management skills, psychotherapy, and hypnosis have also been found useful. Pharmacologic treatment is necessary when events are frequent, put the family or patient at risk of being harmed, or disturb family life (Table 51-9). Benzodiazepines (used continuously or as needed), tricyclic antidepressants, and SSRIs (such as paroxetine) have been successfully used in treatment, though controlled trials are sparse.

TABLE 51-9 ■ Pharmacologic Treatment of Parasomnias

Medication	Effective Dose Range (mg)	Appropriate Patient Population
Non-REM Parasomnias		
Clonazepam	0.5–2.0	First-line treatment
Triazolam	0.125–0.5	First-line treatment
Paroxetine	20–40	Alternative treatment
Zolpidem	5–10	Alternative treatment
Sleep-Related Eating Disorders		
Clonazepam	0.5–2.0	First-line treatment
Lorazepam	1.0–2.0	Side effects with clonazepam
Pramipexole	0.5–1.0	Unresponsive to benzodiazepines, history of substance abuse
Melatonin	3–15	Unresponsive to benzodiazepines, history of substance abuse
REM-Related Parasomnias		
Clonazepam	0.5–2.0	First-line treatment for RBD
Melatonin	3–12	May be effective in RBD
Prazosin	5–15	Nightmares in PTSD
SSRI (e.g., Sertraline)	50–200	History of daytime eating, mood, anxiety disorder
Pramipexole	0.18–0.36	RBD with Parkinson disease
Topiramate	25–400	Binge eating disorder, *insomnia*

RBD, REM-sleep behavior disorder; PTSD, post-traumatic stress disorder.

REM Parasomnias

NIGHTMARES

Nightmares are unpleasant dreams that awaken the individual from REM sleep and are often associated with strong emotions such as fear, anger, sadness, or embarrassment. Although they may occur at any part of the night, they predominantly occur during the final third, when REM sleep is more prominent. Recall is generally vivid and detail oriented. Nightmare disorder can be idiopathic or related to an underlying condition, with recurrent nightmares often linked to psychologic trauma or psychiatric disorders (e.g., post-traumatic stress disorder, affective disorders). Frequent nightmares can lead to disturbed sleep-onset latency, awakenings, restless sleep, insomnia, and a lower overall quality of life.

Although usually seen in children, adults may also experience nightmares that are recurrent, frequent, or both, with causes typically related to stress, post-traumatic stress disorder, antidepressant or antihypertensive medications, withdrawal from alcohol or drugs, narcolepsy, and sleep-related breathing disorders.

Patients should be told to avoid alcohol, drugs, and heavy meals at least 3 hours before bedtime. Clinicians should also assess for any medications or other sleep disorders (e.g., sleep apnea) that might exacerbate nightmares. Though more commonly used to treat hypertension, prazosin is effective as a routine treatment, particularly in post-traumatic nightmares. Imagery rehearsal therapy has shown promising results for nightmare treatment. Patients are taught to "change the dream in any way they wish" and imagine the new dream for 5 to 20 minutes daily.

REM Sleep Behavior Disorder

REM sleep behavior disorder is characterized by forceful motor activity that typically occurs during REM sleep in the absence of the usual muscle atonia. It often involves behaviors dangerous to self or the bed partner, along with unpleasant images or dreams. REM sleep behavior disorder is more frequent in men than women and typically occurs in the middle-aged or elderly. The prevalence is estimated as 0.5 percent. PSG can exclude seizure activity and confirm the presence of increased EMG tone during REM sleep. REM sleep behavior disorder can be idiopathic or related to underlying neurologic conditions (e.g., synucleinopathies), and patients should undergo a thorough physical examination seeking any comorbidities that might interrupt REM sleep.[14] In some patients, REM sleep behavior disorder precedes the development of a synucleinopathy such as Parkinson disease by many years. Acute REM sleep behavior disorder can be induced by medications (e.g., monoamine oxidase inhibitors, SSRIs), benzodiazepine withdrawal, and alcohol.

Measures should be taken to keep the sleep environment safe. The patient should sleep in a separate bed from their partner until events are controlled. Patients usually respond well to clonazepam (0.5 to 2.0 mg). Melatonin, hypnotics, and dopaminergic medications may also be effective in some cases.

Other Parasomnias

Sleep-Related Eating Disorder

Sleep-related eating disorder involves partial arousals from sleep where patients engage in involuntary eating and drinking. It has a higher prevalence in patients with a history of eating disorders or sleepwalking, and can be linked to medications (e.g., zolpidem, anticholinergics, and lithium). Patients may have unexplained weight gain and morning anorexia. They have limited or no memory of events, and foods consumed can even be toxic, inedible, or peculiar such as coffee grounds, frozen or uncooked products, cake mix, eggshells, or cleaning materials. Patients should be evaluated for comorbid sleep disorders such as PLMs and OSA. Topiramate and dopaminergic medications have been effective in some patients.

Sexsomnia

Sexsomnia is characterized by abnormal sexual behaviors during sleep, with patients having little to no memory of the event. Sexual arousal may be accompanied by autonomic activation (e.g., nocturnal penile tumescence, nocturnal emission, vaginal lubrication, and dream orgasm). Many patients have a history of sleepwalking; comorbid sleep disorders should be evaluated. Patients are advised to optimize proper sleep hygiene.

Forensic Implications

Violent behaviors may occur during sleep without conscious awareness, leading to important forensic implications. Behaviors such as murder, assault, or apparent suicide can be linked to disorders of arousal, REM sleep behavior disorder, psychogenic dissociative states, and sleep-related seizures. These sleep-related episodes have been reported in 2 percent of the population, but more prevalence and treatment studies are needed.

Exploding Head Syndrome

Occurring during the switch from wakefulness to sleep, patients may be awakened by the sensation of a loud, explosion-like bursting in the head. Most are usually painless, but patients occasionally note a small stab of pain accompanying the sound. Sleep deprivation and stress often worsen these events, and optimizing sleep hygiene and reassurance that these events are benign are all that is required for treatment.

SLEEP DISORDERS IN PATIENTS WITH NEUROLOGIC DISORDERS

Sleep complaints are common in patients with neurologic disorders. Untreated sleep conditions often worsen neurologic symptoms and increase morbidity and mortality. Neurologists can play a central role in diagnosing these disorders and thereby improve the care of these patients.

Parkinson Disease

Sleep disturbances are common in Parkinson disease, affecting as many as 60 to 98 percent of patients. Common symptoms include difficulty in falling asleep and staying asleep, abnormal movements in sleep, and EDS. Sleep disturbances develop for multiple reasons including: (1) degeneration of the cortical sleep centers that regulate the sleep–wake cycle; (2) side effects of dopaminergic and anticholinergic medications; (3) rigidity, bradykinesia, and dystonia resulting in difficulty in shifting positions during sleep, leading to frequent arousals and sometimes pain; (4) depression and anxiety resulting in insomnia; (5) altered muscle tone in the upper airway facilitating sleep apnea; and (6) dream enactment behavior such as REM sleep behavior disorder. The severity of Parkinson disease is directly related to the severity of the sleep disturbances.

It is helpful to interview the patient in the presence of a close friend or family member when screening for sleep disorders as patients often lack insight into their sleep disturbances. Clinical tools such as the Parkinson Disease Sleepiness Scale or the Epworth Sleepiness Scale can assess need for and response to therapy. Multiple treatment strategies are often needed including medication adjustments, behavioral modifications, and therapy of specific sleep disorders.

Alzheimer Disease

Sleep disturbances are common in dementia and may worsen cognitive function and mood. Additionally, sleep disruption can worsen caregiver burden and serve as a primary reason for institutionalization. Treatment of sleep disorders can improve cognitive functioning in these patients.

Irregular sleep–wake disorder is the most common sleep problem in Alzheimer disease and typically presents with insomnia at night and EDS.[15] The etiology involves degeneration of the suprachiasmatic nucleus in the hypothalamus and dysregulation of the pineal gland and its melatonin output. Although melatonin levels are lower in Alzheimer disease patients than age-matched controls, studies have not shown a benefit of melatonin supplementation in these patients.

A major factor in the development of irregular sleep–wake disorder in Alzheimer disease is lack of appropriate zeitgebers, such as light and physical activity, which are essential for establishing a regular circadian rhythm. Dementia patients, especially those in nursing homes, frequently lack proper light exposure and physical activity. Behavioral interventions include ensuring adequate activity and light during the daytime and minimizing stimulation and disruptions at night.

Sundowning, defined as agitated behavior that appears in the late afternoon or early evening, is common in Alzheimer disease and other forms of dementia. The exact cause is unknown, but it may be due to changes in melatonin secretion, alterations in the cholinergic projections from the nucleus basalis of Meynert, delay in the body temperature rhythm, or degeneration of the suprachiasmatic nucleus. Behavioral interventions, such as maintaining a regular schedule in a known environment with familiar caregivers, can minimize sundowning. Eliminating delirium-provoking medications is also important.

The presence of other primary sleep disorders such as OSA should be assessed. Treatment of OSA can improve cognitive functioning and sleep disturbances in patients with Alzheimer disease. Patients with dementia are generally able to tolerate CPAP therapy as well as other patients.

Epilepsy

The relationship between sleep and epilepsy is bidirectional. Epilepsy and some of the medications used in its treatment can disturb nocturnal sleep and daytime alertness. Additionally, sleep deprivation and sleep disorders can increase the likelihood of having seizures in a predisposed individual, highlighting the need for proper sleep hygiene in patients with epilepsy.

Patients are often unaware of seizures that occur during sleep. They may report daytime sleepiness, difficulty with concentration, or awakenings, which may be misinterpreted as insomnia. Patients with epilepsy have more sleep fragmentation and sleep stage shifts than those without seizures. Antiepileptic medications such as carbamazepine, levetiracetam, phenytoin, phenobarbital, and topiramate can produce hypersomnolence.

Sleep also influences EEG activity, with increased expression of ictal and interictal discharges during NREM sleep. During NREM sleep, the EEG shows synchronous oscillation of cortical neurons that generate sleep spindles, K complexes, and slow waves that promote seizure propagation. As a result, some patients with epilepsy only have seizures during sleep. Conversely, REM sleep is characterized by EEG desynchronization that inhibits epileptiform discharges.

There is a higher prevalence of OSA in patients with epilepsy, especially in those with medically refractory seizures. OSA likely increases the frequency of seizures due to a combination of recurrent oxygen desaturation, sleep fragmentation, and sleep deprivation. Treatment of sleep apnea tends to improve seizure control, cognitive performance, and quality of life in these patients.

Parasomnias can be difficult to differentiate from certain types of epilepsy such as nocturnal frontal lobe epilepsy. Additionally, these two disorders may co-exist in the same patient, highlighting the need for overnight video-EEG and PSG to make a definitive diagnosis. Recent studies have found NREM parasomnias to be more frequent in sporadic and familial forms of nocturnal frontal lobe epilepsy, perhaps due to the two disorders sharing underlying genetic mutations.

Stroke

Sleep apnea is an independent risk factor for hypertension and cardiovascular and cerebrovascular disease. This link is thought is be secondary to increased sympathetic activity in sleep, which influences heart rate and blood pressure. Additionally, proinflammatory vascular risk factors, oxidative stress, and endothelial damage are increased in OSA. Studies also suggest that sleep apnea is a risk factor for new-onset atrial fibrillation, and increases the chance of postablation failure. Other studies have suggested that sleep apnea increases the risk of stroke upon awakening in those with a patent foramen ovale.

Sleep apnea may lead to cognitive decline by increasing small-vessel disease due to systemic chronic hypoxia and sympathetic stress. CPAP treatment may help to prevent cognitive decline in these circumstances.

Sleep apnea is common in patients after stroke and is associated with poorer functional outcome, cognitive functioning, and performance of activities of daily living, along with depressed mood. Data have shown benefit from CPAP use following stroke in those with OSA.[15]

Headache

Studies have established a strong association between sleep disorders and most primary headache types including migraine, tension, cluster, hypnic, and morning headaches. Conversely, sleep dysregulation caused by most sleep disorders, including insomnia, sleep apnea, hypersomnia, and circadian rhythm disorders, increases the risk of chronic daily headaches. Insomnia is the most common sleep disorder found in patients with migraine and tension-type headaches, and depression and anxiety may be associated. Headache histories should therefore always include a screen for sleep disorders.

Headaches that emerge out of sleep have been linked to sleep apnea. OSA increases the relative risk of chronic headache two- to threefold, and the risk of cluster headache eightfold. Studies have shown headache improvement with CPAP use.

Both oversleeping and sleep deprivation are known triggers for migraines. Sleep duration of less than 6 hours and more than 8.5 hours has been associated with increased headache intensity. The optimal sleep duration to reduce headaches in these patients is likely around 7 to 8 hours.

INTRODUCTION

A functional neurologic disorder (FND) is any type of neurologic disorder that arises from dysfunction of the brain when normal function is possible.[1] The name of this disorder has changed over the years. Previously called *hysteria* and *conversion disorder*, it then became *psychogenic neurologic disorder*, and only in recent years has the terminology changed to *functional neurologic disorder*. The change is due to several factors. First, while psychologic factors often seem etiologically relevant, such factors cannot always be identified, and the pathophysiology is not fully understood. Second, patients are more accepting of the diagnostic label, and acceptance of the diagnosis is the first step in treatment.

FNDs fall between neurology and psychiatry. Patients present to neurologists with neurologic symptoms, but the usual treatments have been psychiatric. Neither specialty took an interest in these patients, who were largely neglected in the latter part of the twentieth century when neither neurologists nor psychiatrists were being trained to diagnose and treat them. Fortunately, the situation is changing. In the psychiatric classification DSM-5, “functional neurologic symptom disorder” or “conversion disorder” falls under somatic symptom and related disorders. To make the diagnosis, manifestations need to be inconsistent and incongruent with other neurologic disorders and cause the patient distress. Such formal recognition is important.

FNDs are common. Neurologic practices vary, but typically FND is the second most common diagnosis after headache, accounting for 10 to 30 percent of patients.[2] Women are affected more often than men. The diagnosis in the past was largely based on excluding other neurologic disorders, but the emphasis now is on the identification of positive features. FNDs may accompany other neurologic disorders, thus complicating their diagnosis. For example, many patients with multiple sclerosis also have functional symptoms, and patients with an established seizure disorder can also have functional seizures.

CLINICAL FEATURES OF FUNCTIONAL NEUROLOGIC DISORDERS

As with any other neurologic disorder, the key to diagnosis of FND involves careful assessment of findings detected on neurologic examination, combined with clues from the clinical history. Of critical importance is

Aminoff’s Neurology and General Medicine, Sixth Edition.

that the diagnosis of FND is made on the basis of positive findings, not merely one in which other "organic" diseases are excluded (Table 52-1). Positive findings suggestive of a diagnosis of FND are discussed below.

TABLE 52-1 ■ Positive Signs on Neurologic Examination in Functional Neurologic Disorders

General Features

- Inconsistency
- Distractibility
- Suggestibility

Functional Weakness

- Drift without pronation
- Hoover sign
- Collapsing/give-way weakness

Functional Parkinsonism

- Excessive slowness without decrement in speed or amplitude on repetitive tapping
- Variability in tone during passive manipulation

Functional Tremor

- Variable frequency
- Entrainment or suppressibility of tremor with externally cued movement
- Pause with contralateral ballistic movement

Functional Dystonia

- Resistance to passive manipulation
- Lack of sensory trick
- Face region: tonic lateral deviation of lips or jaw to one side
- Face region: concurrent contraction of orbicularis oculi and contralateral frontalis

Functional Gait/Posture

- Better balance than claimed
- Excessive gait slowness
- Dragging monoplegic gait
- Knee buckling
- Absence of falls despite excessive sway during gait
- Excessive demonstration of effort
- Inconsistent, noneconomic posture

Functional Speech and Voice

- Effortful speech
- Excessive variability in severity during different speech examination activities

Functional Sensory Symptoms

- Splitting of vibration across forehead or sternum
- Precise midline splitting of sensory deficit
- Tubular visual field defect

Motor Disorders

Features suggestive of functional motor disorders include an abrupt onset of symptoms and inconsistency of the abnormal movements. Symptoms may rapidly vary in terms of severity, disappearing with distraction and increasing with attention. Diagnosis is based upon demonstration of motor inconsistency (i.e., varying symptoms with susceptibility to distraction) and/or incongruence (i.e., movements that are incompatible with normal physiologic patterns).

Several features on neurologic examination can point to a diagnosis of functional weakness. Drift without pronation of the weak arm, Hoover sign, dragging monoplegic gait, and collapsing or give-way weakness are all positive signs suggestive of functional weakness.[3] Hoover sign relies on contralateral synkinetic oppositional mirror movements, and is deemed to be positive when weakness of hip extension is corrected upon flexion of the contralateral hip against resistance. Dragging monoplegic gait describes a gait in which the leg is dragged with the knee extended and the ipsilateral hip either externally or internally rotated; this contrasts with the circumduction observed in the setting of organic leg weakness. Collapsing or give-way weakness describes the demonstration of strength followed by sudden collapse. It is important to note that the validity of these signs is variable. Collapsing weakness, for example, can also be seen in patients with pain or with difficulty following instructions in addition to those with functional weakness.

Functional excess movements can include functional tremor, dystonia, and myoclonus, among others. Functional tremor is characterized by its variable frequency and distractibility. The "entrainment test" is commonly used in the diagnosis of functional tremor and highlights its variable frequency. In this maneuver, the patient performs an externally cued rhythmic movement, with resulting suppression or altered frequency of the functional tremor. Features suggestive of functional dystonia include abrupt onset, fixed posture present from early in the course of the disease, and resistance to manipulation. Pain commonly accompanies functional dystonia, and sensory tricks are rare. Functional dystonia involving the cranial region can present with lateral deviation of the mouth, including the lower lip, jaw, and tongue. When functional dystonia involves the eye, spasm of the orbicularis oculi with contraction of the contralateral frontalis muscle may be seen.[1]

Functional parkinsonism can present with excessive slowness in the absence of decrement of repetitive movements, as well as normal speed when spontaneous movements are performed. Inconsistent rigidity and functional tremor may also be present.

Axial Disorders

Functional disorders of gait and posture are commonly seen in patients with FNDs. Features suggestive of functional gait include excessive gait slowness, noneconomic posture, astasia-abasia, sudden knee buckling, and excessive demonstration of effort, referred to as the "huffing and puffing sign." Functional postural abnormalities include propriospinal myoclonus, involving myoclonic-like jerks affecting the trunk.

Nonepileptic Seizures

Nonepileptic seizures (NESs) are the most common type of FND. Differentiating between NES and epileptic seizures (ESs) can be challenging. One difficulty is that the disorder is paroxysmal, and examination of the patient may well be normal. It is important to see an event, and a family member or friend should be asked to video the event if this has not been done already. Signs that may help to reliably distinguish NES from ES include long duration, fluctuating course, eye closure at onset, eye fluttering, ictal crying, memory recall, and preserved awareness. The presence of pelvic thrusting and asynchronous or side-to-side movements may also be used to reliably distinguish NES from ES, with the caveat that frontal-lobe partial seizures can also present with these signs. Although history-taking in patients with seizures often includes questions about the presence of urinary incontinence and tongue biting, these features do not reliably distinguish between ES and NES.[4]

Speech and Voice Disorders

Functional speech and voice disorders can present in a variety of ways affecting articulation, prosody, or phonation. As with other functional neurologic symptoms, functional speech and voice disorders can be distinguished by their variability, suggestibility, and distractibility. Articulation deficits can present as a dysfluency similar to stuttering; functional stuttering can be differentiated from nonfunctional stuttering by its excessive consistency or excessive variability, or by the presentation of accenting the wrong syllable. Prosodic abnormalities affect the rhythm and intonation of speech and can include foreign accent syndrome or child-like prosody. Patients can also present with aphonia or dysphonia in the absence of vocal cord or neurologic pathology sufficient to account for the severity of their voice disorder.[1]

Sensory Symptoms

Functional sensory symptoms present with alteration of normal sensation in the absence of neurologic disease and are characterized by internal inconsistency. Physical signs suggestive of functional sensory loss include splitting of vibration sense across the forehead or sternum, precise midline splitting of a sensory deficit that ignores the crossover of cutaneous sensory nerves, nonanatomic sensory loss, and inconsistencies in sensory testing. Functional sensory signs must be interpreted with caution, however, given the relatively poor reliability and validity of sensory signs. While splitting of vibration sense and midline splitting have been demonstrated to have a high specificity for FNDs, inconsistencies in sensory testing may also be seen in patients with parietal or thalamic lesions.[1]

Functional visual loss can present with nonphysiologic visual field constriction, also referred to as tubular visual field defect, in which the area of the visual field defect remains unchanged despite changing distances from the visual target. Patients with functional vision loss may report a similar visual acuity at full distance and half-distance from the eye chart. Functional monocular vision loss can also present with a "missing half" defect, in which a complete hemianopia is present when both eyes are open, but a normal visual field is present when the unaffected eye is tested alone.[1]

Functional Dizziness

Dizziness is a common complaint and many patients will have an identifiable abnormality of the vestibular or related systems. Many patients have had some sort of vestibular insult that has resolved, or perhaps only an anxiety attack. They then might develop a complex of symptoms including prolonged episodes of dizziness or unsteadiness that are triggered by an upright posture, motion of any part of the body, or complex visual input. Symptoms may worsen over time and lead to significant distress or functional impairment. The symptoms cannot be explained by the objective findings on examination or by quantitative vestibular testing. This is called persistent postural-perceptual dizziness.

DIAGNOSTIC CRITERIA

Diagnostic clinical criteria for NES have been established by the International League Against Epilepsy. These criteria allow for a laboratory-supported diagnosis of documented NES with high interrater reliability. The gold standard for diagnosis of NES entails recording a typical event or ictus on video electroencephalography, with absence of epileptiform activity during the peri-ictal period, as well as ictal semiology and history consistent with NES.[4]

There are several proposed diagnostic criteria for functional movement disorders. While they vary in their characterization of levels of clinical certainty, all of these diagnostic criteria rely on the presence of the positive signs described earlier. Phenotype-specific diagnostic criteria have been proposed by Espay and Lang, allowing functional movement disorders to be diagnosed with clinically definite certainty exclusively on the basis of a careful neurologic examination performed by a neurologist with expertise in movement disorders. Historic elements and psychiatric comorbidities are not deemed a useful part of the diagnostic process according to these criteria, as both may be misleading.[5] Although many patients with a functional movement disorder can be diagnosed on the basis of a careful examination, there is utility in performing electrophysiologic tests in some patients. The Gupta-Lang criteria accordingly introduced a laboratory-supported diagnostic category, in which electrophysiologic tests confirming the diagnosis of functional tremor or functional myoclonus are used to make a definitive diagnosis of functional movement disorder.[1]

ETIOLOGY

There is no single cause for FNDs. Their etiology appears to be multifactorial, with different components important in different people. Current understanding is based on a bio-psycho-social model, with interactions among biologic, psychologic, and social factors. Among the social factors, one important finding is that there is an increase in early childhood trauma of all types including sexual, physical, and psychologic, in patients with FNDs.[6] Trauma at that time increases stress and circulating cortisol, and increased cortisol can damage the developing brain, leading, for example, to smaller hippocampal size. It has even been shown that emotional stress of the mother during pregnancy can influence brain development. This causes a decreased resilience to stress later in life. Other social factors include contemporary stress related to work or family. Due to decreased resilience, the stress does not need to be exceptional, and, indeed, many patients deny that they have greater stress than others.

As regards psychologic factors, many studies show an increased prevalence of anxiety and depression, especially the former, in patients with FNDs. These are important comorbidities and might share etiologic factors with FND. Biologic abnormalities have also been identified. For example, there are changes in local brain volume and changes in the white matter as shown with diffusion tensor imaging. One study with voxel-based morphometry of patients with functional movement disorders found changes in the left amygdala, left striatum, left cerebellum, left fusiform gyrus, bilateral thalamus, and left sensorimotor cortex.[7] Changes in the amygdala might reflect damage by early life trauma.[8] Other changes seem to reflect involvement of the motor system. There may well be some genetic predisposition as well.[9] In certain psychiatric disorders, epigenetic changes, likely due again to early life trauma, appear partly etiologic, and this might be true also of FNDs. Studies of heart rate variability in a patient group with functional movement disorders showed decreased variability, and such a finding might correlate with decreased resilience to stress.

PATHOPHYSIOLOGY

The pathophysiology refers to the genesis of symptoms.[10] There must be a link from etiology to pathophysiology, but this is not understood at this time. The first observation in all FNDs is that elemental motor and sensory function appears to be normal despite any apparent clinical abnormality. For example, in the motor system, despite apparent weakness, strength can be demonstrated with Hoover sign, and transcranial magnetic stimulation can show a normal pathway from motor cortex to muscle. In the sensory system, patients with functional somatic sensory disorders have normal early somatosensory evoked potentials, and those with functional dizziness will have normal vestibular function. The abnormality is therefore at “higher” levels in the central nervous system. In sensory systems, this could be in association areas or in the downward modulation of primary areas. In the motor system, this could be from influences almost anywhere in the brain, as virtually the entire brain influences the motor system. There is a particularly interesting finding in functional weakness that does implicate top–down processes. Motor evoked potentials (MEPs) produced by transcranial magnetic stimulation are ordinarily enhanced when a subject imagines moving the target muscle. In patients, the MEP decreases in size. There is evidence for overactivity of the limbic system, which might be the main source of the problem. Indirect evidence comes from an exaggeration of the startle reflex, which importantly is modulated by the amygdala. Direct evidence comes from a functional magnetic resonance imaging (fMRI) study of the reaction of the brain to faces that show different emotions. Patients with functional movement disorders showed increased activation of the right amygdala to both happy and fearful faces.

The other aspect of the pathophysiology is the involuntary nature of symptoms. This has been studied in functional movement disorders, and there appears to be an abnormality of the right temporoparietal junction region. This region is a major node in the brain’s processing of the sense of agency, the sense that the person is the “agent” that made the movement. Strong evidence for this abnormality came from an fMRI study looking at patients with functional tremor.[11] The fMRI activation was compared between the functional tremor and a voluntary mimic of the tremor. Decreased activity was found at the right temporoparietal junction when patients exhibited functional tremor. Abnormality of this region was subsequently found even in a resting-state fMRI study.[12] Thus, the abnormal movements seem involuntary to the patient. How this all happens is not clear, but there might be an abnormal feedforward signaling from the movement generation process.

TREATMENT

Delivery of the Diagnosis

Appropriate delivery of the diagnosis is the first step and an important part of the therapeutic process, with early diagnosis and acceptance of the diagnosis serving as predictors of positive outcome.[1] The diagnostic encounter serves multiple objectives. The patient should ideally emerge from this encounter with confidence in their diagnosis, a sense of partnership with their neurologist, and an understanding of the multidisciplinary nature of the subsequent management.

FND, in the majority of cases, is a definitive diagnosis and should be presented in this manner to the patient. Patients should be informed that there is an established diagnosis, using clear language they can readily understand. The rationale behind the diagnosis should also be provided. Just as patients with multiple sclerosis are informed about the results of their brain MRI and lumbar puncture, patients with FNDs should be presented with the evidence supporting their diagnosis. Showing patients with FNDs the features of their neurologic examination that led to their diagnosis is integral in establishing confidence in the diagnosis. Patients with functional tremor can have their attention drawn to the entrainment or suppression of their tremor with contralateral tapping, whereas patients with functional weakness can be shown a positive Hoover sign.[13]

The disorder should be explained in layperson’s terms within the biopsychosocial framework described above. Importantly, the potential for reversibility with treatment should be stressed. Given limited public awareness about FNDs, it is helpful to provide the patient with additional educational resources to review after the consultation. Patients can be directed to online resources such as www.nonepilepticattacks.info and www.neurosymptoms.org, and to patient organizations such as www.fndhope.org.

Developing a sense of trust and partnership between the patient and physician at the time of initial diagnosis is important in the context of the growing recognition of the role of the neurologist as coordinator of care for patients with FNDs. In addition, symptomatology in these patients may evolve over time, and patients should feel comfortable in returning for a re-evaluation should new symptoms arise.

Psychologic Treatment

Psychologic treatment has traditionally been considered the standard of care in the treatment of FNDs. While the literature on evidenced-based treatment of FNDs is scarce, evidence has grown nevertheless for the efficacy of psychologic treatment. One meta-analysis demonstrated a substantial reduction in seizure frequency in over three-quarters of patients with NES treated by psychologic interventions.[14] Various types of therapy have shown promise, including disorder-adapted cognitive behavioral therapy (CBT), multimodal cognitive behavioral-informed psychotherapy, CBT-oriented self-management, and interdisciplinary psychodynamic interpersonal therapy. The overall goals of psychologic treatment are to explore and address unhelpful beliefs and behavior, which may influence symptom control, self-esteem, mood, and anxiety. Patients are taught to identify how their thinking affects their emotional state and their behavior and to identify triggers exacerbating symptoms.[15] Pilot studies have demonstrated significant benefit of CBT in treating a range of functional neurologic symptoms, including functional tremor[16] and NES.[17] In addition to improvement in clinical symptoms, patients with functional tremor exhibited significant changes in activation within the emotion-processing network after a 12-week CBT program, as assessed by fMRI during a basic-emotion processing task.[16]

Motor Rehabilitation

Physical therapy has an important role in the multidisciplinary treatment of patients with prominent motor symptoms. A set of consensus recommendations has identified principles to guide this type of therapy. These recommendations suggest that physical therapy programs can and should work within the biopsychosocial model of functional movement disorders, in which a patient's abnormal movements are involuntary but also represent learned habitual movements driven by abnormal self-directed attention. CBT and stress reduction techniques can be incorporated into the physical therapy to normalize illness beliefs and change maladaptive behaviors. Physical therapy for functional movement disorders focuses on function and automatic movements (e.g., walking) rather than on impairments (e.g., weakness) and controlled movements (e.g., strengthening exercises).[18]

Other Treatment Options

If present, comorbid depression or anxiety may be treated pharmacologically. A variety of nonpharmacologic interventions have also been used, including transcutaneous nerve stimulation, transcranial magnetic stimulation, biofeedback, and therapeutic sedation.[15] Further work is needed to evaluate the efficacy of these interventions.

Multidisciplinary Approach

It is often the case that patients need attention from several disciplines, including psychiatry, physical therapy, and social work. It can be debated who should manage the team, but this can certainly be an appropriate role for the neurologist. Patients with FNDs have neurologic symptoms and neurologists are in an optimal position to make continuing assessments and redirect treatment as necessary.

EMBOLIZATION AND STENTING PROCEDURES

Neurologic complications of imaging examinations and image-guided procedures are varied and largely related to excessive or inappropriate use of ionizing radiation-based imaging studies, local complications of the invasive procedure, complications related to exposure to high magnetic fields, or complications arising from the use of intravenous contrast agents. This chapter provides a summary of neurologic complications related to those imaging procedures that are commonly performed in modern radiologic practices. Some historic perspective is presented as well, and the reader must be aware that changes in the practice of radiologic procedures affect the kinds of complications and their incidence over time.

IONIZING RADIATION

The safety of patients and healthcare workers in diagnostic and interventional radiology is based on three fundamental principles of radiation protection of patients: justification for an imaging procedure, optimization of the imaging procedure, and the application of ionizing radiation doses “as low as reasonably achievable” (ALARA).[1]

COMPLICATIONS OF INTRAVENOUS INJECTION OF CONTRAST MATERIAL

Radiographic contrast agents have been in use for over 70 years and are employed in approximately 10 million radiographic procedures annually in the United States. They find wide use in the evaluation of disease processes both within the central nervous system (CNS) and throughout the body. Contrast material helps to define normal vascular anatomy as well as pinpoint patterns of abnormal contrast enhancement indicative of pathologic processes. Most patients tolerate radiographic contrast with few or no side effects.

Iodinated Contrast Media

Iodinated contrast medium is used extensively for intravenous and intra-arterial x-ray imaging examinations.

Aminoff's Neurology and General Medicine, Sixth Edition.

The risk of adverse reactions is low, especially as usage has changed from ionic to nonionic, low-osmolality agents. The latter has largely replaced ionic high-osmolality agents and is associated with an incidence of acute adverse reactions (allergic-like plus physiologic) of less than 1 percent. Another advantage of nonionic agents is their isotonicity, which markedly reduces the sensation of heat and flushing.[2]

Contrast reactions are sporadic and largely unpredictable. A prior allergic reaction to contrast material is a substantial risk factor for a recurrent allergic-like adverse event. Atopic individuals and asthmatics are also at increased risk for allergic-like contrast reactions. In addition, hemodynamic changes may occur during or shortly after injections in patients with various cardiovascular diseases.

Idiosyncratic allergic reactions may occur on first or subsequent contrast administration and range from hives to more severe reactions such as pulmonary or cerebral edema, laryngospasm, bronchospasm, and cardiovascular collapse. Dose-related effects of tonicity and chemical toxicity mainly affect the heart, lungs, and kidneys and include cardiovascular depression and renal failure. Life-threatening reactions occur in approximately 0.05 to 0.16 percent with ionic contrast media injections and 0.03 percent with nonionic contrast materials; the death rate, however, is similar with both types of agents, occurring in approximately 1 to 3 per 100,000 injections.[2,3]

Regardless of the type of contrast medium used, extravasation into the soft tissues of the arm at the time of injection may lead to local tissue injury, including skin necrosis. Swelling, which attends severe extravasation injuries, may also lead to compartment syndromes and therefore to injury of peripheral nerves. This is a rare complication, but the risk increases with the use of automated power injectors, and the administration of contrast to infants, young children, and unconscious or debilitated patients (such as diabetics or patients receiving chemotherapy).

Contrast Media for Magnetic Resonance Imaging

Most contrast agents for magnetic resonance imaging (MRI) are variations of chelates of gadolinium, a lanthanide metal. Gadolinium is toxic in its free form, but through chelation with diethylenetriamine penta-acetic acid (DTPA) or other moieties is typically eliminated from the body by renal clearance. Gadolinium-based contrast media are considered safe and well tolerated by the vast majority of patients; the incidence of complications is less than 0.5 percent. Minor side effects including headache, nausea, and vomiting, are sometimes noted, but the risk of immediate hypersensitivity reactions is extremely low, on the order of 1 per several 100,000 injections.[4] Nonetheless, severe immediate hypersensitivity reactions and death secondary to gadolinium administration do occur. Clement and coworkers have shown that, while rare, allergic hypersensitivity reactions are identified in up to 20 percent of patients experiencing a reaction to intravenous contrast material, including gadolinium,[4] and there is a high incidence of cross reactivity with other agents in the same family, especially for gadolinium agents.

Gadolinium agents cross the placenta, with undetermined effects on developing fetuses, and are seen in small amounts in the breast milk of lactating mothers; therefore, they are not recommended for use in pregnant women unless absolutely necessary. It is unlikely that the small amount of gadolinium absorbed by a nursing infant's gastrointestinal tract is harmful but, if concern exists, the nursing mother can be advised to discard her breast milk for 24 hours after gadolinium administration.

Based on the structures of the chelating ligands, gadolinium contrast agents can be divided into two categories: linear and macrocyclic. According to their charges, gadolinium can also be subclassified into ionic or nonionic agents. Macrocyclic and ionic agents are more stable than linear agents, as the free gadolinium is completely isolated within the preformed cage of the macrocyclic chelate whereas, in linear molecules, free gadolinium is wrapped around with elongated ligands. Gadolinium may become disassociated from its chelated agent and is then deposited in the tissues, including the brain. This occurs primarily in the dentate nucleus of the cerebellum, but in other areas as well. No known deleterious effects have been identified from this deposition seen on T1-weighted MR scans as high signal, particularly with repeated injections of linear gadolinium agents.[5]

Nephrogenic systemic fibrosis, characterized by fibrosis of skin and other organs, is a rare disorder caused by deposition of free gadolinium following administration to patients with acute renal failure. For this reason, the use of linear gadolinium agents is not advised in patients with a glomerular filtration rate of less than 30 mL/min per 1.73 m^2. Macrocyclic gadolinium contrast agents are much less likely to cause this complication and can be safely administered to patients with glomerular filtration rates between 15 and 30 mL/min per 1.73 m^2.

Other novel MRI contrast agents are now available for limited clinical applications. The superparamagnetic iron chelates work on the basis of reducing signal within normal tissues such as lymph nodes and liver and thus provide contrast for nonenhancing abnormal tissues. Chelates of manganese are also approved for liver imaging. Free manganese has a theoretical risk of parkinsonian complications, but the chelated compound caused no serious side effects during phase 2 clinical trials. Intravascular contrast agents are being evaluated and promise to improve magnetic resonance angiography and perfusion of brain tumors.

Deleterious effects of MRI exposure on pregnant women or the developing fetus have not been shown. Nevertheless, it is recommended that women of reproductive age be screened for pregnancy before entering the MR environment. The clinician should confer with the radiologist and document that the information cannot be acquired by other nonionizing means (e.g., ultrasonography), that the information is needed to care for the patient or fetus during the pregnancy, and that it is not prudent to wait until the patient delivers to obtain the scan.

Miscellaneous Complications of Contrast Media

Rare complications of contrast administration include retrograde reflux of contrast material via the abdominal port of a ventriculoperitoneal shunt after bladder rupture sustained during voiding cystourethrography. The extravasated contrast medium then tracked up the ventriculoperitoneal shunt, causing seizures and ventriculitis. Venous air embolism has been documented during infusion of contrast medium, due to either scalp vein malposition or inadvertent trapping of air within power injectors or tubing. Venous air embolism can cause a stroke, especially in infants with patent cardiac foramen ovale or other right-to-left shunts.

Acetazolamide, a vasodilator of the cerebral circulation, is now occasionally administered for perfusion MR or computed tomography (CT) studies. Comparison of studies before and after acetazolamide allows determination of the cerebral vascular reserve. Acetazolamide, although well tolerated, has minor side effects such as nausea and headache. It is a diuretic, so adequate hydration and satisfactory serum potassium levels must be ensured, particularly in those already receiving diuretics for medical reasons. Acetazolamide is probably not indicated in the setting of acute stroke because its diuretic effect may reduce cerebral perfusion.

NONINVASIVE IMAGING PROCEDURES

Computed Tomography

Neurologic complications of x-ray CT are related to complications of sedation, contrast administration, or other mishaps that incidentally attend the procedure. There is a small risk of radiation-induced cataracts, leukemia, and other tumors following multiple CT studies, especially in children. This concern has increased with recent technologic advances: helical-mode scanners are now used routinely in CT angiography and CT perfusion studies to scan rapidly large regions of the body. Multiple scans during infusions of contrast material may result in additional radiation exposure. For this reason, MRI and ultrasound are better methods for following patients who require repeated imaging procedures, as long as their diagnostic benefit is equivalent to or better than that of CT.

Magnetic Resonance Imaging

MRI has rapidly gained wide acceptance in the imaging of the CNS as well as for musculoskeletal and many cardiac and general body applications. Images are produced by placing a patient in an extremely strong static magnetic field (on the order of 15,000 to 30,000 times the Earth's magnetic field) and then probing the magnetic relaxation properties of water protons in the body using radiofrequency pulses; computer mathematical manipulation allows the production of images.

Because of the need for a very strong, continuous magnetic field, the presence of metal objects near the imaging environment can be hazardous, since they can accelerate toward the magnet, acting as missiles with resultant harm to patients and staff. Anyone coming into proximity of an MRI machine is therefore routinely screened for ferromagnetic objects prior to entering the magnet room. The major contraindications to MRI examinations include the prior placement of ferromagnetic aneurysm clips or cardiac pacemakers, intraocular metallic foreign bodies, certain types of prosthetic cardiac valves, electronic or magnetically activated medical devices, and any other large, potentially ferromagnetic foreign body. Pacemakers have long been considered an absolute contraindication to MRI, but recent literature suggests that these studies can be safely performed in some patients as long as precautions are taken before, during, and after the study and the benefit of MRI outweighs the risk of pacemaker malfunction or harm to the patient. Implanted cardiac defibrillators likewise have led to no adverse events from repetitive MRI at 1.5 T in patients with implanted defibrillators.

The hazard of aneurysm clips deserves special attention. Most currently manufactured aneurysm clips have few if any ferromagnetic properties, as judged by lack of deflection within a magnetic field when tested in vitro. At least one instance of fatal clip movement in a patient has, however, been reported, and in that case was due to inaccurate information supplied during the screening process. Newer nonferromagnetic clips, such as titanium alloys, are safe at 1.5 T, but discretion is always advised. At higher field strengths, such as 3 T, titanium alloy clips are preferred if MRI is necessary, but care must be taken while moving patients through the opening of the bore toward the center of the magnet, as the largest torque forces occur during this maneuver. The potential information to be gained from the procedure must be carefully balanced against the potential danger of clip movement. Although the metal from the clip may cause significant artifact on the examination, useful information can often still be gleaned by appropriately tailoring the examination.

The potential risks of metallic stents and endovascular detachable coils also merit consideration. A new generation of MRI scanners, including at 3.0 T, with shorter lengths and wider apertures (e.g., 70 cm diameter and about 160 cm length), results in much larger gradients. Larger magnetic susceptibility of the employed material, larger mass, higher magnetic field, and larger gradient will increase the magnetic force on the metallic implant upon entering the MRI magnet. These devices produce ferromagnetic artifacts, and thus the local anatomy is distorted on MRI. MRI is safe at 1.5 T for patients who have recently had placement of a coronary stent.

Some monitoring devices are potentially dangerous because looped metallic wires may acquire induced currents, resulting in burns to the skin attachment sites. The US Food and Drug Administration (FDA) received 1,568 adverse event reports for MR systems between January 1, 2008 and December 31, 2017. Thermal events were the most commonly reported serious injury (59%). In addition, mechanical events—defined as slips, falls, crush injuries, broken bones, and cuts; and musculoskeletal injuries from lifting or movement of the device—were observed in 11 percent, projectile events in 9 percent, and acoustic events in 6 percent.[6] For this reason, all physiologic monitoring equipment and other devices must be carefully screened and approved specifically for use during MRI. Exposure of electrically conductive leads or wires to the RF transmitted power during MR scanning should be performed with caution and appropriate steps taken to ensure that lead or tissue heating does not result. Patients who require EKG monitoring and who are unconscious, sedated, or anesthetized should be examined after each MR imaging sequence and repositioning of the EKG leads and any other electrically conductive material with which the patient is in contact should be considered. Extensive testing and safety information about specific devices is available from MRIsafety.com as well as from Shellock and associates.[7]

Screening of patients referred for MRI is essential prior to the examination. If patients are unable to fill out a questionnaire or are unconscious and their family is not present or unable to provide the required information, they should be thoroughly examined by medical personnel with attention to surgical scars. If these are present, a radiograph is suggested prior to MRI. When in doubt, the presence of a specific medical device must be documented precisely and in writing before entry of the patient into the magnet. This information can be checked against the known magnetic deflection properties of the device, as appropriate. In patients with a history of possible metallic ocular foreign body, plain radiography of the orbit or low-dose orbital CT can be used to exclude the presence of significant metal fragments, as these can move in the magnetic field and result in ocular injury and blindness.

Another potential hazard related to the static magnetic field required for MRI is that of missile injury, mentioned earlier. The missile effect is perhaps the most serious potential hazard because many clinicians entering the MR environment are not aware that the magnet is always "on." Paper clips, scissors, vacuum cleaners, chairs, floor buffers, oxygen tanks, anesthetic equipment, and other ferromagnetic metallic items have been pulled rapidly into the bore of a magnet when inappropriately brought close to it, sometimes with fatal results. Proper introduction to safety precautions for visitors is important. The American College of Radiology recommends that zones of access be created and labeled to inform the public as they get closer to the magnet room itself.

The rapid switching of the gradient coils used in MRI may result in induced voltage and current in implanted wires, such as cardiac leads or brain-implanted electrodes, as well as thermal injuries. MRI gradients may cause a loud vibration or banging noise that can result in hyperacusis or tinnitus. Both temporary and permanent instances of hearing loss have also been reported; for these reasons, the use of earplugs is mandatory during

MR examination for all patients as well as accompanying parents or visitors within the magnet room. These are especially recommended in cases requiring very rapid switching of gradient coils, as with most MR angiography sequences and ultrafast techniques such as fast spin-echo and echo-planar techniques (e.g., diffusion and perfusion imaging and functional MRI). Tissue heating is also a potential but relatively insignificant complication of MRI. The FDA limits the specific absorption rate, which is the radiofrequency energy deposition, to 0.4 W/kg averaged over the body. In animal studies, levels at 10 times this rate over a 75-minute period raise the skin and eye temperature of a sheep by only 1.5°C, with no observed side effects. Nonetheless, the FDA has determined limits, particularly for small infants and children.

SPINAL PROCEDURES

Myelography and Intrathecal Injections of Contrast Media

The number of myelographic procedures has diminished dramatically since the introduction of MRI and CT. MRI is superior to myelography in the evaluation of lumbar disc disease, discitis and vertebral osteomyelitis, myelopathy, and extradural and intradural spinal mass lesions.

When myelography is recommended, it usually is performed in conjunction with CT. CT myelography is preferred to plain-film myelography for evaluating the thecal sac in those patients who cannot tolerate MRI because of severe claustrophobia or because of other contraindications to the magnetic environment, discussed previously. Many patients with severe spondylitic disease of the spine or failed-back syndrome may benefit from CT myelography. In such instances, a lumbar puncture is performed for instillation of 5 to 8 ml of iodinated nonionic contrast before thin-section CT scanning is performed. In many patients, CT myelography may complement MRI, especially in patients who have bony osteophytes that may be difficult to distinguish on MR or in those with metal implants that obscure MR images.

Few indications remain for traditional plain-film (high-dose) myelography. Those with suspected cerebrospinal fluid (CSF) loculations or arachnoid cysts may still benefit from myelography because the septations separating these CSF-filled structures can be difficult to detect on MRI and the dynamic nature of myelography can be useful. In addition, myelography in combination with CT is required occasionally to locate precisely the site of a spinal CSF leak. Conventional myelography is also indicated occasionally for the evaluation of patients with back pain after orthopedic instrumentation because CT and MRI are often compromised by metallic artifacts.

The reduction in myelograms performed at teaching institutions has reduced the exposure of trainees in radiology to this procedure. As with any procedure, the incidence of complications associated with a procedure relates to the experience of the practitioner. In the case of myelography, it is our impression that the rate of complications is on the rise because of the decrease in experience of recent trainees. It is therefore appropriate to review the neurologic complications of myelography and intrathecal injections of contrast material despite their decline in use.

TERMINOLOGY

Myelography entails plain-film examination of the spine following intrathecal instillation of iodinated contrast media through either a lumbar puncture or a cervical puncture at the C1–C2 level, posterior to the spinal cord. Water-soluble, nonionic contrast agents are used exclusively. Using a tilt-table and fluoroscopy, the contrast is positioned by gravity into the area of interest. Cervical, thoracic, and lumbar myelography as well as “total” myelography can be accomplished through a single needle puncture. Before MRI, the choice of a lumbar or C1–C2 puncture was largely determined on the basis of clinical symptomatology. Low-dose (lower than routinely administered for plain-film myelography) injections before CT scanning, so-called *CT myelography*, has replaced formal plain-film myelography. Current multidetector high-speed CT scanners are capable of high-resolution, less than 1-mm contiguous scans through the entire spinal canal in less than 30 seconds and, from these, superb tomographic reformations in the sagittal and coronal planes are possible. Occasionally contrast must be positioned intracranially to opacify the CSF cisterns. MRI has now largely replaced CT cisternography, but it is still used occasionally to evaluate for CSF leak and the presence of intracranial arachnoid cyst.

TECHNIQUE

Several approaches are used to perform intrathecal injections. Typically, a 22-gauge or smaller spinal needle is positioned with fluoroscopic or CT guidance in the lumbar subarachnoid space. This requires topical and subcutaneous anesthesia and is contraindicated in those with bleeding disorders. While lateral fluoroscopy was for many years the preferred technique for C1–C2 puncture, the puncture is performed more safely using CT guidance so that the needle can be placed posterior to the spinal cord. C1–C2 puncture carries a risk of cervical cord puncture, and efforts must be taken to avoid this by proper positioning of the patient and careful technique. Alternatively, low-dose injection of contrast medium via the lumbar route is adequate to examine the cervical spine and is associated with fewer potential complications than the C1–C2 route. CT is performed immediately after instillation of contrast medium. Delayed CT was used in the past to evaluate for syringomyelia, but MRI now best evaluates this condition.

Cisternal puncture in the suboccipital region is rarely if ever performed. The authors have never performed this procedure themselves and see little indication for its use in the current era of MRI.

COMPLICATIONS OF INTRATHECAL PUNCTURE

The neurologic complications of myelography and intrathecal injections can be separated according to those related to intrathecal needle puncture itself and those related to the administration of intrathecal contrast material.

Vasovagal Response

Vasovagal syncope occurs infrequently during lumbar puncture. Its occurrence can be anticipated by communication with the patient and by noting the initial appearance of diaphoresis. This usually occurs during head elevation and can be countered by prompt lowering of the patient's head.

Headache

Headache and associated nausea and vomiting are the most frequent complications of lumbar puncture and myelography. The incidence of headache after myelography decreased with the development of nonionic, water-soluble contrast agents. The etiology of the headache is often obscure and may be related to neurotoxic effects of the contrast agent, persistent CSF leak at the puncture site, or psychologic factors. The incidence of postdural puncture headache can be reduced by the use of a small-gauge lumbar-puncture needle. Other factors that have been identified include sex (11.1% female vs. 3.6% male), age (11.0% 31 to 50 years of age vs. 4.2% others), previous history of postpuncture headache (26.4% positive vs. 6.2% negative), and needle bevel orientation (16.1% perpendicular vs 5.7% parallel to the spinal axis). The latency between lumbar puncture and headache onset ranges from 6 to 72 hours and the duration from 3 to 15 days. In 34 of 48 (71%) patients with postlumbar puncture headache, at least one of the following was present: neck stiffness, tinnitus, hypoacusis, photophobia, or nausea. The condition is usually self-limiting; caffeine alleviates the symptoms and reduces the course of the illness. When bed rest and caffeine prove ineffective, an autologous epidural blood patch at the site of puncture works well for the majority of patients.

After myelography, it is common practice to keep patients in a supine position, with the head elevated approximately 25 to 45 degrees. Short-duration (1 hour) is as effective as long-duration (4 hours) supine recumbency in preventing postlumbar puncture headache. Oral hydration is also encouraged.

Hearing Loss

Hearing loss has been described as an adverse reaction after lumbar puncture as well as after myelography. It may be uni- or bilateral, and transient or permanent. Alteration in the pressure equilibrium between CSF and perilymph in the setting of a patent cochlear aqueduct may result in the release of perilymphatic fluid into the subarachnoid space; alternatively, a direct toxic effect of contrast material on the inner ear may be a factor in hearing loss. The use of small-gauge spinal needles has been recommended to reduce the leakage of CSF through the dural puncture. The use of nonionic myelographic agents is now standard, and these agents have been shown to be safer than ionic formulations.

Epidermoid Tumors

Iatrogenic intraspinal epidermoid tumors have been reported as sequelae of lumbar puncture. It is believed that implantation of epithelial cells from the skin into the thecal sac or the epidural space during lumbar puncture may allow this benign tumor to grow gradually. The incidence of iatrogenic epidermoid tumors is exceedingly rare, but up to 40 percent of those occurring in the lumbar spine are thought to relate to prior lumbar puncture. The time from lumbar puncture to tumor presentation is typically from 2 to 8 years. Epidermoid tumors appear on MRI as masses with signal characteristics similar to CSF, but with reduced apparent diffusion coefficient derived from diffusion-weighted images. The presence of this rare tumor should arouse suspicion of possible iatrogenic causes, and a history of prior lumbar puncture should be sought.

Hemorrhage

Intracranial hemorrhage secondary to myelography has been well documented. It is likely that this complication relates to persistent CSF leakage and low intracranial CSF volume, which then result in the production of subdural hematomas or intracranial hemorrhages. Direct laceration of a vessel is rare. Acute epidural hematoma complicating myelography in a normotensive patient with normal blood coagulability is rare but has been reported.

Spinal punctures should not be performed in the setting of abnormal coagulation factors. In patients receiving systemic anticoagulants, there is an increased risk of epidural hematoma at the site of puncture. The Society of Interventional Radiology published consensus guidelines in 2019 for the management of coagulation status prior to image-guided procedures.[8] It recommends that prior to spinal procedures such as lumbar puncture, vertebroplasty, and nerve blocks or epidural injections, an INR above 1.5 and platelet count below 40,000/μL should be corrected, and that clopidogrel (Plavix) should be stopped for 5 days and low-molecular-weight heparin for 1 day prior to the procedure.

Puncture of the Spinal Cord

Although uncommon, puncture of the spinal cord has been described during lumbar puncture. This complication can be avoided by restricting lumbar punctures to below the L2 level. A low-lying conus or tethered cord will increase the risk of cord puncture, and it is therefore important to review the MR or other spinal imaging studies prior to lumbar puncture.

COMPLICATIONS OF C1–C2 PUNCTURE

Complications related to the C1–C2 approach have been well documented in the literature and include direct puncture of the spinal cord, laceration of epidural and vertebral venous and arterial structures, and spinal cord compression related to neck hyperextension during the procedure. Spinal cord and blood vessel punctures are the most serious complications and occur during fluoroscopic-guided procedures primarily because of incorrect positioning of the patient's neck and misdirection of the x-ray beam.

The indications for C1–C2 puncture are infrequent. In those patients who cannot undergo MRI but who require cervical myelography, low-dose CT myelography through a lumbar puncture often suffices. This route of administration has been associated with a slightly higher incidence of headache, nausea, and vomiting than with the C1–C2 puncture; however, the use of low-dose, nonionic, water-soluble agents has reduced these complications to an acceptable level. Rarely, a patient who cannot undergo MRI may require C1–C2 puncture to determine the upper margin of a spinal block or a CSF leak in the cervical-thoracic junction.

The injection of contrast material into the spinal cord may be associated with hemorrhagic necrosis of the gray matter and acute neurologic decline. Acute and permanent trigeminal dysesthesias and quadriparesis are reported complications of spinal cord injection. These may be ameliorated by prompt administration of high-dose corticosteroids.

Injection into the epidural venous plexus and intra-arterial injection into an aberrant vertebral artery have also been documented. In approximately 2 percent of patients, the vertebral artery swings inferiorly into the posterior C1–C2 interspace; in such cases, an approach by lateral C1–C2 puncture may then inadvertently lacerate or puncture it. Death of a patient after C1–C2 myelography due to acute subdural hemorrhage as a consequence of laceration of an anomalous intraspinal vertebral artery has been described.

The majority of complications can be attributed to cervical spine hyperextension during the procedure and the remainder to direct complications of the C1–C2 puncture. The narrow sagittal diameter of the spinal canal and severe cervical spondylosis are factors that contribute to hyperextension injury of the cervical spinal cord during prone C1–C2 puncture. Should cervical CT myelography be required, it is our recommendation that it be performed if possible via a low-dose lumbar injection followed by thin-section CT rather than C1–C2 puncture.

COMPLICATIONS FROM INTRATHECAL ADMINISTRATION OF CONTRAST AGENTS

Neurologic complications related to the intrathecal administration of contrast agents range from aseptic meningitis to encephalopathy and seizures. Other reported complications include hyperthermia, hallucinations, depression and anxiety states, and headache. The development of nonionic, water-soluble contrast agents has reduced these neurotoxic side effects significantly. On occasion, intrathecal gadolinium has been used to perform MR myelography in search of a CSF leak. A small amount (<0.3 ml) of gadolinium is administered intrathecally and MR scans are performed following this with fat-suppressed T1-weighted images. An inadvertent overdose of intrathecal gadolinium reportedly has resulted in transient neurotoxic manifestations, including a decreased level of consciousness, global aphasia, rigidity, and visual disturbance.

Meningitis

Both aseptic and bacterial meningitis are reported complications of lumbar puncture and myelography. Bacterial meningitis, which is characterized by the abrupt onset of fever, usually within 24 hours after the intrathecal instillation of contrast, must always be excluded when it is a clinical possibility. Use of facemasks by physicians performing lumbar puncture has been advocated to reduce the possibility of oral contamination. In aseptic meningitis, transient CSF pleocytosis (neutrophils and lymphocytes) and elevated protein concentrations accompany symptoms and signs that are similar to those of bacterial meningitis. Once a bacterial infection has been excluded, the use of corticosteroids may be helpful in relieving symptoms of aseptic meningitis. Persistent leakage of CSF at the puncture site must also be considered in patients with postural headache and pleocytosis, since the clinical picture may be confused with aseptic meningitis.

Seizures

Intrathecal contrast material may cause other, less frequent but potentially serious complications. Encephalopathy, seizures, and focal neurologic deficits have all been reported after myelography, presumably owing to reflux of contrast material into the subarachnoid space about the brain. The risk of seizures is on the order of 0.1 to 0.3 percent with the nonionic, water-soluble contrast agent iopamidol. Increased risk of seizures is present when the total dose of iodine is greater than 4,500 mg, there is a pre-existing seizure disorder, a cervical route of injection is chosen, or the patient is concurrently taking a drug known to lower the seizure threshold.

Inadvertent administration of ionic contrast media used for urography or angiography during myelography causes convulsions that probably arise within the spinal cord itself as well as the brain. These water-soluble, ionic contrast agents are visually indistinguishable from the nonionic contrasts used for myelography; therefore, care must be taken in identifying by their label those indicated for myelography.

Arachnoiditis

Arachnoiditis, or inflammation of the leptomeninges, has also been ascribed to the use of contrast agents for myelography. Iophendylate (Pantopaque), an oil-soluble contrast agent no longer used in clinical practice, was first noted to cause arachnoiditis, especially when accompanied by subarachnoid blood (i.e., after a traumatic tap). Water-soluble contrast agents reduced the incidence of arachnoiditis and were proven safe in the setting of subarachnoid hemorrhage. In many cases it is difficult to ascribe this syndrome with confidence to the contrast agent because confounding variables such as trauma, surgery, infection, or bleeding may have occurred within the spinal subarachnoid space and these have also been associated with arachnoiditis. The issue is further complicated by the observation that arachnoiditis can be induced by intrathecal corticosteroid injections. Clinically, patients usually have symptoms of constant low back pain aggravated by movement. Evidence of multifocal radiculopathy is found on examination. On repeat myelography or MRI, the nerve roots of the cauda equina appear thickened, clumped, and adherent to the periphery of the thecal sac. Enhancement of the roots may occur following intravenous contrast administration. Arachnoiditis is now rarely seen with the use of water-soluble, nonionic contrast agents.

Discography

The value of discography is unclear. The procedure has been advocated in the past primarily as a provocative test that attempts to recreate the patient's back pain syndrome, with the goal of isolating the generator of pain. A needle is placed in the nucleus pulposus of a lumbar or cervical disc and water-soluble contrast agent is injected while observing the patient's response. CT can be performed after discography for added spatial resolution. Although the MRI findings and discography correlate in many instances, MRI does not reliably predict which disc is the cause of a patient's pain.

Discography is a controversial procedure. Carragee and associates found that discography resulted in accelerated disc degeneration, disc herniation, loss of disc height and signal, and the development of reactive endplate changes compared to matched controls.[9]

Complications of discography are related mainly to septic or aseptic discitis. Antibiotics are often added to the contrast media used for discography, but evidence of benefit for their routine use is lacking. Care must be taken to prevent intrathecal instillation of antibiotic-contrast solutions. The incidence of discitis may be related to the length of the procedure, the use of a single needle rather than coaxial technique, and breaks in sterile technique.

Epidural and Transforaminal Anesthetic Neural Block

Patients with back or neck pain often benefit from local anesthetic blockade either to confirm the location of the pain generator or to reduce pain, or both. Diagnostic and therapeutic nerve root blocks involve the local injection of anesthetics (e.g., 0.75% bupivacaine or 1% lidocaine) with or without steroid compounds around exiting nerves or into the epidural space of patients suffering from local or radicular back or neck pain. Injections are administered via a 22- to 25-gauge needle placed into the area of interest using fluoroscopic or CT guidance. Direct injections are made into the epidural compartment of the spine, facet joints, or focally around an exiting nerve near the neural foramen. Complications of these procedures include spinal cord or cerebellar infarction secondary to injection into or spasm of the vertebral or radiculomedullary arteries, inadvertent injection into the spinal cord or nerve root itself, infection, and rare allergic or other side effects related to the injected agents. Botwin and co-workers reviewed the incidence of complications of fluoroscopically guided lumbar epidural injections in 207 patients and found a 9.6 percent incidence of minor complications ranging from transient headache, back pain, leg pain, facial flushing, vasovagal reaction, and increased blood glucose levels, most likely induced by systemic absorption of corticosteroid.[10] Serious complications such as epidural hematoma, spinal cord injection, and paraplegia or quadriplegia secondary to inadvertent injection into the spinal or vertebral artery have been reported following transforaminal epidural nerve block. An outbreak of fungal meningitis caused by contaminated steroid mixtures occurred in 2012.

ANGIOGRAPHY

Angiography is essential in the diagnostic evaluation of many patients with vascular disease, but it carries the greatest risk of morbidity among diagnostic imaging procedures. This risk is generated by the necessity of inserting a catheter into a blood vessel, directing the catheter to the required location, injecting contrast material to visualize the vessel, and removing the catheter while maintaining hemostasis. Skill, experience, and judgment are elements that help reduce the risk of this invasive procedure, but risk cannot be eliminated completely. Moreover, therapeutic transcatheter procedures (embolizations) have become important definitive and adjunctive therapies in patients with cerebrovascular, visceral, and peripheral vascular disease. The decision to undertake a diagnostic or therapeutic angiographic procedure requires sober assessment of the goals of the investigation and its risks.

Neurologic complications of angiography or embolization are the most feared because of the relative permanence of the deficit, which can profoundly impair the patient. Neurologic sequelae are encountered most often in angiographic procedures undertaken to evaluate or treat the vessels of the brain and spinal cord, but they can result from procedures undertaken to evaluate vascular disease elsewhere.

Cerebral and Aortic Angiography

Most aortic arch, carotid, and vertebral arteriograms are carried out by transfemoral arterial access. A common femoral arterial puncture provides retrograde access through the aorta to the aortic arch and great vessels. Selective catheterization of the carotid or vertebral arteries can be accomplished with a wide variety of catheter–guide wire combinations.

While minor complications such as hematoma at the site of vascular access are more common, the most feared complication of cerebral angiography is stroke (Table 53-1). Thrombus can form on or inside the tip of the catheter, especially if the catheter is not flushed properly with heparinized saline at regular intervals. Atherosclerotic intimal plaque may be present along the arterial wall, especially at the common carotid bifurcation. This thrombus or plaque can embolize distally into the cerebral circulation by force of injection or from dislodgment of plaque by the catheter or guide wire. The duration and extent of the resulting ischemic neurologic deficit depend on the size and length of the embolus, its composition (fresh thrombus is thought to fragment more readily), its location, and the available collateral circulation. Identified risk factors for ischemic complications include lack of experience on the part of the angiographer, atherosclerosis, vasospasm, low cardiac output, decreased oxygen-carrying capacity, duration of the procedure, and advanced age.[11] The risk of a neurologic complication has been estimated by many authors and is variable,

TABLE 53-1 ■ Summary of the Most Common Major Complications of Cerebral Angiography

Complication	Rate (%)
Access related	
Hematoma	0.5–1.7
Pseudoaneurysm/AVF	0.04–0.1
Vascular occlusion	0.14–0.76
Infection	0–1
TIA	1.2–2.5
Ischemic stroke	0.1–1
Systemic complications	
Severe allergic reaction to contrast	0.05–0.1
Renal failure	0–0.15
Conscious sedation–related	1.7
Death	0.06–0.1

AVF, arteriovenous fistula; TIA, transient ischemic attack.
Adapted from Alakbarzade V, Pereira AC: Cerebral catheter angiography and its complications. Pract Neurol 18:393, 2018.

but the risk of permanent neurologic deficit is probably between 0.1 and 1 percent depending on the previously mentioned cofactors.[12] A prospective evaluation of 2,899 consecutive angiograms performed by Willinsky and colleagues estimated the risk of neurologic complications to be 1.3 percent, but the vast majority were reversible; permanent ischemic stroke rate was only 0.5 percent.[11]

After cerebral angiography, clinically symptomatic infarcts are rare, but clinically silent infarction as assessed by diffusion-weighted MRI is far more frequent. Among 100 consecutive patients evaluated by Bendszus and colleagues, 23 developed a new lesion on diffusion-weighted imaging after cerebral angiography or embolization.[13] The frequency of lesions was significantly higher in patients with a history of vasculopathy or with vessels difficult to probe. Fluoroscopy time, amount of contrast used, and use of additional catheters were also correlated with the appearance of lesions.

Ischemic complications can also result from intimal dissection of the carotid or vertebral artery by direct trauma from the tip of the catheter or guide wire, allowing thrombus to form underneath a dissected intima and increasing the possibility of a thromboembolic complication. Catheter-induced spasm of an artery also raises the potential for neurologic complications. Although usually temporary, this phenomenon can result in a transient deficit if the spasm prevents adequate blood flow distally, or if a dissection results from further contrast injections within a spastic arterial segment.

Intravascular contrast material injected into the cerebral vasculature may have a hypoxic effect on the brain. In particular, patients with dolichoectasia of the basilar artery may sustain reversible brainstem dysfunction and acute short-term memory loss after multiple contrast injections into the vertebrobasilar system due to reduced contrast washout in the enlarged vessel. Limiting angiographic studies and, if required, the amount of contrast reduces the occurrence of this phenomenon.

Rarely, an intracranial aneurysm ruptures during an angiographic contrast injection, causing subarachnoid hemorrhage. This is reported to result from the force of the injection, although this theory is not accepted universally.

Before catheter insertion into the common femoral artery, the local soft tissues must be infiltrated with an anesthetic agent, usually lidocaine. If the anesthetic agent is inadvertently injected into the femoral nerve, transient dysesthesias may occur along the course of the nerve, which lies medial to the common femoral artery in the inguinal space.

In decades past, common practice dictated the use of a direct carotid artery puncture for the performance of cerebral angiography. Although this technique is now outmoded, rare circumstances might require its use. Administration of a local anesthetic for such a procedure may result in direct intracarotid injection of lidocaine, which can cause generalized seizures. Moreover, intimal damage may occur at the puncture site from the puncture needle or from subintimal contrast or saline injection, the most common cause of a neurologic deficit occurring during direct carotid angiography. Poor hemostatic control of the carotid puncture site may cause an expanding hematoma. Radial artery access is associated with lower bleeding and vascular complications than transfemoral access for patients with acute coronary syndrome, and has become a potential access pathway for cerebral angiography.

Spinal Angiography

Spinal angiography may be indicated to evaluate vascular malformations, fistulas, and tumors and to identify the artery of Adamkiewicz before aortic aneurysm repair. Although the procedure requires the use of relatively large volumes of contrast and is tedious and lengthy compared with most other angiographic procedures, the incidence of complications is low. Chen and Gailloud retrospectively reviewed 302 consecutive spinal angiograms and found no neurologic complications, and an access-related complication rate similar to cerebral angiography of 1 percent.[14]

Peripheral Angiography

Peripheral (noncerebral-noncardiac) angiography also uses a transfemoral approach where possible. Although the cerebral vasculature is not examined per se, there is a risk of producing a cerebral embolic event if the subclavian or axillary arteries require examination because of the adjacent origins of the vertebral and carotid arteries.

Many patients undergo peripheral angiography to evaluate atherosclerotic disease of the abdominal aorta and iliofemoral system, which itself may preclude the use of a femoral artery puncture. If transfemoral access is not possible because of severe atherosclerosis, the axillary or brachial routes may be used. Each has its own set of risks. An axillary puncture is performed with the arm abducted. The axillary artery is palpated, and the puncture is made as deep into the axilla as possible. The left axilla is chosen for most examinations of the descending aorta and its branches; the right axilla is preferred for studies of the carotid and vertebral arteries. For peripheral angiography, an axillary approach carries a twofold to fourfold greater risk of neurologic complications than a transfemoral approach. Stroke can result from dislodgement of atherosclerotic plaque at the origin of the vertebral artery during catheter passage to the aorta. Hemostasis at the puncture site is a much more crucial issue than with a femoral puncture: the axillary artery is more difficult to compress after removal of the catheter, and an expanding hematoma may injure the brachial plexus or its branches. The rate of infection related to catheterization is quite small (see Table 53-1).

Brachial artery access requires the use of a smaller-diameter catheter because of the smaller size of the artery. Risks of cerebral thromboemboli exist as with the transaxillary route. The median nerve can be damaged by needle puncture or by compression from a developing hematoma. Radial artery access may mitigate these risks, but the smaller size of the radial artery requires the use of smaller-caliber catheters.

EMBOLIZATION AND STENTING PROCEDURES

The development of new materials and techniques has advanced the field of interventional neuroradiology, providing in many cases the standard-of-care therapeutic option for patients with difficult and dangerous neurovascular problems. A variety of procedures is available to treat ischemic and hemorrhagic stroke. Stent-assisted percutanous catheter embolectomy has become the primary treatment of acute ischemic stroke, providing a very effective treatment, with a number needed to treat to reduce disability for one patient of 2.6.[15] In addition to being the primary treatment for ischemic stroke within 24 hours of symptom onset, endovascular embolization techniques have become the primary treatment method for most ruptured and unruptured cerebral aneurysms, dural arteriovenous fistulas (DAVFs), vein of Galen malformations, and cerebral vasospasm. For arteriovenous malformations (AVMs), embolization is typically used as a preoperative adjunct to improve surgical outcomes. Intracranial and cervical vascular stenoses are treated with endovascular stenting in select cases, and catheter chemotherapy infusions may be a useful adjunctive tool to surgery in cases of specific tumors in the head and neck and retinoblastoma. Many of these diseases place the patient at high risk of cerebral hemorrhage, stroke, or death. These endovascular treatments have their own risks, and therapy should be tailored to the disease risk of individual patients.

The highest complication rates are found predictably with therapies geared to treating the highest-risk diseases. Among potential complications of endovascular aneurysm therapy are aneurysmal rupture and stroke from thromboemboli. The advent of the electrolytically detachable coil reduced these rates compared to prior balloon techniques. Several studies have evaluated the risks of surgery compared to endovascular coiling. The International Subarachnoid Aneurysm Trial compared outcomes after endovascular and surgical therapy for ruptured aneurysms, and demonstrated a benefit for endovascular therapy at 1 year and 10 years. The patients treated with coil embolization had a slightly higher incidence of rebleeding, but the risk was small and the probability of disease-free survival was much greater than in patients treated by open neurosurgical clipping (OR 1.35).[16]

Endovascular treatment of AVMs is frequently used as a preoperative adjunct to surgical resection or stereotactic radiosurgery. The advent of ethyl vinyl alcohol copolymer has expanded the number of embolizations being performed for AVMs. Other available embolic materials include liquid adhesives such as *n*-butyl cyanoacrylic acid, polyvinyl alcohol particles, and coils. The two most common risks of embolization of AVMs include intracerebral hemorrhage from AVM rupture or vessel wall injury, and stroke from inadvertent embolization of normal arteries or from catheterization. In several studies using different embolic agents (liquid adhesives and polyvinyl alcohol particles) for AVM embolization, the risk of postprocedure neurologic deficit was approximately 8 percent. In many instances, however, deficits were transient and the rate of persistent neurologic deficit was approximately 1.3 percent.[17]

Endovascular therapy is also applicable to vascular problems involving the spinal cord. In the treatment of intramedullary spinal AVMs, which often present with hemorrhage, embolization may provide definitive, palliative, or adjunctive therapy. The major risk is occlusion of normal spinal arteries with embolic material. The spinal DAVF represents a shunt between a dural artery on the nerve root sleeve and an adjacent radicular vein that drains toward the spinal cord, resulting in a venous engorgement syndrome. The risk involved in endovascular treatment of this dural process is lower than when a radiculomedullary artery, which supplies the spinal cord, is involved.

Stents are increasingly used to treat diseases of the supra-aortic vessels. Carotid stenting has been evaluated in comparison to carotid endarterectomy within several clinical trials, with improved results in patients with prior carotid endarterectomy, neck irradiation, or significant cardiac risk factors. Otherwise, the two techniques have similar risk and benefit profiles as well as 10-year outcomes. A 10-year multicenter prospective trial found that the rate of stroke ipsilateral to endarterectomy was 6.9 percent, and after stenting was 5.6 percent, but this difference did not reach statistical significance (hazard ratio 0.99, CI 0.64 to 1.52) in the 2,502 patients enrolled.[18] The primary risk of carotid artery stenting is transient or permanent neurologic deficits secondary to emboli, dissection, or occlusion of the vessel; other complications of carotid artery stenting include transient bradycardia, hypotension, and those related to femoral artery access.

Although advances in imaging capabilities, catheters, and embolic materials will advance endovascular capabilities, the knowledge, judgment, and experience of the angiographer have the greatest impact on the risks of endovascular therapy.

INTRODUCTION

Perioperative care of the patient with neurologic disease provides practitioners with a number of unique challenges ranging from timing of surgery, administration of medications, and anesthetic choices, to postoperative care. This chapter focuses on common neurologic disorders and the perioperative considerations that accompany them.

MOVEMENT DISORDERS

Parkinson disease remains a common neurodegenerative disease particularly among persons over age 70 years. Therefore, thousands of parkinsonian patients will undergo various surgical procedures each year, and many will experience unique perioperative and surgical challenges related to their underlying disorder.

A key factor in caring for parkinsonian patients in any setting is establishing their specific medication regimen and the timing of these medications. Patients with Parkinson disease are often taking medications that prolong the QT interval, and in these patients a preoperative electrocardiogram may be warranted. Antiparkinsonian medications are almost exclusively oral, making challenging the “nil by mouth” (NPO) status prior to surgery and the timing and administration of perioperative medications. The patient’s typical dopaminergic medication regimen should be continued on the day of surgery and as close as possible to the time of anesthesia while monoamine oxidase B inhibitors are generally stopped a few weeks before surgery due to medication interactions. Levodopa has a short half-life, on the order of 1 to 3 hours; if the planned duration of surgery is long and general anesthesia is being employed, consideration should be given to placing a nasogastric tube and continuing levodopa intraoperatively. Missed doses may precipitate a parkinsonian crisis resulting in severe rigidity and akinesia, leading to prolonged intubation and recovery time. The possibility of resting or orthostatic hypotension, which is common in Parkinson disease and a side effect of many

medications used to treat it, should also be considered, and anesthetic agents that commonly cause hypotension should be avoided.

When a patient is unable to take dopaminergic medications orally in the perioperative period, one strategy is to switch patients to a transdermal dopamine agonist, rotigotine, with a half-life of approximately 24 hours. However, this may be challenging for patients taking a complex oral regimen as conversion between various dopaminergic formulations varies widely from patient to patient.

Regional anesthesia has the added benefit of minimizing postoperative nausea and vomiting, which will allow for the timely resumption of oral medications. If general anesthesia is necessary, halothane should be avoided in patients taking levodopa as it sensitizes the heart to catecholamines. Propofol has been associated with worsening dyskinesias but has also been observed to improve tremor; it is often avoided in patients undergoing deep brain stimulation (DBS) surgery. Antiemetics are commonly administered intraoperatively and postoperatively, but dopamine antagonists such as prochlorperazine and metoclopramide can worsen parkinsonism and block the effects of levodopa therapy; therefore, they should be avoided in favor of ondansetron and domperidone.

Extubation of parkinsonian patients may be complicated. Up to one-third of patients have an obstructive ventilatory pattern related to upper airway dysfunction including laryngeal dysmotility and retained secretions. This dysfunction places parkinsonian patients at increased risk of aspiration. It is critical to resume a patient's home medication regimen as soon as possible with particular adherence to the timing of medications even if it deviates from hospital medication administration times. For patients with dysphagia, carbidopa/levodopa comes in an orally disintegrating formulation and an immediate release formulation that can be administered via feeding tube.

Parkinsonian patients are also at a substantially increased risk of developing postoperative confusion and hallucinations, in some cases due to underlying diffuse Lewy body pathology; therefore, these patients must be monitored carefully in the postoperative setting and strategies to prevent delirium should be planned in advance. An elevated risk of urinary tract infections, aspiration pneumonias, and bacterial infections among parkinsonian patients can result in longer hospital stays and increased perioperative morbidity. Improved surgical outcomes occur when medication regimens are optimized by a neurologist; with early mobilization; when postoperative complications are carefully monitored; and when conversations regarding long-term care and prolonged rehabilitation occur early in the hospitalization.

Special Considerations for Deep Brain Stimulation

DBS is now a well-accepted treatment for medication-resistant Parkinson disease. Given the potential risk of intracerebral hemorrhage with insertion of DBS leads, all antiplatelet medications should be discontinued for 7 to 10 days prior to surgery. Typically, antiparkinsonian medications are discontinued the night before surgery. General anesthesia is avoided so that the patient is awake and parkinsonian symptoms can be monitored intraoperatively. Postoperatively, patients should be kept normotensive to minimize the risk of hemorrhage, and antiparkinsonian medications should be resumed immediately.

Movement-Disorder Emergencies in the Perioperative Period

Perioperative movement-disorder emergencies commonly occur because a patient's usual medication regimen is discontinued or because of new medications introduced in the perioperative period. Diagnosis requires a detailed knowledge of the patient's pre-existing conditions and a careful review of preoperative, intraoperative, and postoperative medications. Patients with Parkinson disease who have their levodopa discontinued suddenly may experience life-threatening parkinsonism-hyperpyrexia, characterized by fever, severe rigidity, autonomic instability, and an elevated serum creatine kinase level. Treatment includes restoration of dopaminergic therapy, and the management strategies discussed later.

Somewhat clinically similar to the parkinsonism-hyperpyrexia syndrome, neuroleptic malignant syndrome results from dopamine receptor blockade. Commonly implicated medications include neuroleptics, antiemetics (e.g., metoclopramide and prochlorperazine), and droperidol, which should be withdrawn promptly. In these syndromes, symptoms may last for days and be life-threatening. Treatment often requires care in the intensive care unit, with aggressive hydration and cooling. Dantrolene, bromocriptine, or amantadine is typically initiated, but the evidence for their efficacy is derived mainly from case reports.

A third and clinically distinct disorder, serotonin syndrome, results from excessive serotonin activity. It may occur as a consequence of drug interactions, overdose of certain medications, or therapeutic (or recreational) drug use. Though rare, of particular note is that patients with Parkinson disease taking monoamine oxidase B inhibitors (e.g., selegiline and rasagiline) are at risk for serotonin syndrome when combined with other serotonergic medications including some antibiotics and opiates (tramadol). Manifestations may include hypertension, tachycardia, hyperthermia, diaphoresis, myoclonus, tremulousness, hyperreflexia, confusion, agitation, and even coma. Treatment involves discontinuation of offending agents and often requires care in the ICU, control of the blood pressure, and management with cyproheptadine or benzodiazepines. A final related condition, discussed later, is malignant hyperthermia, a rare genetic disorder triggered by inhalational anesthetics or succinylcholine.

MULTIPLE SCLEROSIS

Anesthetic and surgical complications related to multiple sclerosis (MS) are relatively rare, but certain preoperative, intraoperative, and postoperative considerations are important. There is not abundant evidence to suggest that anesthesia or surgery consistently leads to disease exacerbations, but physiologic stress is commonly considered a cause of exacerbations and is heightened in the perioperative period. Accordingly, patients should be counseled about the potential risk of MS exacerbation with surgery and monitored for such postoperatively.

Disease-modifying therapies aimed at reducing the frequency and severity of MS exacerbations should be continued in the perioperative period. In patients with low medullary and high cervical demyelinating lesions, ventilatory dysfunction should be anticipated, as respiratory effort may be impaired.

Consideration should also be given to choice of anesthetic and anesthetic technique in patients with MS. Systemic administration of certain local anesthetics (e.g., lidocaine) may unmask clinically silent MS plaques or transiently worsen pre-existing symptoms. Results of studies involving spinal anesthesia are mixed with some demonstrating a higher relapse rate in MS compared to general anesthesia, while others do not. Epidural anesthesia may have a lesser risk than intradural anesthesia due to decreased concentrations of anesthetics penetrating the thecal sac. Overall, the evidence for neuraxial anesthesia affecting neurologic function in patients with pre-existing CNS disorders is not definitive and an individual risk–benefit analysis should be employed when selecting a method of anesthesia.

Although general anesthesia has been linked to MS exacerbations, it has often been used successfully, and there is no solid evidence to suggest that any single intravenous or inhalational anesthetic is preferable to another. If a patient experiences an MS relapse in the immediate postoperative period, the intraoperative temperature recordings should be checked as hyperthermia may cause MS pseudoexacerbations (Uhthoff phenomenon, i.e., symptoms that are not caused by new MS lesions and improve with a return to normothermia).

Caution should also be exercised in patients with MS receiving intrathecal baclofen for spasticity, as abrupt withdrawal may precipitate a potentially life-threatening syndrome characterized by seizures, hallucinations, and autonomic instability. Management includes resumption of baclofen as soon as possible and treatment with high-dose benzodiazepines in the interim.

Patients with MS should be monitored closely in the postoperative period. The appearance of new demyelinating plaques or increased neurologic deficits related to existing plaques may result from the stress of surgery or infection. Such exacerbations may result in impaired respiratory function and in autonomic dysfunction causing labile blood pressure. Baseline neurologic dysfunction in patients with MS combined with the stress of surgery may result in longer recovery times and necessitate rehabilitation upon discharge, even in the absence of any clinical deterioration.

DELIRIUM AND DEMENTIA

Delirium

Delirium is a complex entity characterized by the relatively acute onset of disorientation and attentional deficits that follow a fluctuating course. The incidence of postoperative delirium in the elderly ranges from 10 to 60 percent and varies somewhat with the type of surgery performed (Table 54-1).[1] Due to its variable forms—hyperactive, hypoactive, and mixed—delirium is often under-recognized. Hyperactive delirium involves agitation, combativeness, and hypervigilance, as is commonly seen in alcohol withdrawal. This form is easily recognized by clinicians. The hypoactive form, which may present with lethargy, stupor, or even coma, is sometimes difficult to recognize, as patients are less obtrusive and do not seek care or attention. It is not uncommon

TABLE 54-1 ■ Incidence of Postoperative Delirium in the Elderly by Surgical Type

Type of Surgery	Incidence Range (%)
Cataract	1–3
General	10–14
Orthopedic (mainly hip)	32–55
Open heart	32–79

for these patients to be misdiagnosed with severe depression or for their cognitive dysfunction to be unrecognized.

Research has focused mainly on identifying baseline characteristics that predispose to the development of postoperative delirium and on iatrogenic risks of developing delirium, with relatively less emphasis until recently on the management and the long-term consequences of postoperative delirium. The vast majority of cases of postoperative delirium occur within 3 days of surgery and later onset delirium should raise concern for withdrawal from medications or alcohol.[1] The consensus opinion is that the route of anesthesia, general versus regional, does not have a major impact on the rates of postoperative delirium. However, the type of anesthesia may be relevant when considering the timing of postoperative altered mental status. Patients receiving regional anesthesia tend to maintain or recover cognitive function more quickly than those receiving general anesthesia. Especially in the first 24 to 48 hours, it is important to consider which type of anesthesia the patient received as this may account for differences in mentation.[1]

Factors that are associated with the development of delirium are well established (Table 54-2). It is important to recognize the possibility of postoperative delirium in elderly patients and those with baseline cognitive impairment ranging from mild cognitive impairment to frank dementia. In patients undergoing elective surgery, it is especially important to obtain an accurate history of substance use as both intoxication and withdrawal may manifest as delirium following surgery. Even mild pre- to postoperative electrolyte shifts, such as subtle hypo- or hypernatremia, may result in postoperative delirium. Postoperative pain management poses a particular challenge. Both untreated pain and analgesic use may worsen delirium. There remains a tendency to utilize physical restraints postoperatively to prevent patients from disrupting their wounds; such restraints may increase the risk of delirium and therefore should be discontinued as soon as possible.

TABLE 54-2 ■ Factors Commonly Associated With Delirium

Risk Factors

- Advanced age
- Baseline cognitive impairment
- Infection
    - Urinary tract infection
    - Pneumonia
- Toxic derangements
    - Intoxication
    - Withdrawal (alcohol, benzodiazepines)
- Poor baseline nutritional status (low serum albumin)
- Metabolic derangements
    - Hepatic encephalopathy
    - Uremic encephalopathy
    - Dehydration
    - Hypoxia and hypercarbia
    - Electrolytes: hyponatremia/hypernatremia, hypercalcemia, hypermagnesemia, hypophosphatemia
- Iatrogenic
    - Poor sleep hygiene
    - Physical restraints
    - Urinary catheters
    - Multiple surgical procedures
    - Untreated pain
- Medications
    - Anticholinergics
    - Benzodiazepines
    - Barbiturates
    - Opiates
    - Corticosteroids
    - Muscle relaxants
    - Antibiotics (cephalosporins and fluoroquinolones)

Postoperative delirium has been associated with a number of poor outcomes. Length of stay, postoperative complications, and mortality are known to increase in the setting of postoperative delirium.[2] Such patients are more likely to be discharged to a rehabilitation or long-term nursing facility than those without delirium. It is important to remember that while delirium may only last a few days in many patients, a substantial number of patients will experience delirium that persists until hospital discharge or beyond.[2] Postoperative delirium has also been associated with an increased risk of developing dementia in elderly patients with no known baseline cognitive dysfunction, suggesting that delirium may in itself cause long-term neurologic damage.

Prevention of postoperative delirium is critical, but if postoperative altered mental status develops, the focus should shift to early identification and exclusion of other potentially treatable causes. This workup usually includes neuroimaging to assess for stroke, hemorrhage, or mass lesion; an electroencephalogram (EEG) to evaluate for seizures; and possibly a lumbar puncture to evaluate for evidence of a cerebral inflammatory or infectious disorder. Treatment depends on identification and reversal of the underlying cause. In the postoperative period, delirium precautions should be instituted, including frequent reorientation, opening blinds to allow for natural light to enter, and maintaining normal sleep–wake cycles. Physical restraints should be discontinued as soon as is safe and replaced with close monitoring from nursing staff, sitters, or family members to ensure patient safety. Unnecessary lines and tubes, particularly urinary catheters, should be discontinued. Early postoperative mobilization, even range-of-motion exercises for bedbound patients, and simple acts such as making patients' eyeglasses and hearing aids available are important in treating as well as preventing delirium. Psychoactive medications, particularly anticholinergics, should be discontinued whenever possible. Postoperative pain control should be with minimum levels of analgesics required for relief. If these nonpharmacologic interventions are insufficient, pharmacologic treatment should be considered only if patients pose a risk of direct harm to themselves or the staff, while taking care to avoid the benzodiazepine class of medications, which has a particularly poor cognitive side-effect profile. Common practice is to consider using a low dose of an antipsychotic medication, such as quetiapine, at bedtime.

Dementia

Patients with dementia who undergo surgery require special consideration. It is crucial to establish the patient's preoperative baseline cognitive and physical function with family and caregivers in order to assess accurately their postoperative level of functioning. Patients with dementia are often elderly and have numerous medical comorbidities as well as poor nutritional status, dehydration, and baseline electrolyte abnormalities. These conditions should be optimized or corrected preoperatively in order to maximize recovery and shorten length of hospital stay. Acetylcholinesterase inhibitors used to treat dementia should be continued throughout the perioperative period, although this class of medications may prolong the effects of succinylcholine.

Patients with dementia are at an increased risk of numerous postoperative complications including renal failure, pneumonia, urinary tract infections, sepsis, and strokes. They also have an increased risk of postoperative delirium related to their baseline cognitive impairment and comorbidities.

Postoperative care for patients with dementia mostly revolves around the prevention and treatment of delirium. Pre- and postoperative consultation with geriatrics or neurology can be helpful, and when possible, patients with dementia should be cared for on hospital units that focus on acute care of elderly patients. Although surgery alone may be sufficient to precipitate delirium in a patient with dementia, other triggers should still be investigated. Patients with Alzheimer disease, and probably many other neurodegenerative conditions, are at increased risk of seizures, emphasizing the need to obtain an electroencephalogram for those with an unexplained altered mental state postoperatively. Postoperative pain control can be challenging as patients with severe dementia may not be able to verbalize whether they are in pain. Pharmacologic management of delirium in patients with dementia should be used as infrequently as possible. Benzodiazepines in particular should be avoided, and low-dose antipsychotics should be used sparingly—a US Food and Drug Administration black box warning links antipsychotics to increased mortality among elderly patients. In patients with Lewy body dementia, antipsychotics should be avoided due to their profound sedating and extrapyramidal effects, which may be irreversible. Patients with dementia and their families should be counseled early regarding the possibility of a prolonged postoperative hospital course and the potential for discharge to a rehabilitation or nursing facility; in the setting of elective surgeries, these considerations may impact the decision to proceed.

HEADACHE

A detailed headache history is important when evaluating patients with postoperative headaches, as preexisting primary headache disorders, such as migraine and tension headache, are common and often exacerbated by the stress of surgery and the dehydration that accompanies the NPO status. There are numerous warning features in the history and physical examination that signal the possibility of a secondary headache phenomenon related to a structural brain injury (Table 54-3).

Migraine

Patients with migraine should have their prophylactic medications continued in the perioperative period. Their migraine-abortive agents should also be continued postoperatively, though caution should be exercised when prescribing triptan medications after vascular surgeries given their vasoactive properties. Intravenous hydration with normal saline and administration of antiemetics such as prochlorperazine may be useful for

TABLE 54-3 ■ Common Warning Features Associated With Secondary Headaches

Subjective	Physical Examination
New headache after age 50	Focal neurologic deficit
Change in character of prior headache	Fever
Worsens with Valsalva, exertion, cough, or sneezing	Hypertension
Awakens patient from sleep or typically occurs in the morning	Altered mental status
Associated seizure	Papilledema
Positional component	Meningismus
Thunderclap in onset	Scalp tenderness (especially over temporal artery)
Immunocompromised state	
Jaw claudication	

attacks even when the migraine is not accompanied by significant nausea and vomiting. A brief course of a nonsteroidal anti-inflammatory drug (e.g., naproxen or intravenous ketorolac) may be used in refractory cases. Migraine, particularly that with aura, has been associated with an increased risk of perioperative ischemic stroke and 30-day hospital readmission, although the precise mechanism for this association remains unclear.[3]

Medication Overuse

Analgesic overuse for the treatment of pain including headache is common among the general population as is medication-overuse headache. While postoperative pain may require narcotics, treatment of headaches with short-acting narcotics sometimes exacerbates the primary headache disorder and prolongs the period of recovery. Nearly all agents given to abort headache may be associated with medication-overuse headache. Treatment for this condition is gradual discontinuation of the medication; however, symptoms of opiate withdrawal including headache, nausea, vomiting, tachycardia, and insomnia are common, and therefore these medications are best weaned outside the perioperative period.

Caffeine Withdrawal

Due to the high frequency of consumption, caffeine withdrawal has become a widely recognized source of headache. Cessation of caffeine intake in people with low-to-moderate daily caffeine consumption can result in higher depression scores, fatigue, and headache. Headaches from caffeine withdrawal may begin 24 hours after cessation and last up to 5 or 6 days. In patients with postoperative headache, a careful caffeine history should be taken and—when caffeine withdrawal is responsible—resumption of normal caffeine intake permitted.

Intracranial Hypotension

Dural puncture with resultant intracranial hypotension remains a common cause of perioperative headache after spinal anesthesia and particularly after accidental dural puncture with a large-bore needle during epidural anesthesia. Among such headaches, the vast majority will begin within 48 to 72 hours of the dural puncture. A headache immediately following the procedure should raise suspicion of an alternate etiology. The headache of intracranial hypotension is typically located in the frontal and occipital regions, is exacerbated by an upright posture, and is alleviated by recumbency. Accompanying symptoms may include nausea, vomiting, tinnitus, vertigo, paresthesias, diplopia, and cranial nerve palsies. The findings on magnetic resonance imaging (MRI) of intracranial hypotension include diffuse pachymeningeal enhancement, subdural fluid collections, engorged cerebral venous sinuses, and descent of the cerebellar tonsils (Fig. 54-1).[4]

Prevention of postdural puncture headache involves using a smaller gauge or noncutting needle. Vigorous hydration, caffeine, gabapentin, theophylline, and hydrocortisone have some efficacy in the treatment of such headaches. Epidural blood patch remains the mainstay of treatment; providing complete or partial relief in a large majority of patients. If the initial blood patch does not relieve symptoms, a second blood patch should be administered, often with an extended period of lying supine following the procedure.

SEIZURES AND EPILEPSY

Epilepsy is a common neurologic disorder and perioperative seizures are seen in approximately 2 to 6 percent of persons with epilepsy.[5] The most important predictors of perioperative seizure risk are baseline seizure frequency and timing of most recent seizure, particularly in the month preceding surgery. Patients with epilepsy should be advised to take their antiepileptic medications on the morning of surgery, and these medications should be resumed as soon as possible postoperatively. Preferably, these drugs should be administered orally,

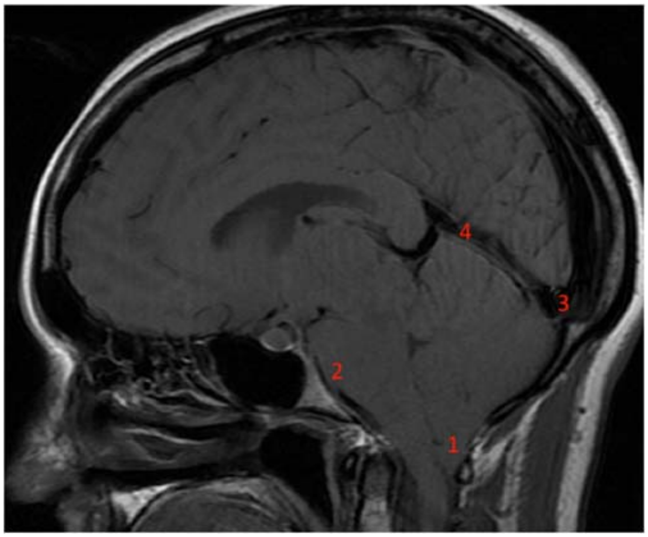

FIGURE 54-1 ■ Noncontrast sagittal T1 magnetic resonance image of a patient with cerebrospinal fluid leak and resultant intracranial hypotension. Image demonstrates downward descent of the cerebellar tonsils (1), effacement of the prepontine cistern with the pons apposed to the clivus (2), and prominent venous vasculature including the torcula (3) and straight sinus (4).

although intravenous preparations of phenytoin, sodium valproate, levetiracetam, phenobarbital, lacosamide, and benzodiazepines are an alternative for those with limited oral intake. Oral and intravenous dosages are largely equivalent, but the frequency of administration may vary from one preparation to another, and some extended-release formulations may not be easily converted to an intravenous dose.

Both phenytoin and fosphenytoin can precipitate hypotension and arrhythmias with rapid intravenous infusion; however, fosphenytoin can generally be infused at a faster rate and with a lower risk of local adverse effects following extravasation, and therefore is the intravenous phenytoin preparation of choice. Phenytoin can be administered via feeding tube, but levels are altered by enteral feedings, making the intravenous preparation preferable in such instances.

Antiepileptic drug levels need not be checked routinely in the perioperative period unless there has been a recent change in seizure frequency or concern for drug toxicity. Antiepileptic medications have many drug interactions, particularly in the case of the cytochrome P-450–inducing agents phenytoin, carbamazepine, phenobarbital, and primidone, which can result in decreased levels of many medications including some antibiotics, immunosuppressants, analgesics, and neuromuscular blocking agents.

It is widely believed that some general anesthetics can have both pro- and anticonvulsant properties depending on the dose and clinical situation. Enflurane, sevoflurane, and etomidate induce epileptiform activity on the EEG and should generally be avoided in patients with epilepsy, while isoflurane and halothane have anticonvulsant properties.[5] Intravenous anesthetics including barbiturates and propofol are used for the treatment of status epilepticus, but at induction have been reported to be excitatory and can rarely precipitate a seizure. Some opioids, particularly meperidine and to a lesser extent fentanyl, have been linked to seizures, especially with intrathecal use. Propofol and opioids can also cause myoclonus and tremulousness that may clinically mimic seizures. Neuromuscular blocking agents have not been linked to seizures; however, if seizures are suspected while these drugs are being administered, continuous electroencephalographic monitoring is required as clinical manifestations of seizures will be masked.

Evidence regarding the epileptic potential of local anesthetics is conflicting. While they can cross the blood–brain barrier, evidence that they increase the risk of perioperative seizures is lacking.

Postoperative seizures should be considered as an etiology for delayed awakening after anesthesia. A relatively high frequency of seizures has been found in patients with altered mental status or “spells,” both in the intensive care unit and in general medical wards. If possible, an extended electroencephalogram should be obtained to exclude nonconvulsive seizures, but this should not delay treatment in cases where the suspicion of seizures is high.

The evaluation of perioperative seizures is similar to the evaluation of seizures occurring in other settings. Consideration should be given to withdrawal syndromes, missed doses of antiepileptic medications or malabsorption of medications, medication interactions, metabolic derangements (e.g., hyponatremia, hypocalcemia, hypomagnesemia, glucose shifts), infection, and structural brain abnormalities. Treatment should focus on stopping seizures promptly and correcting obvious provoking factors.

NEUROMUSCULAR DISORDERS

Neuromuscular diseases present the neurologist, surgeon, and anesthesiologist with some important general considerations common to this group of disorders as well as challenges inherent to specific diseases. All patients with severe neuromuscular disease are at risk of increased ventilatory complications due to respiratory weakness, and preoperative pulmonary assessment with forced vital capacity (FVC) and maximal inspiratory force should be performed. Complications in patients with respiratory weakness include an increased sensitivity to respiratory depression from opioids, barbiturates, and benzodiazepines, as well as difficulty in weaning from the ventilator. Patients with some neuromuscular disorders including the muscular dystrophies have an increased risk of life-threatening cardiac dysrhythmias along with depressed cardiac contractility, warranting a preoperative assessment with electrocardiography and echocardiography. Depolarizing neuromuscular blockers such as succinylcholine can lead to hyperkalemia and resultant cardiac dysfunction in these patients and should be avoided.

Motor Neuron Disease

The timing of surgical procedures and anesthetic choice in patients with amyotrophic lateral sclerosis is important given an often profound progressive underlying respiratory weakness. Measurement of preoperative FVC is critical as an FVC of less than 50 percent predicted is associated with higher likelihood of postoperative respiratory failure. Noninvasive positive-pressure ventilation can be used to prevent pulmonary complications in the immediate postoperative period and reduce the chances of reintubation. Nondepolarizing neuromuscular blockade may precipitate severe weakness in patients with amyotrophic lateral sclerosis. However, due to the previously described effects of succinylcholine in many neuromuscular disorders, low doses of nondepolarizing blockers are preferred when neuromuscular blockade is necessary. Regional and epidural anesthesia may be used safely in these patients without exacerbating neurologic symptoms. Given the potential complications and prolonged recovery times following anesthesia and surgery, a multidisciplinary preoperative approach with cardiac and pulmonary screening is warranted, with appropriate preoperative counseling of the patient and family members regarding these risks.

Peripheral Nerve Disorders

Diabetic autonomic neuropathy is a relatively common complication of both type 1 and type 2 diabetes. Poor glycemic control and duration of disease are felt to be risk factors for the development and progression of the neuropathy. These patients are at increased risk of significant bradycardia during induction of anesthesia as well as intraoperative hypotension requiring vasopressor support. Although there are no specific guidelines for anesthetic choice, etomidate and opioids may minimize hemodynamic instability while thiopental and propofol may carry a higher risk of hypotension.

Charcot–Marie–Tooth disease, the most common hereditary motor and sensory polyneuropathy, is associated with autonomic dysfunction as well as respiratory muscle weakness in a minority of patients. While few complications have been reported for patients with Charcot–Marie–Tooth disease undergoing surgery, succinylcholine provides a theoretical risk for complications and should be avoided if at all possible.

Case series describe surgery as a potential trigger for acute inflammatory demyelinating polyradiculoneuropathy (AIDP; Guillain–Barré syndrome), a relatively common cause of acute paralysis. The precise mechanism for this association is unknown, but one theory is that surgery alters the immune system, igniting a pathway leading to molecular mimicry against peripheral nerve components, perhaps in the setting of postoperative infection.

With both AIDP and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), perioperative FVC and maximal inspiratory force should be monitored serially to provide some indication as to whether a patient can be extubated safely. Patients with AIDP and CIDP are sensitive to nondepolarizing muscle relaxants, which may necessitate prolonged postoperative ventilation when administered. Reports of worsening neurologic function in patients with AIDP following epidural anesthesia exist. Local anesthesia has been linked to hypotension, bradycardia, and cardiac complications in patients with AIDP, presumably due to involvement of the autonomic nervous system. There are no firm recommendations regarding the preferred anesthetic technique for patients with AIDP and CIDP.

Myopathies

Patients with muscular dystrophies including Duchenne, Becker, and Emery–Dreifuss often undergo a series of surgeries in their lifetime involving tendon releases and correction of scoliosis. Due to the systemic nature of these disorders, a multidisciplinary perioperative approach involving a neurologist, pulmonologist, cardiologist, and anesthesiologist is often warranted. Many of these disorders are associated with cardiomyopathy and disorders of cardiac conduction. Respiratory function is often compromised because of ventilatory muscle weakness as well as poor mechanics secondary to skeletal abnormalities. A thorough preoperative pulmonary evaluation including measurement of FVC, maximal inspiratory force, and peak cough flow should be strongly considered. Patients found to have a FVC of less than 50 percent of the predicted value should be considered for preoperative training of noninvasive positive-pressure ventilation, given the risk of ventilatory compromise following surgery. Most muscular dystrophies are not linked to an increased incidence of malignant hyperthermia. Inhaled anesthetics such as halothane have been associated with rhabdomyolysis in the absence of succinylcholine in patients with elevated serum creatine kinase levels at baseline.

Patients with other myopathies face similar risks associated with surgery and anesthesia. Reports of hyperkalemic cardiac arrest in children undergoing anesthesia have been linked to previously unrecognized myopathies. Central core myopathy, an autosomal dominant disorder, has been closely linked to malignant hyperthermia, via a common mutation in the ryanodine receptor gene (*RYR1*). The prevalence of malignant hyperthermia has been estimated at 1 per 100,000 hospital discharges in all patients. This rare genetic condition is triggered by exposure to inhalational anesthetics or succinylcholine in susceptible individuals and is characterized by muscle rigidity, tachycardia, hyperthermia, hypercapnea, and metabolic acidosis. Malignant hyperthermia or a malignant hyperthermia-like syndrome has been described in a variety of myopathies and channelopathies (e.g., periodic paralysis). The mainstay of treatment for malignant hyperthermia other than supportive care remains dantrolene, which decreases skeletal muscle calcium release, thereby inhibiting muscle contraction. If anesthesia is required in patients with myotonic dystrophy, depolarizing muscle-relaxant drugs should be avoided because they may cause myotonic spasm, and nondepolarizing drugs are given in reduced dosage to patients who are taking quinine for their myotonia.

Myasthenia Gravis

Myasthenia gravis (MG) is the most common neuromuscular junction disorder, and consequently most of the research into the perioperative care of patients with such disorders has focused on MG. The preoperative care of patients with MG begins with appropriate counseling of the patient and family, emphasizing that the stress associated with elective surgery may temporarily worsen the disease, necessitate postoperative care in the intensive care unit, and lead to prolonged intubation. Since thymectomy is a treatment for MG, this surgery provides a natural avenue to study the perioperative care of patients with MG. A study of risk stratification of patients with MG undergoing thymectomy demonstrated that disease duration of greater than 6 years, coexistent chronic respiratory disease, daily pyridostigmine dose exceeding 750 mg, and a FVC of less than 2.9 liters predicted the need for postoperative ventilation.[6] This predictive tool may not apply to patients with MG undergoing surgeries other than thymectomy. A preoperative neurologic examination focusing on facial strength, dysarthria, dysphagia, neck flexion strength, and formal pulmonary function testing, especially in those patients with bulbar weakness, allows for anticipation of postoperative ventilatory compromise and pulmonary complications including aspiration.

Studies have investigated the effects of pyridostigmine on neuromuscular blockade in the perioperative period. There is not sufficient evidence to conclude that changing a patient's pyridostigmine dose prior to surgery significantly impacts neuromuscular blockade or the duration of ventilation, and thus the general recommendation is to continue the patient's usual preoperative regimen. Most immunosuppressants in patients with MG do not interact with anesthetics; however, azathioprine extends the effect of succinylcholine and inhibits nondepolarizing neuromuscular blockers.

Elective surgeries should be undertaken when respiratory function is stable and patients are on the lowest possible doses of corticosteroids. In the case of more urgent surgery, presurgical plasma exchange or treatment with intravenous immunoglobulin should be considered to optimize preoperative respiratory status. These preoperative treatments have the potential to decrease the duration of postoperative ventilation and length of stay in the intensive care unit.

When possible, regional anesthesia is preferable to general anesthesia in patients with MG, as it minimizes the need for neuromuscular blockade and ventilation. Patients with MG have a decreased number of functional acetylcholine (ACh) receptors and thus their response to neuromuscular blockade may be abnormal during general anesthesia. Patients may have a prolonged blockade when either succinylcholine or nondepolarizing neuromuscular blockers are used. The dosing of neuromuscular blockade should be individualized based on the severity of the patient's myasthenia; however, 50 percent of a routine dose is likely adequate and an extended recovery time should still be anticipated.

Postoperative recovery in patients with MG may be prolonged. Electrolytes, particularly potassium, should be monitored closely, as hypokalemia may worsen weakness in MG. Whenever possible, postoperative analgesia should be minimized and opioids, benzodiazepines, and barbiturates should be avoided if possible due to their respiratory depressant effects. Patients with MG should have their medications reviewed frequently to ensure that they are not receiving drugs that may worsen weakness, such as aminoglycosides. If pyridostigmine cannot be given orally, the parenteral dose should be administered at roughly one-thirtieth of the enteral dose. Atropine should be given before or concurrent with intravenous pyridostigmine to prevent bradycardia and excessive bronchial secretions. Although no precise clinical criteria can determine the timing of extubation, clinical examination including evaluation of neck flexor strength can guide the decision. After extubation, aggressive pulmonary toilet and use of incentive spirometry should be encouraged. Early mobilization shortens the duration of recovery.

Postoperative myasthenic crisis is not uncommon in patients with MG, occurring in up to one-third of patients. The likelihood of postoperative crisis has been related to a prior history of myasthenic crisis, preoperative bulbar weakness, preoperative serum ACh receptor antibody levels, and intraoperative blood loss. Management should involve urgent assessment of the patient's respiratory status, recognizing that intubation is usually necessary. Effective treatment options include prompt initiation of plasma exchange or intravenous immunoglobulin.

PERIOPERATIVE STROKE

Incidence

The incidence of perioperative stroke, defined as stroke within 30 days following surgery, varies with the type of surgery being performed (Table 54-4).[7–12] The incidence is relatively low among general surgeries but increases in those patients with a history of stroke or transient ischemic attack (TIA). Cardiac and aortic surgeries are associated with the highest risk of perioperative stroke, and this incidence increases with a number of intraoperative factors. Aortic manipulation in the setting of known ascending aortic atherosclerosis increases stroke risk. Similarly, cerebral hypoperfusion related to intraoperative hypotension or reduced cardiac output, as can be seen with use of cardiopulmonary bypass, confers an increased stroke risk. Additional discussion regarding stroke after cardiac surgery in children can be found in Chapters 3 and 4. The risk of perioperative stroke following carotid endarterectomy for symptomatic carotid stenosis has not changed significantly over time from the combined risk found in the European Carotid Surgery Trial and the North American Symptomatic Carotid Endarterectomy Trial. The type of anesthesia, general versus regional, has not been shown definitively to affect the perioperative stroke risk in patients undergoing carotid endarterectomy and should be a joint decision involving the patient, surgeon, and anesthesiologist. Regional anesthesia has the advantage of allowing for intraoperative monitoring of neurologic function in an awake patient.

TABLE 54-4 ■ Incidence of Perioperative Stroke

Type of Surgery	Incidence (%)
General (no prior history of stroke)[7,8]	0.1–0.8
General (prior history of stroke)[9]	2.9
CABG[10]	3.8
Head and neck[11]	4.8
Cardiac valve[10]	4.8–8.8
CABG plus cardiac valve[10]	7.4
Aortic[12]	8.7
Multiple cardiac valves[10]	9.7

CABG, coronary artery bypass graft.

Pathophysiology and Timing

The majority of perioperative strokes are ischemic, and a significant proportion demonstrate multiple areas of infarction, suggesting an embolic etiology. A minority of perioperative strokes are recognized immediately after the procedure itself, with the majority detected within the first 1 to 2 days postoperatively. Early embolic strokes in the postoperative period have been attributed to physical manipulation of the heart or aorta during surgery leading to unstable plaque that can break off in the coming days, while more delayed embolic strokes may result from atrial fibrillation or decreased cardiac output in the postoperative period. Notably, intraoperative hypoperfusion does not appear to be a common etiology for perioperative stroke but should be considered in the setting of deep watershed infarcts ipsilateral to carotid stenosis.[11]

Risk Factors

Both preoperative and postoperative risk factors can be identified and largely follow general cardiovascular disease risk factors. Perhaps the most important preoperative risk factor is the presence of a prior stroke or TIA and risks related to timing of surgery following a stroke are discussed below. A history of hypertension, diabetes, chronic obstructive pulmonary disease, peripheral vascular disease, decreased cardiac output, atrial fibrillation, aortic atherosclerosis, and female sex also serve as preoperative stroke risk factors. Additional preoperative risk factors include recent myocardial infarction, pre-existing renal failure, and increased age. Carotid stenosis and discontinuation of antithrombotic therapies are discussed separately.

Postoperative risk factors for stroke include the combination of low cardiac output and atrial fibrillation. Blood loss (intraoperative or postoperative), hypotension, and dehydration may contribute to a hypercoagulable state leading to an increased risk of postoperative stroke.

Risk Factor Modification and Postoperative Stroke Care

In patients with recent stroke or TIA, it is important preoperatively to determine the etiology and whether it was treated appropriately. In cases of possible or known aortic atherosclerosis, the extent of the atherosclerotic plaque can be assessed preoperatively with transesophageal echocardiography, since some surgical techniques may need to be modified in order to minimize the risk of plaque rupture. Some patients with otherwise unexplained stroke will be found to have atrial fibrillation with extended cardiac telemetry.

New-onset atrial fibrillation following cardiac surgery occurs in 30 to 50 percent of patients.[11] The peak incidence occurs on postoperative days 2 to 4, and consideration should be given for postoperative cardiac telemetry monitoring. Evidence regarding initiating β-blockers in the preoperative period is mixed in relation to stroke risk; however, patients with known atrial fibrillation should have their antiarrhythmic and rate-controlling medications continued throughout the perioperative period and those that were anticoagulated preoperatively should have their anticoagulation resumed as soon as possible in the postoperative period.

The duration of surgery, particularly the amount of time spent on cardiopulmonary bypass, should be minimized to decrease the perioperative stroke risk. Care should be taken to avoid manipulation of plaque in patients with aortic atheromas. There is a lack of robust data to suggest an optimal intraoperative blood pressure range. In general, care should be taken to maintain a patient's blood pressure near their baseline range, particularly if a patient is known to have intracranial stenoses.

Stroke care in the postoperative period differs in some respects from stroke care in other circumstances. Preoperative statin use, regardless of cholesterol levels, decreases a variety of postoperative cardiac and cerebrovascular events (e.g., death from cardiac causes, myocardial infarction, unstable angina, and stroke) in patients undergoing vascular surgery and poses little risk. Intravenous tissue plasminogen activator is contraindicated following major surgery but many reports document the safety of intra-arterial thrombolysis or thrombectomy for perioperative stroke.

Antithrombotics and Anticoagulation in the Perioperative Period

A recent prospective, randomized, double-blind placebo-controlled trial examined perioperative aspirin use for patients with cardiovascular disease undergoing noncardiac surgery.[13] The use of perioperative aspirin was not associated with a decrease in death or nonfatal MI but was associated with an increased risk of major bleeding. Starting aspirin in patients who had not been taking it preoperatively was associated with a decreased risk of stroke but the absolute number of events was very small. The decision to start or stop aspirin perioperatively is individualized and should involve a multidisciplinary discussion. Based on this trial, a general recommendation is to not initiate aspirin preoperatively in patients who are not already taking it and to hold aspirin for 5 to 7 days prior to major surgery in patients who are taking aspirin and are undergoing noncardiac surgery. Postoperatively, aspirin should be resumed as soon as is safe from a surgical perspective in patients with a long-term indication for the medication. Importantly, this recommendation should not apply to patients with prior cardiac or carotid stents, particularly those taking dual antiplatelet therapy, and the trial did not include patients undergoing carotid endarterectomy or intracranial surgeries.

Less data are available for other antiplatelet agents such as clopidogrel, but similar recommendations likely apply. When being used for stroke prevention, clopidogrel should be discontinued approximately 3 to 7 days prior to noncardiovascular surgery. Antiplatelet medications should generally be continued through the perioperative period for patients undergoing carotid endearterectomy.

The decision to continue or interrupt anticoagulation during the perioperative period is complex. In the absence of rigorous data, one must balance the risk of thromboembolic events against the risk of major hemorrhage. Neurologists commonly encounter this clinical dilemma in patients who are anticoagulated for atrial fibrillation. Examples of patients at high risk for thromboembolic events include those with atrial fibrillation who have experienced a recent stroke or those patients with a prosthetic heart valve. For procedures with a low risk of bleeding including dental procedures, endoscopy, colonoscopy, and cataract surgery among others, it is often best to continue anticoagulation without interruption, particularly in patients at high risk for thromboembolism.

When interrupting anticoagulation, it is important to consider whether the patient is taking warfarin or a direct oral anticoagulant. Warfarin should be stopped approximately 5 days prior to planned surgery and the prothrombin time and international normalized ratio checked prior to surgery. Warfarin can generally be restarted within 12 to 24 hours of an uncomplicated surgery as it often takes 5 days or more to reach full anticoagulant effect. Direct oral anticoagulants should generally be stopped 2 to 3 days prior to surgery, but the half-life of the specific agent involved should be considered. Since these medications rapidly achieve anticoagulant effect, they should only be resumed when safe from a postoperative hemorrhage standpoint.

The decision to bridge with a short-acting anticoagulant such as low-molecular-weight heparin again involves assessing the risk of thromboembolism versus hemorrhage. In selected patients who are at high risk for thromboembolism and in whom surgery cannot be delayed, bridging anticoagulation can be considered. However, in studies of patients receiving warfarin or direct oral anticoagulants for atrial fibrillation, forgoing bridging anticoagulation was not inferior to bridging with low-molecular-weight heparin when examining thromboembolic events, and this strategy reduced the risk of major hemorrhage.[14,15]

Timing of Elective Surgery Following a Stroke

There are few data to guide the timing of elective surgery following a stroke or TIA. Recent stroke or TIA patients require a thorough evaluation of stroke etiology prior to being considered for elective surgery. This should include evaluation of the carotid arteries as carotid endarterectomy may be warranted prior to elective surgery for symptomatic disease. Delaying elective surgery following a stroke or TIA is based on an increased risk of recurrent stroke in the immediate postevent period due to changes in cerebral autoregulation and ongoing inflammation as the brain heals. Accordingly, delaying elective surgery for 3 months or more appears to be sufficient to allow for elimination of this added risk but must be balanced against the risk of delaying an individual surgery. In cases where surgery cannot be delayed, patients should be counseled about the increased risk of recurrent stroke as part of the surgical consent process.

Perioperative Considerations Pertaining to Carotid Disease

Discovery of a carotid bruit is not uncommon as part of the preoperative clinical evaluation. An asymptomatic carotid bruit is a marker of general vascular disease but does not correlate with severity of carotid stenosis. Asymptomatic carotid bruits generally do not require further evaluation unless a surgery is planned with a high risk of hypotension, as unilateral asymptomatic stenosis alone does not increase perioperative stroke risk. If the carotid stenosis is symptomatic (e.g., symptoms of a stroke or TIA over the past 6 months), imaging should be undertaken.

The decision to recommend carotid endarterectomy prior to another surgery remains controversial in many cases and depends on whether the patient's carotid stenosis is symptomatic or asymptomatic, unilateral or bilateral, and the type of surgery planned. Unilateral asymptomatic carotid stenosis generally does not require intervention prior to another surgery, but in cases of asymptomatic, severe bilateral carotid stenosis, preoperative carotid surgery may be considered, particularly if a cardiac surgery is planned that carries a high risk of intraoperative hypotension. In patients with recently symptomatic severe carotid stenosis who require routine or elective cardiac or vascular surgery, the recommendation is to perform carotid endarterectomy within 2 weeks of the cerebrovascular event for nondisabling stroke or TIA and to delay elective surgeries until after the endarterectomy. Patients with concomitant symptomatic carotid and cardiac disease requiring more urgent cardiac surgery are complicated. Studies examining a staged approach where carotid endarterectomy is performed prior to cardiac surgery compared with performing the two procedures simultaneously demonstrated no significant differences in mortality or neurologic complications between the two approaches and found that the staged procedure was associated with a higher overall complication rate.

Current rates of anesthetic complications are low regardless of the type of anesthesia (general, regional, or local). Yet among the complications that may occur, those affecting the nervous system are perhaps the most feared (Table 55-1). This chapter reviews anesthetic-related perioperative neurologic problems as well as perioperative complications that are not caused by anesthesia but are often erroneously attributed to it. Considerations regarding the challenges of anesthesia in patients with established neurologic disease are considered but are discussed in more detail in Chapter 54.

PERIOPERATIVE MENTAL STATUS CHANGES

Postoperative Coma and Delayed Awakening

Failure to arouse and delayed awakening are the most common early neurologic problems following general anesthesia. True prolonged postoperative coma is relatively uncommon, with estimates ranging from 0.005 to 0.08 percent following general surgery, but with higher rates reported after cardiac surgery.[1] Advanced age, urgent surgery, pre-existing brain disorders, perioperative hypotension, postoperative organ failure, and sepsis are independently associated with postoperative coma.[1]

Delayed emergence from anesthesia is the most common cause of early failure to regain alertness after surgery; although this situation is benign, more serious alternative causes include stroke, hypoxic-ischemic brain injury, and status epilepticus. Sepsis and multiorgan failure may produce severe encephalopathy and prolong unresponsiveness, sometimes for days after their resolution. The main causes of impairment of consciousness following surgery are found in Table 55-2.

When a neurologist is asked to evaluate an unresponsive patient following surgery, the principal goal is to determine whether any form of severe acute neurologic disease is responsible. It is therefore important to obtain a detailed history of the patient's preoperative status, review pertinent intraoperative information, and clarify the condition of the patient since surgery. In these situations, direct communication with the anesthesia and surgical teams may provide additional relevant information, such as the presence of clinical features suggesting seizure occurrence or a history of immediate awakening followed by unconsciousness, the latter suggesting cerebral embolism or seizures. It should be determined whether the patient during or immediately after surgery became hypoxemic, hypotensive, or had marked lability of blood

pressure; profuse blood loss; poor hemostasis; or cardiac arrhythmias. Intraoperative hypotension and fluctuations in hemodynamic parameters are common in patients with postoperative coma following cardiovascular surgery.

The general clinical examination is important. A slow respiratory pattern and darkened skin color raise the possibility of CO_2 narcosis. An irregular pulse may signify atrial fibrillation and its increased risk of postoperative stroke. Splinter hemorrhages in the conjunctiva or nail bed suggest fat embolism after long-bone fracture surgery. The neurologic examination should focus on the assessment of level of consciousness, brainstem reflexes, gaze (conjugate versus dysconjugate, presence of skew deviation), eye movements (roving, ocular dipping or bobbing, nystagmoid jerks), muscle tone, response to central (sternal or supraorbital) and peripheral (limb) pain, and presence of adventitious movements. The presence of lateralizing signs requires brain imaging. Brainstem findings or bilateral focal signs should raise suspicion of basilar thromboembolism, prompting vessel imaging. Subtle abnormal movements of the eyes, facial muscles, or fingers may be the only manifestations of underlying status epilepticus and necessitate urgent electroencephalography (EEG). Drug toxicity should be suspected in patients with rigidity, hyperreflexia, and tremors, with or without concurrent fever. Myoclonus may occur with any toxic or metabolic encephalopathy, but can also follow severe global brain anoxia. Asterixis may be a sign of hyperammonemia but also occurs in other metabolic encephalopathies and as a side effect of medications. In patients lacking motor responses following pharmacologic neuromuscular blockade, it must be determined—sometimes by nerve-stimulation studies—whether blockade is continuing; when paralysis is persistent, administration of an antidote may require consideration.

Additional testing is directed by the history and physical findings. If the examination is reassuring and nonfocal, further investigations can be postponed. Brain imaging is indicated in patients with new focal deficits. Computerized tomography (CT) scan is reliable for the detection of acute hemorrhage and can document territorial ischemic infarctions and massive brain edema. Magnetic resonance imaging (MRI) may be necessary to diagnose an embolic shower and subtle manifestations of global hypoxic-ischemic injury such as early cortical injury. In patients with brainstem signs, MRI of the brain can be combined with MR angiography to exclude vertebrobasilar occlusion. EEG should be reserved for those with suspected seizures, and the use of continuous monitoring may increase the diagnostic yield. Lumbar puncture is rarely necessary in patients with postoperative encephalopathy unless central nervous system infection is suspected. Serum studies should be used judiciously, including arterial blood gas to exclude CO_2 retention, as well as determination of glucose, sodium, creatinine and blood urea nitrogen, and ammonia to exclude various metabolic disturbances.

A history of delayed arousal after a previous surgery makes a diagnosis of delayed emergence from anesthesia more likely. Older age and renal and hepatic insufficiency may compromise drug metabolism and clearance, increasing the risk of delayed arousal. Review of the anesthesia course may guide the use of naloxone (for reversal of opioid effect), flumazenil (to reverse benzodiazepines), and physostigmine (to reverse neuromuscular blockade) in appropriate cases.

The prognosis of patients with postoperative coma varies markedly depending on etiology. Although the prognosis is favorable in patients with reversible toxic or

metabolic causes, the mortality may exceed 80 percent in patients with multifocal infarctions revealed by brain MRI. In survivors of prolonged postoperative coma, long-term functional outcome is frequently poor.

Postoperative Delirium

Postoperative delirium is common, with a reported incidence as high as 40 to 60 percent of patients.[2] Delirium can occur immediately following anesthesia or after some interval from a seemingly normal recovery from the anesthetic; the latter is more commonly persistent and often multifactorial in etiology. The risk of delirium is increased in the elderly and in patients with previous cognitive impairment, a history of substance use (including alcohol), and those receiving polypharmacy before surgery and narcotics or benzodiazepines perioperatively.[2] A previous episode of postoperative delirium predicts recurrence. Perioperative hypoxemia and hemodynamic instability, profuse intraoperative blood loss, and postoperative organ failure may also increase the risk of postoperative delirium. There is limited evidence that the type and route of anesthesia influence the risk of postoperative delirium, with higher rates following general anesthesia.

Evaluation of patients with postoperative delirium begins by considering risk factors for its development (see Table 54-2 in Chapter 54). Time should be spent reviewing the medications that the patient was taking prior to surgery and those administered during and after the operation. Toxic and metabolic factors are the most frequent causes. Exclusion of acute structural brain injury, seizures, and meningoencephalitis (a rare cause of perioperative coma) is the primary responsibility of the consulting neurologist. Primary neurologic diagnoses to be considered include ischemic infarctions (often bilateral or in the brainstem), intracranial hemorrhage (intraparenchymal, subdural, or rarely subarachnoid), nonconvulsive status epilepticus, and posterior reversible encephalopathy syndrome.

Management of delirium depends on its cause. Discontinuation of sedatives and narcotics is often the only intervention required. When agitation is present and patients may harm themselves or others, oral quetiapine, olanzapine, or, in more severe cases, intravenous haloperidol may be necessary, although these medications have not been shown to be effective in usual cases of delirium. Dexmedetodimine, a central α_2-adrenergic agonist, is particularly useful for additional sedation or when agitation is accompanied by sympathetic hyperactivity. Benzodiazepines may worsen delirium and therefore should be reserved for specific indications, such as alcohol withdrawal.

In most cases, postoperative delirium is transient and reversible. Complications sometimes stemming from it include aspiration, self-removal of the endotracheal tube or indwelling catheters, and delays in mobilization that, in turn, result in an increased risk of thromboembolism, infections, and deconditioning. In addition, the occurrence of postoperative delirium is related to a greater risk of postoperative cognitive dysfunction, particularly during the first few months following surgery.[2,3]

POSTOPERATIVE NEUROLOGIC DEFICITS

Cognitive Dysfunction

Postoperative cognitive dysfunction after exposure to general anesthesia occurs more often in older patients and in those with postoperative delirium.[3,4] Mild global cognitive decline is typically observed, although short-term memory and executive function are predominantly affected. Its incidence is greatest after major cardiovascular surgery, ranging from 30 to 80 percent during the first few weeks after surgery and 10 to 60 percent after 3 to 6 months.[3] Patients undergoing noncardiac surgery may also develop postoperative cognitive dysfunction, which has been shown to be associated with the occurrence of perioperative infarctions detectable by MRI.[5] Additional risk factors include alcohol abuse, lower educational level, and previous stroke. Patients affected by this complication, even when transient, may have worse long-term cognitive outcomes, greater disability (particularly in the elderly), and a higher mortality.[3] The impact of anesthesia exposure in early life (i.e., neonates and infants) on subsequent intellectual development has been quite extensively investigated but remains a matter of persistent debate due to inconsistent results across studies.[6]

There is no definitive evidence that the choice of anesthetic regimen (such as general or regional anesthesia) or the depth of anesthesia alters the risk of postoperative cognitive dysfunction. Activation of neuroinflammatory responses has been proposed as a key mechanism underlying the development of cognitive changes after exposure to anesthesia and surgery.[7] Maintenance of physiologic homeostasis during and after surgery may minimize the risk of this complication.

Paraparesis

Epidural hematoma is probably the most feared complication of spinal and epidural anesthesia (Table 55-3). Although rare, patients at higher risk include those with advanced age, alcoholism, anatomic abnormalities of the vertebral column leading to difficulties with needle placement, and, most importantly, coagulopathy due to a bleeding diathesis or anticoagulant effect.[8]

Symptoms of epidural hematoma typically present within the first few hours after the surgery. Attributing them to anesthetic effects may delay the diagnosis and decrease the chances of recovery after surgical evacuation. The neurologist should contact the anesthesiologist to clarify the anesthetic approach used, the effects of the drugs administered, and the expectation of the duration of their effect. In the acute phase, it may be difficult to differentiate between a compressive epidural hematoma and spinal cord ischemia. Preservation of posterior column sensation is expected with an anterior spinal artery infarction. Spinal CT scan allows visualization of the hematoma in most cases, but its sensitivity is suboptimal

when hardware is present. Therefore, MRI of the spine should be obtained urgently if possible. Urgent surgical evacuation of the hematoma may result in excellent functional recovery.

The American Society of Regional Anesthesia and Pain Medicine has published recommendations for the management of patients receiving antithrombotics who require regional anesthesia.[8] Warfarin should be discontinued 5 days before planned regional anesthesia, and anticoagulation with warfarin should be reversed until the international normalized ratio is 1.5 or less before urgent interventions. Patients at high risk of thromboembolism should receive bridging with unfractionated heparin (to be stopped 4 hours before surgery) or low-molecular-weight heparin (reduced to half of the usual daily dose and stopped 24 hours before surgery). After surgery, warfarin can be resumed on the first day and heparin products restarted after 24 hours following minor surgeries or 48 to 72 hours after major surgeries. Although continuation of aspirin is acceptable if necessary, clopidogrel should be discontinued 5 to 10 days before the surgery and can be restarted 24 hours after it. It is recommendable to discontinue dabigatran 5 days before the procedure, although 3 days may be an acceptable interval in patients with creatinine clearance greater than or equal to 80 mL/min. Dabigatran should not be restarted until at least 6 hours following removal of the neuraxial catheter. The factor Xa inhibitors rivaroxaban and apixaban should be discontinued 3 days before the intervention and not restarted until at least 6 hours after removal of the neuraxial catheter. Neuroaxial blocks are discouraged in patients with severe impairment of renal function (creatinine clearance ≤ 30 mL/min).

Epidural abscess can also cause postoperative paraparesis, but its presentation is usually delayed (at least for days after surgery), and cases exclusively related to neuroaxial blockade are rare (Table 55-4).

TABLE 55-4 ■ **Patterns of Onset and Resolution of Four Neurologic Syndromes Occurring in Rare Patients Following Spinal or Epidural Block**

Neurologic Syndrome	Onset of Symptoms	Resolution of Symptoms
Aseptic meningitis	<24 h	<7–10 days
Cauda equina syndrome	Immediate or several days' delay	Permanent or temporary
Adhesive arachnoiditis	Weeks after block	Permanent
Epidural abscess	Days to months after block	Permanent or temporary

Neuropathy

The incidence of neuropathy has been estimated to be less than 0.04 percent after neuroaxial blockade and less than 3 percent following peripheral blockade, although these rates should be considered general approximations.[9] Neurologic symptoms and deficits are typically transient. Although prospective studies with blinded assessment are lacking, persistent postoperative neuropathy after regional anesthesia is quite infrequent.

Neuropathies can occur due to various mechanisms, some of which are not strictly related to anesthesia. Mechanical stress from stretch or compression of nerves as a result of malpositioning during surgery is a common cause; neuropathies are more likely to occur after prolonged surgeries. Other risk factors include male sex, diabetes mellitus, smoking, hypertension, vascular disease, obesity or extremely thin body habitus, and pre-existing clinical or subclinical nerve dysfunction. Some of these associations suggest that ischemic and metabolic insults play a role in pathogenesis.

The most frequently affected nerves in the upper extremities are the ulnar nerve and brachial plexus and in the lower extremities the sciatic, femoral, and fibular (peroneal) nerves and the lumbosacral plexus.[9] The predisposition of these particular nerves probably relates to their susceptibility to stretch and compression. The most common deficits that result are pure sensory and sensorimotor disturbances. Positioning strategies to reduce the risk of each of these peripheral neuropathies have been

described.[10] Avoidance of arm abduction beyond 90 degrees in supine patients diminishes stretch of the brachial plexus. Minimizing pressure over the ulnar groove, avoidance of excessive flexion of the elbow (Fig. 55-1), and use of protective elbow padding are recommended to reduce ulnar nerve injuries. Restricting stretch of the hamstring muscle and the degree of hip flexion when the patient is in the lithotomy position lessens the risk of sciatic neuropathy. Perioperative fibular (peroneal) neuropathies can be averted through careful avoidance of prolonged pressure over the fibular head and the use of protective padding. Limb position and external compression play a lesser role in the pathogenesis of perioperative femoral neuropathies, which are attributed most often to damage from inappropriate retractor placement or pelvic hematoma (Fig. 55-2).

Cauda equina syndrome is a rare complication of spinal anesthesia, attributed speculatively to maldistribution of the local anesthetic into the subarachnoid space. Most reported cases have occurred after continuous spinal anesthesia, and the predominant manifestations are localized to the S1 nerve roots, presumably because of their more posterior location.

Full recovery from these neuropathies is often seen after days to weeks, but some patients suffer persistent disability. There is insufficient information to guide prognostication, except that electrodiagnostic evidence of demyelination (conduction block) rather than axonal loss implies a better prognosis than otherwise.

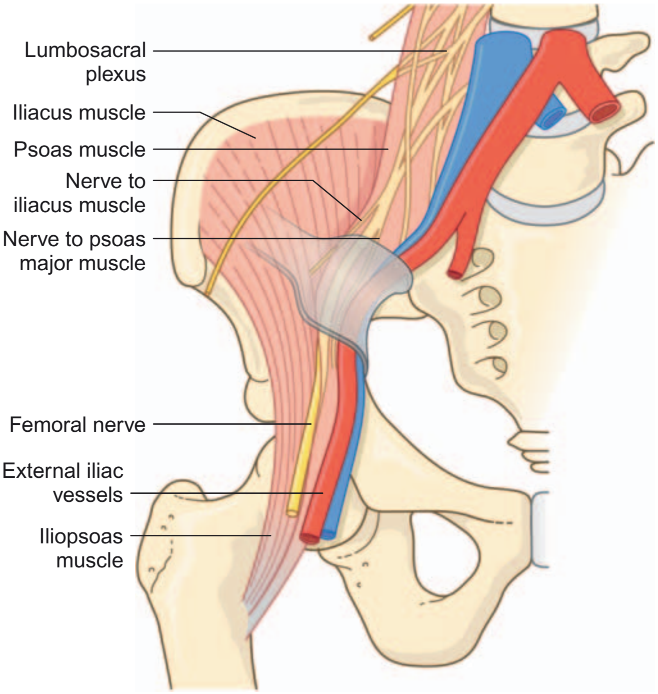

FIGURE 55-2 ■ Illustration of the common mechanism of compression of the femoral nerve through pressure applied with the surgical separator.

Transient Neurologic Symptoms

A syndrome known to anesthesiologists as *transient neurologic symptoms* is characterized by early postoperative pain in the buttocks and legs after spinal anesthesia. The pain, which may be severe, typically develops after an initial asymptomatic period of a few hours and is frequently bilateral. The syndrome resolves spontaneously within 2 to 5 days. The risk of this complication is higher with lidocaine and mepivacaine than with other local anesthetics and is not influenced by the dose or concentration of the drug.[10] The main differential diagnoses include cauda equina syndrome, aseptic meningitis, adhesive arachnoiditis, and epidural hematoma or abscess. Imaging reveals no structural abnormality that can explain the symptoms, and the etiology remains uncertain.

Visual Loss

Posterior ischemic optic neuropathy is a rare complication of complex spine surgeries that require prolonged prone positioning, associated with intraoperative blood loss and hemodynamic instability.[11] The performance of staged surgeries, a more liberal intraoperative transfusion strategy, avoidance of intraoperative hypotension, and maintenance of the head at or above the level of the heart have each been recommended, but the etiology of the condition is unclear and the value of these strategies is unproven. Although the visual impairment can be transient, it is often severe and bilateral and may be permanent. Cardiac surgeries also may be complicated in rare instances by visual loss, typically due to anterior ischemic optic neuropathy or retinal embolism. Anesthesia technique does not appear to be associated with the risk of this type of perioperative visual loss.[11]

Hearing Loss

Ear blockage may occur after general anesthesia with nitrous oxide in patients susceptible to Eustachian tube obstruction. Presumably mucosal edema facilitates the development of the condition. Prognosis is favorable, with resolution over hours to a few days.

Transient hypoacusis, typically subtle, may follow spinal anesthesia. The proposed mechanism is a decrease in cerebrospinal fluid volume reducing perilymphatic pressure and leading to endolymphatic hydrops. The hypoacusis is frequently, but not always, associated with headache. Use of smaller-diameter spinal needles may reduce the risk.

Cranial Nerve Palsies

Abducens nerve palsy has been described after spinal anesthesia, and it can be unilateral or, rarely, bilateral. Typically accompanied by positional headache, it occurs in cases with substantial cerebrospinal fluid loss. The risk is related to the diameter of the spinal needle.

Pupillary changes may follow neuroaxial blocks. Horner syndrome sometimes occurs after epidural anesthesia, typically after labor; the condition lasts only for the duration of the anesthetic block. It can also occur transiently after brachial plexus blockade. Anisocoria found after surgery should not be attributed to anesthetic blockade except when the patient is fully lucid and the examination clearly reveals an isolated Horner syndrome.

Bilateral pupillary dilatation in the immediate perioperative period may be caused by “total” spinal anesthesia, a condition provoked by the unintentional injection of the anesthetic drug into the subarachnoid space. Marked mydriasis and unconsciousness are common, and the problem is typically recognized in the operating room.

Exceptional cases of unilateral and transient trigeminal and facial nerve dysfunction have also been reported after epidural anesthesia for women in labor.

PERIOPERATIVE RIGIDITY

The differential diagnosis of a febrile and rigid patient includes serotonin syndrome, neuroleptic malignant syndrome, and malignant hyperthermia. Serotonin syndrome is most common in the postoperative period, and any patient receiving serotonergic drugs, especially in combination, is at risk for this disorder. Commonly used serotonergic medications include antidepressants, mood stabilizers, antihistamines, triptans, muscle relaxants, and amphetamines, and those prescribed frequently after surgery include opiates (particularly fentanyl), tramadol, and antiemetics. Diagnosis is based on the presence of alterations in consciousness (sometimes with agitation), signs of neuromuscular irritability (hyperreflexia, clonus, rigidity, tremors, myoclonus), and features of autonomic instability (fever, tachycardia, hypertension, diaphoresis). Patients often have mydriasis and hyperactive bowel sounds with diarrhea. The predominance of the rigidity in the lower limbs compared with the upper limbs is distinctive. In severe cases, pronounced rigidity is associated with fever and muscle injury. Recovery follows prompt discontinuation of all serotonergic drugs, usually over hours to days. Cyproheptadine or chlorpromazine might accelerate recovery in more severe cases. Induced neuromuscular paralysis may be necessary in patients with extreme rigidity, fever, and rhabdomyolysis.

The neuroleptic malignant syndrome is uncommon. It presents 1 to 3 days after exposure to an antidopaminergic drug, with clinical features that include extreme rigidity, fever, dysautonomia, and an elevated serum creatine kinase level. Bradykinesia, lead-pipe rigidity without leg predominance, hyporeflexia, and normal bowel sounds distinguish it from the serotonin syndrome. When the diagnosis of neuroleptic malignant syndrome is suspected, antidopaminergic medications should be stopped and patients should be monitored for dysautonomic complications. Bromocriptine, a dopamine agonist, may diminish the rigidity; severe cases are treated with dantrolene, a potent muscle relaxant.

Malignant hyperthermia occurs in the operating room upon anesthesia induction and neuromuscular paralysis, or within minutes of anesthesia cessation. It is caused by mutations affecting receptors that control the transport of calcium from the sarcoplasmic reticulum to the cytoplasm. Exposure to inhalational anesthetics, especially when succinylcholine is administered, results in excessive availability of calcium in the cytoplasm which, in turn, provokes sustained muscle contraction. A hypermetabolic crisis follows, manifest by hypercapnia, hyperthermia, and mixed acidosis. Severe rhabdomyolysis and cardiac arrhythmias may occur if the diagnosis is delayed. Immediate discontinuation of the anesthetic agent and administration of dantrolene are extremely effective in reversing the syndrome.

PERIOPERATIVE SEIZURES

Surgery—with the exception of neurosurgery—does not predispose to seizures in general. Some anesthetics have antiepileptic properties while others lower the seizure threshold (Table 55-5). Seizures following anesthesia are uncommon overall. Risk factors include a history of epilepsy (especially in children), previous structural brain injury, and substance abuse.

When postoperative seizures occur in patients with epilepsy, they are generally related to poor preoperative control of the epilepsy and not to the anesthetic.[12] In patients with epilepsy, drugs known to lower the seizure threshold should be avoided. Epileptic seizures should

be differentiated from seizure-like movements (including myoclonus, often seen upon propofol withdrawal) and psychogenic nonepileptic seizures.

Postoperative seizures in patients without a history of epilepsy should lead to evaluation for a structural brain lesion, such as an acute stroke, more commonly seen after cardiovascular surgery. Old cortical strokes may also serve as a substrate for postoperative seizures, usually occurring with some delay after the surgery and not precipitated by anesthesia itself.

Postcraniotomy seizures are more frequent and vary depending on the type of surgery. Seizures can even occur, albeit rarely, after operations in the posterior fossa. The value of prophylactic antiseizure medications is unclear.

PERIOPERATIVE HEADACHE

TABLE 55-6 ■ Causes of Perioperative Headache

- Exacerbation of pre-existent primary headache disorder
- Myofascial headache
- Caffeine withdrawal
- Postdural puncture headache
- Closed air-space headache (e.g., effects of nitrous oxide on inflamed sinus or middle ear)
- Trigeminal branch neuropathy
- Structural intracranial lesion
- CNS infection

Although there are many causes of postoperative headache (Table 55-6), those most directly related to anesthesia follow regional anesthesia. Dural puncture can cause a persistent leak of cerebrospinal fluid and the ensuing intracranial hypotension classically manifests with orthostatic headaches (i.e., they are worsened when the patient is upright and ameliorated by recumbency). This complication is more common in thin young women, and it sometimes occurs in obstetric patients when inadvertent dural puncture occurs during epidural anesthesia. Use of smaller needle size and good technique (e.g., bevel inserted parallel to the plane of the dural fibers, use of a single pass) decrease the incidence of this complication.

An arbitrary period of recumbency following dural puncture does not decrease the incidence of headache, and early ambulation may actually be preferable. Caffeine is often recommended for treatment and seems to work in practice but its value, or that of nonsteroidal anti-inflammatory agents, has not been demonstrated conclusively. Morphine, cosyntropin, and aminophylline are the agents best supported by evidence of efficacy, but they are rarely prescribed for the headaches that follow dural puncture.[13] Epidural blood patch is the best treatment for this type of headache, and it is effective in more than three-quarters of patients. Its efficacy may be lower if placed more than 4 days after the puncture.

Another cause of headache directly related to anesthesia is sinus or middle ear block in patients receiving nitrous oxide. As the gas equilibrates with the air contained in these cavities, pressure may mount in patients with mucosal inflammation.

Compression of the supraorbital or infraorbital branches of the trigeminal nerve from a tight face mask used during anesthesia may also be a rare cause of severe headache after surgery.

ANESTHESIA IN PATIENTS WITH NEUROLOGIC DISEASE

Neurologists are often asked by patients with chronic neurologic disease or their families whether exposure to anesthesia during surgery can exacerbate their underlying condition. The answer depends on the disease in question, the type of surgery, and the condition of the patient.

There are no studies comparing the safety of regional to general anesthesia in patients with pre-existing neurologic disease. It has been postulated that techniques of regional anesthesia may exacerbate previous peripheral neurologic injury by inducing a secondary insult, particularly in patients with pre-existing neuropathies. However, the results from most studies indicate that anesthesia can generally be used safely in patients with various neurologic diseases.

Alzheimer Disease

Anesthetic drugs, especially inhalational agents, have the potential to induce or accelerate the neurodegenerative changes characteristic of Alzheimer disease.[14] Potential mechanisms include neuronal calcium dysregulation, increased amyloid beta production and aggregation, increased tau phosphorylation, and activation of apoptotic pathways in the predisposed brain exposed to isoflurane. The evidence for these effects comes from experimental models, and there is no conclusive clinical data associating anesthetic exposure with a greater risk of Alzheimer disease; indeed, some epidemiologic studies appear to refute any such association. Various anesthetic gases may have different effects. Isoflurane, but not desflurane, has been associated with an increase in Aβ40 protein levels in human cerebrospinal fluid 24 hours after surgery compared with control patients undergoing spinal anesthesia.

Many general anesthetics decrease central acetylcholine release and depress cholinergic transmission in the basal forebrain, a condition that mimics changes found in Alzheimer disease. Most anesthetic agents also interact with muscarinic and nicotinic receptors in the brain, typically in a dose-dependent manner. Propofol and remifentanil interfere less with cholinergic function than inhalational drugs and other opioids.

Observational studies indicate that presurgical cognitive impairment and dementia are associated with postoperative cognitive decline, poor functional recovery, and an increased risk of death. Whether adjustments in the anesthetic regimen (such as the use of propofol instead of inhalational agents) can decrease this risk remains unclear. Hypnotics, opioids, inhalational drugs, and neuromuscular blocking agents produce more variable responses with advanced age and should be used prudently in patients with documented cognitive impairment.

Parkinson Disease

For patients with Parkinson disease who require surgery, the main problem relates to transient discontinuation of their antiparkinsonian regimen. These medications should be continued to as close to the beginning of anesthesia as possible, and restarted as soon after surgery as feasible to minimize parkinsonian complications. In prolonged surgeries, intraoperative administration of levodopa via a nasogastric tube can be considered. During the early postoperative period, patients with Parkinson disease have an increased risk of postextubation respiratory failure and aspiration pneumonia due to upper airway dysfunction, as well as hemodynamic instability from impairment of autonomic control. Delirium is also common postoperatively in patients with Parkinson disease.

Succinylcholine may be unsafe in patients with Parkinson disease who are very rigid because of an increased risk of inducing severe hyperkalemia; nondepolarizing muscle relaxants can be used safely instead. Propofol is generally the preferred induction agent for these patients. Inhalational anesthetics should be administered cautiously due to a greater risk of inducing hypotension and cardiac arrhythmia. Ketamine use may be associated with an excessive sympathetic response. Thiopental can theoretically decrease striatal dopamine release, but is probably safe.

Antidopaminergic drugs should be avoided, including various antiemetics commonly prescribed in the recovery room (e.g., droperidol, metoclopramide). Meperidine should not be used in patients who have taken selegiline or rasagiline in the preceding 2 weeks because this combination can result in severe hypertension or hypotension, respiratory depression, convulsions, malignant hyperthermia, excitation, peripheral vascular collapse, coma, and death. Tramadol, methadone, tapentadol, and propoxyphene must also be avoided for the same reason. When fentanyl is administered, greater rigidity can be expected, and occasionally opioids of all types can cause severe acute dystonia responsive to naloxone.

Functional neurosurgery (deep brain stimulation) for the treatment of Parkinson disease represents a particular challenge because—depending on technique—patients are kept awake to allow for adequate monitoring and targeting of deep brain structures during lead insertion. The advantages of awake craniotomy need to be balanced against the risk of operative complications such as intracranial hemorrhage, which may increase when patients are uncomfortable and not fully cooperative. When trying to preserve patient cooperation, dexmedetomidine can be helpful in providing mild sedation. Propofol is also a good agent as it does not affect electrophysiologic monitoring.

Epilepsy

The risk of perioperative seizures is very small in patients with epilepsy undergoing general anesthesia, and epileptic patients do not appear to have an increased risk of other perioperative adverse effects. Children with epilepsy may be more susceptible than adults to develop seizures associated with anesthesia. Regional blockade can be performed safely.

Many anesthetic agents produce complex effects on brain electrical activity and may have proconvulsant and anticonvulsant properties depending on the dose and concentration (Table 55-5). Although most anesthetic regimens are safe for patients with epilepsy, some agents should be used cautiously because of their proconvulsant potential at usual doses, including etomidate and intravenous lidocaine. Sevoflurane is more epileptogenic than the other inhaled anesthetics, and short-acting opioids (e.g., alfentanil, sulfentanil, remifentanil) increase epileptiform activity during intraoperative electrocorticography for epilepsy surgery. Propofol, barbiturates, benzodiazepines, and other volatile agents (especially isoflurane and desflurane) conversely have antiepileptic effects and are the preferred options in patients with epilepsy.

Other Chronic Diseases of the Central Nervous System

Patients with multiple system atrophy and an accompanying dysautonomia may develop dangerous hemodynamic instability in the perioperative period. General anesthesia can be used safely in these patients, but agents that lead to hypotension should be avoided; spinal anesthesia may be preferable.

Patients with amyotrophic lateral sclerosis are particularly susceptible to the effects of muscle relaxants. Succinylcholine should be avoided in all patients with severe neuromuscular disease because it can induce hyperkalemia. When muscle relaxation is deemed indispensable, nondepolarizing blocking agents should be administered in low doses using nerve stimulator monitoring. A regimen of propofol and remifentanil without muscle relaxation is safe in these patients. In patients with amyotrophic lateral sclerosis requiring gastrostomy tube placement, opiates may decrease the ventilatory drive, precipitating respiratory failure.

Worsening myelopathic symptoms following spinal anesthesia have been reported rarely in patients with multiple sclerosis or other demyelinating conditions, but a large case series of patients with multiple sclerosis, amyotrophic lateral sclerosis, and postpolio syndrome revealed no instances of severe exacerbation of preoperative neurologic deficits after spinal or epidural anesthesia.

Patients with Huntington disease may need closer monitoring due to their hyperkinetic movement disorder, but can generally receive anesthesia safely. Responses to muscle relaxants, induction agents, volatile anesthetics, benzodiazepines, and opioids are usually normal.

Neuromuscular Disorders

Severe neurologic complications are rare in patients with diabetic and nondiabetic peripheral neuropathy who undergo surgery using regional anesthesia. The risk of cauda equina syndrome may be increased in patients with spinal stenosis.

The surgical planning of patients with myasthenia gravis should incorporate input from the treating neurologist. Preoperative treatment with plasma exchange or intravenous immunoglobulin can reduce the risk of postoperative myasthenic crisis. After surgery, early weaning from mechanical ventilation and prompt reinstitution of aceylcholinesterase inhibitors are advisable. Various medications may worsen myasthenia gravis, including muscle relaxants and certain antibiotics such as the aminoglycosides.

The risk of malignant hyperthermia may be increased in patients with muscular dystrophies, although the degree of this risk is not well defined. Succinylcholine is contraindicated in patients with muscular dystrophies and metabolic myopathies because of the danger of life-threatening hyperkalemia and rhabdomyolysis.

ANESTHESIA IN THE NEUROCRITICAL CARE UNIT

Anesthetic drugs are commonly prescribed in the intensive care unit (ICU) for sedation, control of intracranial hypertension, and treatment of refractory seizures. The prolonged administration and high doses used for some of these indications may provoke complications not encountered with regular perioperative use.

Prolonged sedation in the ICU is associated with a greater incidence of delirium. Daily sedative interruption in patients receiving mechanical ventilation decreases the duration of mechanical ventilation and length of stay in the ICU. This practice should be combined with daily monitoring for signs of delirium employing validated scores, such as the Confusion Assessment Method for the intensive care unit (CAM-ICU). Dexmedetomidine, a central α_2-agonist, is associated with reduced rates of delirium when compared with benzodiazepines such as midazolam.[15]

Propofol infusion syndrome is a potentially life-threatening complication caused by the prolonged administration of high doses of this drug (usually exceeding 4 to 5 mg/kg per hour for more than 48 hours). Initially recognized in children, who appear to be at higher risk, it also can occur in adults and presents with lactic acidosis, rhabdomyolysis, hyperlipidemia, hyperkalemia, renal failure, and refractory bradycardia with cardiac failure. In the most severe cases, cardiac arrest may occur. Uncoupling of the respiratory chain causing impaired mitochondrial free fatty acid metabolism is involved in the pathogenesis of this disorder. Propofol infusion syndrome has been reported during the treatment of refractory status epilepticus and in severe traumatic brain injury patients with refractory intracranial hypertension. Since other options exist for control of refractory seizures or recalcitrant intracranial hypertension, it is advisable to avoid using large doses of propofol for these indications.

Patients with prolonged refractory status epilepticus are commonly treated with anesthetics. Options include midazolam, propofol, ketamine, barbiturates, and less commonly inhalational anesthetics such as isoflurane. Midazolam is safe and effective, but tachyphylaxis develops over time. Continuous infusion of high-dose lorazepam may produce severe acidosis from propylene glycol toxicity and therefore its use should be discouraged. Ketamine, an *N*-methyl-D-aspartate antagonist, can be very useful when started early and used in adequate doses. Barbiturates are highly effective, but almost invariably associated with complications, including hypotension from myocardial depression, ileus, hepatotoxicity, and increased susceptibility to infections (particularly pneumonia). Isoflurane can be effective in aborting seizures, but may induce neurotoxicity with prolonged use.

CONCLUDING COMMENTS

Injury to other organ systems may have a direct or remote effect on the neurologic system. Hepatic, cardiac, pancreatic, and renal dysfunction can directly affect neurologic transmission and function through a variety of mechanisms. This chapter will examine what is currently understood about the immediate and long-term effects of critical illness on both the central and peripheral nervous systems. Methods to examine, prognosticate, and potentially treat these processes are important for all clinicians.

SEPSIS-ASSOCIATED ENCEPHALOPATHY

Septic encephalopathy is a nebulous term used to describe the encephalopathy encountered in the critically ill patient. It excludes patients that have direct neurologic injury, indirect effects of other failing organ systems, or exogenous toxins. Thus, it is a diagnosis of exclusion. The terminology itself is confusing since sepsis is common but is not necessary for the diagnosis. Historically defined as "altered brain function due to the presence of microorganisms or toxins in the blood," this definition is not entirely accurate since bacteria are not often identified and exogenous substances are excluded from the definition. Sepsis-associated encephalopathy has now been generally accepted as the most appropriate terminology.[1]

Epidemiology

Sepsis is common and accounts for the majority of deaths in an intensive care unit. Mortality remains high despite recent advances in treatment. The encephalopathy associated with sepsis has an even worse prognosis. Studies report up to 71 percent of critically ill patients develop an encephalopathy. The presence and severity of the encephalopathy have significant impact on both immediate mortality and long-term cognitive capabilities.[2]

Overview of the Mechanisms of Sepsis

A response to an infection is initiated when pattern-recognizing receptors on macrophages bind cellular components of microbial cell walls. Binding of these receptors initiates a signaling cascade, via the nuclear factor−κβ system, to release cytosolic factors which translocate to the nucleus. These translocated factors

activate gene transcription for proinflammatory cytokines [tumor necrosis factor (TNF), and interleukin-1 (IL-1)], chemokines, intercellular adhesion molecule 1 (ICAM1), vascular cell adhesion molecule 1, and nitric oxide. These activated factors subsequently attract polymorphonuclear leukocytes (PMNs) to the site of the injury. PMNs release local substances which account for the changes seen with inflammation (erythema, edema, warmth).[3]

Inflammation is then regulated through a balance between proinflammatory cytokines released by macrophages and anti-inflammatory factors released by PMNs. This balance typically will contain an infection locally. Sepsis occurs when the response to an infection generalizes beyond local boundaries to affect remote organ systems. The systemic inflammatory response syndrome (SIRS) reflects a similar process that is not initiated by an acute infection. Systemic release of proinflammatory cytokines, predominantly IL-1 and TNF, can become self-sustaining, leading to systemic inflammation, complement activation, and stimulation of both coagulation and fibrinolytic cascades. All of the above substances and features have been shown to be extensively involved in the development of sepsis and multiorgan failure in multiple animal models. Various single-nucleotide polymorphisms have been demonstrated to increase genetic susceptibility to sepsis.

Sepsis affects all organ systems primarily through its effect on the endothelium of vascular tissues. Sepsis induces both vasodilation (most likely through nitric oxide) and myocardial depression, leading to significant hypotension. Regional circulation is altered, affecting appropriate distribution to ischemic organs. Endothelial dysfunction leads to increased vascular permeability with subsequent tissue edema. Decreased functional capillaries at the microcirculatory level may be due to extrinsic compression from tissue edema or secondary to intravascular coagulation. Red cell deformability is decreased in sepsis, which further inhibits oxygen delivery.[3]

Oxygen utilization at the mitochondrial level is directly affected by proinflammatory mediators which cause direct mitochondrial dysfunction, most likely through direct inhibition of respiratory chain enzymatic function. Oxidative stress damage is believed to account for an increase in mitochondrial breakdown products. Direct cell death may therefore be attributed to cellular inability to utilize oxygen. Secondary cell death through apoptosis is typically decreased in sepsis. The net effect however may be to worsen apoptosis as septic mediators and proinflammatory cytokines delay apoptosis in macrophages and neutrophils.[3]

Pathogenesis of the Encephalopathy

The endothelial and microvascular effect of sepsis affects all organs. Subsequent hypoxia from pulmonary fibrosis, uremia from renal failure, or alterations in amino acid metabolism from hepatic failure, all may contribute to the encephalopathy commonly encountered in septic patients. However, an encephalopathy can develop early in the course of sepsis or SIRS prior to the development of the effects of secondary organ failure. While the exact source and mechanism of how neurologic dysfunction occurs with inflammation is unknown, it is generally believed that septic mediators, primarily proinflammatory cytokines and complement factors, gain access to the brain neuropil leading to functional disruption of neurologic transmission and eventual cell damage and death.

How these factors gain access to the brain has been an area of considerable study. Animal experiments have supported a direct toxic effect of some mediators to the integrity of the blood–brain barrier (BBB). Neonatal kittens exposed to *Escherichia coli* lipopolysaccharide develop diffuse cerebral white matter disruption with noted extravasation of Evans blue dye throughout the brain. Similarly, horseradish peroxidase is transported retrograde into septic rat neuropil demonstrating a patchy disruption of the BBB.[3,4] More recently, lipopolysaccharide exposures have been linked to direct transport of cytokines across the BBB. Inflammatory mediators may also gain direct access to the brain through the circumventricular organs located around the midline ventricular system.

However, the exact factors that increase BBB permeability are unknown. Proinflammatory molecules are increased in patients with septic-associated encephalopathy and increase the permeability of endothelial cells through pinocytosis. The loss of BBB integrity leads to perimicrovascular edema with disruption of astrocytic end feet. Similar findings have been reported with complement activation and inflammatory cytokines. Evidence from murine models implicate TNF, anaphylaxin C5a, and the cytokines IL-6 and IL-1b as mediators of BBB disruption. ICAM is increased on microvessels in sepsis and mediates adherence and entry of leukocytes into the brain.[4]

Once inflammatory mediators have gained access to the brain parenchyma, the results of these septic mediators are similar to their effects on other organs. Activated leukocytes generate free radicals that react with erythrocyte membranes causing increased swelling. This process can lead to cerebral hypoperfusion and may contribute to the encephalopathy. Inflammatory mediators in the brain as in other organs may impair oxygen extraction, utilization, or both at the mitochondrial level. Thus decreased cerebral blood flow in sepsis may be an expected response to decreased cerebral metabolism.

Cerebral ischemia itself, however, does appear to be present in sepsis. Dead neurons have been identified in septic pigs with maintained cerebral perfusion, and microvascular lesions are commonly found on imaging and pathology. Brain apoptosis in sepsis has been documented in exposure to lipopolysaccharide, presumably due to mitochondrial dysfunction.[4] Postmortem studies have shown inducible nitric oxide synthase leadng to neural apoptosis in the hippocampus and cardiovascular centers.[4] Neuronal damage is most evident in the highly metabolic neurons of the hippocampus.

An increased production of nitric oxide has also been postulated to contribute to the development of the encephalopathy. In several animal models, tumor necrosis factors increase the formation of intracellular nitric oxide. While the exact mechanism is unknown, several putative mechanisms involve the release of glutamate from both neurons and astrocytes, leading to excitotoxic death mediated through *N*-methyl-D-aspartate (NMDA) receptors; NMDA receptor blockade has limited the long-term cerebral effects of sepsis in animal models. Nitric oxide may also alter cerebral blood flow and metabolism and coupling as it is also an inhibitor of mitochondrial respiration. Neurotransmission is also impacted in septic-associated encephalopathy. Altered levels of amino acid neurotransmitters have been reported in the rat model of sepsis. Disrupted glutamate transmission appears to be particularly involved.

The parasympathetic and sympathetic nervous system also may play a role in the development of the encephalopathy. Parasympathetic activity may in part mediate the inflammatory response as increased vagal tone appears to decrease inflammation and improve mortality. Similarly, adrenergic activation appears to produce an anti-inflammatory effect which may be neuroprotective.[4]

Presentation and Evaluation

The encephalopathy associated with sepsis and inflammation may present acutely or subtly with a slow progression. Disorientation, impaired cognition, and inattentiveness can progress to agitation, delirium, stupor, and coma. Pupils are typically small and minimally reactive. Brainstem reflexes are generally maintained until late in the course. Focal signs are rare but can occur.[1]

The diagnosis remains one of exclusion. The patient should be evaluated for meningitis and infectious or autoimmune/paraneoplastic encephalitides. Similarly, encephalopathies secondary to failure of other organ systems (hepatic, renal, pulmonary, pancreatic) must be evaluated and treated if present. Failure of clearance and metabolism of the sedative medications commonly employed to treat critically ill patients can be delayed in multiorgan failure, thus complicating the evaluation. Cerebral hypoperfusion from cardiac failure can also contribute to encephalopathy.

Serum levels of neuron-specific enolase and S-100B are markers of neuronal and astrocytic damage. Both are increased with septic encephalopathy and correlate with worse outcome.[5] The electroencephalogram (EEG) can be normal but becomes slower, progressing from theta to delta activity and finally burst suppression as the encephalopathy worsens (Fig. 56-1).[6] Mortality similarly correlates with worse EEG findings. Nonconvulsive status epilepticus can occur and is probably under-recognized. Continuous EEG monitoring may be beneficial to demonstrate seizures and guide management. Magnetic resonance imaging (MRI) is sensitive to the changes that can occur during sepsis; microhemorrhages and small ischemic lesions are detected in approximately 10 percent of cases; white matter changes are common; and cortical atrophy is noted in long-term cases. Somatosensory evoked potentials, functional MRI, and positron emission tomography require more study as to their use in evaluating the encephalopathy associated with infection.

Long-Term Effects of Sepsis-Associated Encephalopathy

The long-term neurologic effects of sepsis have come under increasing scrutiny. Mild to moderate neurocognitive deficits have been reported consistently in septic patients and can be persistent. While recovery is possible in younger patients who are less severely affected, global cognitive impairment has been reported in 17 percent of patients evaluated 3 years postevent. Short-term memory appears to be particularly vulnerable. Analyses from long-term epidemiologic studies suggest that early dementia is twice as likely in patients who have an episode of sepsis.[7]

Management and Future Studies

There are no specific treatments for the encephalopathy associated with sepsis and inflammation. Early recognition and treatment of the underlying illness is the most effective therapy.

The multitude of inflammatory mediators that are believed to be involved in the development of the encephalopathy makes development of specific targets of treatment difficult. Inhibitors of nitric oxide synthase have been disappointing in animal studies.[8] Inhibitors of glutamate, antioxidants, and complement factors have shown promise, but their use in humans remains a future direction.[4]

NEUROMUSCULAR CONDITIONS IN CRITICALLY ILL PATIENTS

Critically ill patients may have neuromuscular dysfunction due to many possible etiologies that can affect the central as well as the peripheral nervous system (Table 56-1). This makes lesion localization particularly challenging to the clinician who is faced with multiple confounding features in the setting of critical illness. Compounding this difficulty is the frequent inability to obtain a history from the patient given mental state changes and physical impediments such as endotracheal tubes. In the modern ICU, the multiplicity of invasive lines, tubings, electrodes and wiring for monitoring equipment, limb splints, restraints, occlusive dressings, and bandages all represent formidable physical obstructions to the clinical examination that may otherwise be helpful in diagnosis.

Neuromuscular diagnoses are often delayed in critically ill patients due to the severity of their underlying

or comorbid illnesses. Another complicating factor is that many primary critical care conditions will present with respiratory dysfunction and motor impairment, mimicking a primary neuromuscular illness.

Electrodiagnostic testing is often needed as part of the routine evaluation of critically ill patients with unexplained neuromuscular deficits. However, these investigations are significantly hampered by ICU factors including electrical interference, cool and edematous limbs, restricted access to sites of stimulation and recording due to physical barriers, and limited patient cooperation.

In making the diagnosis of critical illness weakness, the clinician should be diligent in excluding other conditions listed in Table 56-2. Fortunately, the more extensive use of electrodiagnostic testing has allowed for the sometimes fortuitous diagnosis of relatively uncommon neuromuscular conditions including Lambert—Eaton myasthenic syndrome and primary motor neuron disease, which may also be "unmasked" by intercurrent critical illness. More routinely, electrodiagnostic studies are ordered to support clinical diagnoses of more common conditions such as Guillain—Barré syndrome and myasthenia gravis.

Muscle biopsies are increasingly employed in critical care patients with clinical suspicion for myopathy and the need to distinguish between primary (e.g., dermatomyositis, polymyositis, metabolic, mitochondrial) and secondary (e.g., steroid- or statin-related) etiologies.

Phrenic nerve conduction studies and needle electrode examination of the diaphragm, with or without neuromuscular ultrasound, have proven useful in

TABLE 56-2 ■ Generalized Neuromuscular Conditions Associated With Critical Illness

Condition	Incidence	Clinical Features	Electrophysiologic Findings	Serum Creatine Kinase Level	Muscle Biopsy	Prognosis
Polyneuropathy						
Critical illness polyneuropathy	Common	Flaccid limbs and respiratory weakness	Axonal degeneration of motor and sensory fibers	Nearly normal	Denervation atrophy	Variable
Neuromuscular Transmission Defect						
Transient neuromuscular blockade	Common with neuromuscular blocking agents	Flaccid limbs and respiratory weakness	Abnormal repetitive nerve stimulation studies	Normal	Normal	Good
Critical Illness Myopathy						
Thick-filament myosin loss	Common with steroids, neuromuscular blocking agents, and sepsis	Flaccid limbs and respiratory weakness	Abnormal spontaneous activity	Mildly elevated	Loss of thick (myosin) filaments	Good
Rhabdomyolysis	Rare	Flaccid limbs	Near normal	Markedly elevated (myoglobinuria)	Normal or mild necrosis	Good
Necrotizing myopathy of intensive care	Rare	Flaccid weakness and myoglobinuria	Severe myopathy	Markedly elevated (myoglobinuria)	Marked necrosis	Poor
Disuse (cachectic) myopathy	Common	Muscle wasting	Normal	Normal	Normal or type II fiber atrophy	Good
Combined polyneuropathy and myopathy	Common	Flaccid limbs and respiratory weakness	Indicate combined polyneuropathy and myopathy	Variable	Denervation atrophy and myopathy	Variable

establishing a neuromuscular basis for respiratory impairment in critically ill patients. These diagnostic modalities may also indirectly implicate impairment of "central drive" when the deficit is in the CNS centers of respiration. This electrodiagnostic testing complements other indicators of respiratory function including vital capacity and maximum inspiratory and expiratory pressures; it may help with the decision for intubation and ventilatory support.

Disorders of Nerve

CRITICAL ILLNESS POLYNEUROPATHY

Critical illness polyneuropathy (CIP) was first described in the 1980s by Bolton, Zochodne, and colleagues, and the diagnostic criteria currently employed are shown in Table 56-3. It is the most frequent acute polyneuropathy seen in critical care, and it may affect half to three-quarters of ICU patients to some degree.[9] Patients may exhibit both limb and respiratory muscle weakness; failure to wean from mechanical ventilation is a common presenting feature and may be the only identified sign of the condition. This cause of failure to wean is important to differentiate from other potential etiologies including encephalopathy-related central drive failure, phrenic nerve trauma, neuromuscular junction dysfunction, and myopathy. Decreased maximal inspiratory and expiratory pressures and vital capacities usually correlate with limb muscle weakness and are associated with delayed extubation, prolonged ventilation, and unplanned readmission to the ICU.

Facial muscles are typically spared in CIP. This feature allows for the recognition of a fairly specific pattern of preserved facial grimacing with flaccid or absent limb movements in response to centrally/axially located noxious stimuli such as sternal rub or supraorbital ridge pressure (the usual length-dependent axon loss pattern may make deep nailbed pressure a less reliable noxious stimulus option). Typically there is loss of

TABLE 56-3 ■ Diagnostic Criteria for Critical Illness Polyneuropathy

1. The patient is critically ill (multiorgan dysfunction and failures)
2. Limb weakness or difficulty weaning patient from ventilator after non-neuromuscular causes such as heart and lung disease have been excluded
3. Electrophysiologic evidence of axonal motor and sensory polyneuropathy
4. Absence of a decremental response on repetitive nerve stimulation

Definite diagnosis of critical illness polyneuropathy is established if all four criteria are fulfilled. Probable diagnosis of critical illness polyneuropathy is established if criteria 1, 3, and 4 are fulfilled. Diagnosis of intensive care unit—acquired weakness is established if only criteria 1 and 2 are fulfilled.

Reprinted with permission from Latronico N, Bolton CF: Critical illness polyneuropathy and myopathy: a major cause of muscle weakness and paralysis. Lancet Neurol 10:931, 2011, modified from Bolton CF: Neuromuscular manifestations of critical illness. Muscle Nerve 32:140, 2005.

deep tendon reflexes which were previously demonstrable. In the uncommon circumstance where the patient is sufficiently alert, muscle strength can be tested using the Medical Research Council (MRC) scale or handgrip dynamometry. An "MRC sum score" of less than 48 establishes ICU-acquired paresis and is associated with protracted mechanical ventilation and length of stay in the ICU, increased mortality, and reduced quality of life in survivors.[10,11] Although predominantly motor deficits are manifest, loss of pain, temperature, joint position, and vibration sensation may also be noted. In some instances, weakness may appear to be more generalized rather than clearly length-dependent. Although most patients improve, the degree of residual disability after discharge from the acute care setting is variable and correlates robustly with the severity of electrodiagnostic findings.

Laboratory findings may be consistent with SIRS, sepsis, multiorgan failure, or a combination of the three. Lumbar puncture is not usually required but will typically show a normal CSF protein concentration and no albuminocytologic dissociation as would be seen with Guillain—Barré syndrome.

The pattern of electrodiagnostic abnormalities seen in CIP is typically consistent with a length-dependent, sensorimotor, axonal polyneuropathy. Hence, the initial changes are marked by a reduction in the amplitude of sensory nerve action potentials (SNAPs) and compound muscle action potentials (CMAPs), predominantly in the lower extremities. In keeping with this axon-loss picture, demyelinating features including prolongation in distal latencies, slowing of conduction velocities, temporal dispersion of CMAPs, and conduction block are either absent or minimal (Fig. 56-2).

It may not be possible to elicit motor unit potentials on needle electrode examination if consciousness is markedly depressed. It typically takes 2 to 3 weeks after

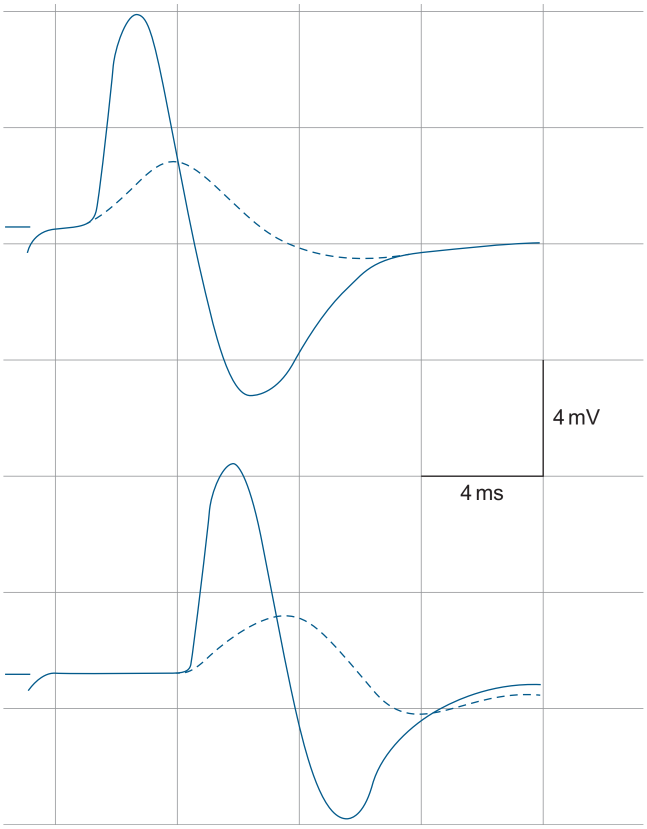

FIGURE 56-2 ■ Compound muscle action potential recording from the thenar muscle on stimulation of the median nerve at the wrist and elbow, at the onset of sepsis (*A, solid line*) and 3 weeks later (*B, dotted line*). Note the marked drop in amplitude and mild but definite increase in duration without a change in latency. (Reprinted with permission from Latronico N, Bolton CF: Critical illness polyneuropathy and myopathy: a major cause of muscle weakness and paralysis. Lancet Neurol 10:931, 2011, modified from Bolton CF, Young BG, Zochodne DW: Neurological changes during severe sepsis. p. 180. In Dobb GJ, Burehardi H, Dellinger RP (eds): Current Topics in Intensive Care, Saunders, London, 1994.)

initial nerve injury for the emergence of abnormal spontaneous activity including positive sharp waves and fibrillation potentials. By this time, there is further reduction of the SNAPs and CMAPs due to ongoing axon loss.

As recovery occurs in CIP, spontaneous activity tends to subside. By about 2 months, motor unit potential morphology changes will include increased amplitude and duration along with the presence of polyphasia. Patients at risk for CIP may benefit from having serial fibular (peroneal) motor nerve conduction studies.

The specific clinical and electrodiagnostic features of CIP usually obviate the need for tissue diagnosis. However, distal-predominant motor and sensory nerve fiber degeneration have been demonstrated on nerve and muscle biopsies as well at autopsy in patients with CIP (Figs. 56-3 and 56-4). Histopathologic examination reveals acute denervation atrophy of muscle, including both type I and type II fibers, with scattered, angulated fibers (Fig. 56-5). As the process advances, there is some degree of reinnervation, and therefore fiber-type grouping. Inflammation in either nerve or muscle is conspicuously absent. The CNS is generally devoid of changes except for chromatolysis of the anterior horn cells secondary to distal motor axonal injury. Intercostal and phrenic nerves undergo a similar process of motor axon loss, resulting in denervation atrophy of respiratory muscles, which explains the associated respiratory compromise.

The major risk factors for CIP include SIRS, sepsis, multiorgan failure, and hyperglycemia. Associations with corticosteroids are often cited but have not been definitively proven.

More recent research has demonstrated a component of potentially reversible functional disruption

that precedes structural degeneration of nerves in CIP. Such a phenomenon is mirrored simultaneously in multiple failing organs and is likely a result of shared microcirculatory, cellular, and metabolic pathophysiologic mechanisms. This may be the basis for electrophysiologic changes in peripheral nerves, which have rapid onset and may be reversible. Correspondingly, onset of clinical signs can also be rapid and reversible. Data have suggested that the physiologic basis of this reversible peripheral nerve dysfunction may lie in abnormal nerve excitability due to an induced channelopathy, namely a shift in the voltage dependence of sodium channel fast inactivation toward a more negative potential.

Apart from mitigating systemic and microcirculatory factors that promote peripheral nerve ischemia, there is evidence for mitochondrial dysfunction with reduced ATP biosynthesis and energy generation (cytopathic hypoxia).[9] Metabolic disruptions include an increase in the production of cytokines, nitric oxide, and stress hormones which can lead to hyperglycemia from increased insulin resistance. Decreased metabolic demands reduce hormonal stimulation which, in conjunction with direct mitochondrial inhibition from nitrogen and oxygen reactive species, leads to mitochondrial ATP generation failure.[9] Consequently, impairment in the axonal transport systems due to energy failure may be responsible for distal-predominant nerve fiber involvement.

In patients with CIP, the vascular endothelium of epineurial and endoneurial vessels demonstrates increased expression of E-selectin, a marker of endothelial cell activation. As a consequence, activated leukocytes within the endoneurial space produce local cytokines, which increase microvascular permeability. The subsequent endoneurial edema compromises the blood–nerve barrier. Such deleterious fluid dynamics are enhanced by hyperglycemia and hypoalbuminemia. The peripheral nerve axon which is "exposed" to this process is therefore further susceptible to circulating toxins in the setting of sepsis.

Recommendations for patient management will necessarily include the prevention and aggressive treatment of sepsis and related multiple organ failure. Although malnutrition is not clearly implicated in the pathogenesis of CIP, benefits are predictable if nutritional status is optimized with the timely use of total parenteral or enteral nutrition. Early intervention with rehabilitative exercises should be encouraged.

In the treatment of CIP, there is no definite evidence to support the use of intravenous immunoglobulin or other agents (e.g., antioxidants, hormones) thought to abort the septic cascade. Intensive insulin therapy to maintain euglycemia reduces the incidence of CIP and the duration of mechanical ventilation in both surgical and medical critically ill patients. Studies have demonstrated a 20 to 44 percent reduction in the incidence of neuromuscular dysfunction in patients receiving intensive treatment for hyperglycemia.[9] However, the optimum glycemic target is undetermined because intensive insulin therapy required to maintain strict blood glucose control also increases mortality in adult ICU patients.

The underlying condition is responsible for a mortality rate of up to 50 percent in patients with CIP. About one-fifth of patients with CIP have severe residual deficits one year after acute illness.

MOTOR NEUROPATHY AND NEUROMUSCULAR BLOCKING AGENTS

Competitive (nondepolarizing) neuromuscular blocking agents including pancuronium and vecuronium have been associated with electrophysiologic evidence of long-term neuromuscular junction dysfunction and polyneuropathy. These agents have been traditionally used for muscular relaxation during mechanical ventilation. Discontinuation after prolonged use is associated with difficulty in weaning the patient from the ventilator. In these cases, limb weakness is also common. Under these circumstances, injury appears to occur at multiple sites. A myopathic component is suggested by a mild-to-moderate elevation in the serum creatine kinase (CK). Impairment of postsynaptic neuromuscular junction transmission can be found on low-frequency repetitive nerve stimulation testing. Motor-predominant axonal loss is detected on nerve conduction studies.

It is unclear whether denervation occurs as a primary or secondary process. In some circumstances there may be no actual axonal disruption. Electrodiagnostic findings may thus be the result of profound and prolonged neuromuscular junction blocking. This phenomenon is thought to produce a "functional denervation" in affected muscles, which may manifest varying degrees of denervation atrophy and muscle necrosis.

There has been speculation about a major role of sepsis in the pathogenesis of this condition. Proponents of this believe that if the various systemic complications of sepsis can be treated successfully, spontaneous improvement and rapid recovery may ensue. It is generally recommended that dose and duration of neuromuscular blocking agents be judiciously minimized as a reasonable preventive measure.

Fortunately, the routine use of pancuronium and vecuronium for ventilated, critically ill patients is less common. When neuromuscular blockade is required, the use of alternative nondepolarizing agents is recommended. It appears that cisatracurium besylate improves survival and decreases mechanical ventilation time in patients with the acute respiratory distress syndrome, with no significant deleterious effects on muscle function.

Chronic Polyneuropathies

On occasion, the neuropathy found in the critically ill patient may represent an exacerbation or worsening of previous deficits associated with a longstanding chronic polyneuropathy. This neurologic decompensation may manifest itself as sensorimotor deficits in the limbs as well as respiratory muscle weakness. Patients who may be affected in this manner include those with chronic inflammatory demyelinating polyneuropathy and even patients with significant diabetic polyneuropathy.

These cases are best confirmed with electrodiagnostic studies. Apart from conventional limb EMG, phrenic nerve conduction study and diaphragmatic needle electrode examination (possibly with neuromuscular ultrasound) are often helpful.

Neuromuscular Junction Transmission Disorders and Myopathies

Features of pre-existing neuromuscular junction transmission disorders and myopathies are difficult to differentiate from the myriad of possible causes of muscular weakness in the critical care setting. A fatigable pattern of weakness with prominent oculobulbar findings should raise suspicion for a neuromuscular junction disorder. It is not unusual for myopathies to transiently worsen with intercurrent illness as well. One should be particularly mindful of the patient with central core disease in whom malignant hyperthermia is a significant risk. Succinylcholine and volatile anesthetics should be strictly avoided. Electrodiagnostic studies with repetitive nerve stimulation and (infrequently) muscle biopsy may be employed to establish the specific diagnosis and differentiate from the more common etiologies in the ICU.

Transient Neuromuscular Junction Blockade

In cases where neuromuscular junction blocking agents are used for muscle relaxation in mechanically ventilated patients, normal liver and kidney function facilitates rapid metabolism and clearance of the drug. However, in critical illness, renal and hepatic function may be compromised. Consequently, it has been postulated that neuromuscular junction blocking agents may remain active long after discontinuation due to the protracted half-life in these patients. This feature may augment some of the neuromuscular junction injuries attributed to sepsis itself, and convalescence may require weeks to months. Electrodiagnostic evaluation with repetitive nerve stimulation may help in the confirmation and quantification of this deficit.

Critical Illness Myopathy

While CIP was being better characterized in the 1980s, clinicians were also appreciating an acute myopathy in severely ill patients treated for conditions like status asthmaticus and organ transplantation. Various terms have marked the condition's etymologic evolution including acute quadriplegic myopathy, critical care myopathy, acute necrotizing myopathy of intensive care, thick filament myopathy, pancuronium-associated myopathy, and acute corticosteroid myopathy. Eventually, the name critical illness myopathy was accepted for standard reference.

Although critical illness myopathy may occur independently of CIP, the conditions most often co-exist. Difficulty with differentiation has led to the nonspecific but frequent reference to "polyneuromyopathy" in the literature. Data have shown a strong correlation between severity of critical illness including sepsis and the early onset and severity of CIP and myopathy. Patients at particular risk for critical illness myopathy include those with status asthmaticus, among whom up to one-third may be affected. It may also be seen in about 7 percent of patients after orthotopic liver and heart transplantation.[9] A predisposition for myopathy in transplant populations with renal failure has been demonstrated. Data also support corticosteroids and neuromuscular junction blockers as risk factors, especially when biopsy shows myosin loss.

Although this is an acute illness, the exact time of onset is often difficult to decipher in the context of a septic encephalopathy and administration of centrally acting sedative medications and neuromuscular blocking agents. The most prominent clinical feature is that of generalized flaccid weakness affecting appendicular, truncal, and cranial musculature. There is usually no myalgia or muscle tenderness. An important manifestation is neck flexor weakness, which correlates with diaphragmatic muscular weakness and difficulty in weaning from mechanical ventilation. Although a pupil-sparing ophthalmoparesis may be present, this feature often prompts further exclusion of a neuromuscular junction transmission disorder. The loss of deep tendon reflexes is a variable finding, although in most cases they are depressed.

In the laboratory evaluation of these patients, serum CK levels are usually mildly increased with studies showing elevation in at least 50 percent. This is in contrast to patients with CIP who typically have normal to minimally elevated serum CK levels. A patient receiving corticosteroids may have at least a 10-day delay in CK elevation related to critical illness myopathy. Most striking elevations of serum CK are seen with necrotizing myopathies and rhabdomyolysis where there is often concomitant myoglobinuria.

In critical illness myopathy, typical findings on nerve conduction studies are low-amplitude CMAPs, which are often two to three times longer in duration than in healthy individuals and are most pronounced in the lower limbs. Slowing of muscle fiber conduction has been one proposed explanation. SNAPs are expected to be normal but may be technically difficult to obtain due to skin conditions and tissue edema.

The needle electrode examination often shows evidence of spontaneous activity including fibrillation potentials and positive sharp waves, which are thought to reflect muscle fiber membrane disruption. Activation typically reveals "myopathic" motor unit potentials with short duration and low amplitudes; there is an increased number of polyphasic potentials and normal or early recruitment, with high-frequency components. In unresponsive patients, some authors have suggested utility of recordings from the tibialis anterior, employing reflexive activation after plantar stimulation. Alternatively, direct muscle stimulation may be used; although this is a technically challenging test with limited availability, it can demonstrate reduced muscle membrane excitability, established if the CMAP amplitude after direct muscle stimulation is less than 3 mV and the ratio of the CMAP amplitude after nerve stimulation to that obtained after direct muscle stimulation is more than 0.5. Additionally, since a response to direct muscle stimulation but not corresponding nerve stimulation is seen in CIP, this electrodiagnostic test may be helpful in differentiating between these two related conditions. It is less helpful when both disorders co-exist. For a diagnosis of "definite" critical illness myopathy, repetitive nerve stimulation testing should be done to demonstrate the absence of a decremental response seen in neuromuscular junction transmission disorders such as myasthenia gravis. Other criteria are shown in Table 56-4.

In the critically ill myopathic patient with respiratory impairment, findings on phrenic nerve conduction studies and needle electrode examination of the diaphragm may be similar to those in CIP. Motor unit potentials occurring during attempted inspiration or sniffing tend to have a myopathic appearance, thus posing difficulty in distinguishing neuropathy from myopathy.

Being able to recognize the described pattern of clinical features, laboratory abnormalities, and electrodiagnostic findings should minimize cases requiring biopsy for diagnosis. A biopsy is helpful in cases where another myopathic process needs to be excluded or where a tissue diagnosis will change management. Typical muscle biopsy findings

TABLE 56-4 ■ Diagnostic Criteria for Critical Illness Myopathy

1. The patient is critically ill (multiorgan dysfunction and failures)
2. Limb weakness or difficulty weaning patient from ventilator after non-neuromuscular causes such as heart and lung disease have been excluded
3. CMAP amplitudes less than 80% of the lower limit of normal in two or more nerves without conduction block
4. Sensory nerve action potential amplitudes more than 80% of the lower limit of normal
5. Needle electromyography with short-duration, low-amplitude motor unit potentials with early or normal full recruitment, with or without fibrillation potentials in conscious and collaborative patients; or increased CMAP duration or reduced muscle membrane excitability on direct muscle stimulation in noncollaborative patients
6. Absence of a decremental response on repetitive nerve stimulation
7. Muscle histopathologic findings of primary myopathy (e.g., myosin loss or muscle necrosis)

Definite diagnosis of critical illness myopathy is established if all seven criteria are fulfilled. Probable diagnosis of critical illness myopathy is established if criteria 1 and 3–6 are fulfilled. Diagnosis of intensive care unit-acquired weakness is established if only criteria 1 and 2 are fulfilled. CMAP, compound muscle action potential.

Reprinted with permission from Latronico N, Bolton CF: Critical illness polyneuropathy and myopathy: a major cause of muscle weakness and paralysis. Lancet Neurol 10:931, 2011, modified from Lacomis D, Zochodne DW, Bird SJ: Critical illness myopathy. Muscle Nerve 23:1758, 2000.

in this condition include type II—predominant fiber atrophy with myofibrillar disorganization. There may be variable degrees of both necrosis and myofiber regeneration. Thick-filament myosin loss is the most characteristic feature and may be related to a decreased transcription rate or loss of myosin messenger RNA.

The underlying pathophysiology of critical illness myopathy is still being elucidated. Studies have demonstrated electrical inexcitability of muscle due to a shift in the voltage dependence of sodium channel fast inactivation similar to that seen in CIP. This process seems to be augmented by sepsis. Evidence also supports muscle perfusion deficits at the capillary level. Muscle wasting is primarily due to degradation of myofibrillar proteins, which comprise 60 to 70 percent of total muscle protein. As a consequence, there is prominent loss of myosin filaments with sarcomeric disorganization. Similar to what is seen in CIP and other organ failure during sepsis, there is muscle fiber bioenergetic failure due to mitochondrial dysfunction. Toxicity appears to be mediated by ATP depletion, intracellular antioxidant diminution, and nitric oxide production.

A paradigm shift is occurring in the rehabilitation management of patients with critical illness myopathy. New evidence supports earlier initiation of rehabilitative exercises without the previous delay until the patient was deemed clinically stable or "medically optimized." Serial muscle biopsies have shown that repeated daily passive mobilization prevents muscle atrophy. Although muscle strength is not greatly improved, early physical and occupational therapy while in the ICU improves functional independence, decreases delirium, and increases the number of ventilator-free days compared to standard care. Although the application has been relatively limited thus far, the use of a bedside ergometer for daily cycle sessions as early as possible after ICU admission improves functional exercise capacity, quadriceps muscle force, and perceived functional status.[12]

Consistent with current practice trends, paralytic agents in the mechanically ventilated patient should be limited. Furthermore, the duration of mechanical ventilation, coma, and the overall ICU and hospital stay may be reduced with a protocol of coordinated daily interruption of sedatives and interruption of mechanical ventilation with spontaneous breathing trials. With these "sedation vacation exercises," there is also improvement in 1-year survival.

THICK-FILAMENT MYOSIN LOSS

This feature has been specifically associated with the term "acute quadriplegic myopathy" and is also referred to as "myosin-deficient" myopathy. Classically, cases are seen in severe asthmatic and post-transplant patients who are intubated and mechanically ventilated after receiving high-dose corticosteroids and neuromuscular blocking agents. There may be a slight elevation in serum CK, and muscle biopsy shows selective loss of thick (myosin) filaments. Although these changes can be seen on light microscopy, they are better appreciated on electron microscopy where varying degrees of necrosis can also be seen (Fig. 56-6).

In the absence of any specific treatment, it is recommended that corticosteroids and neuromuscular

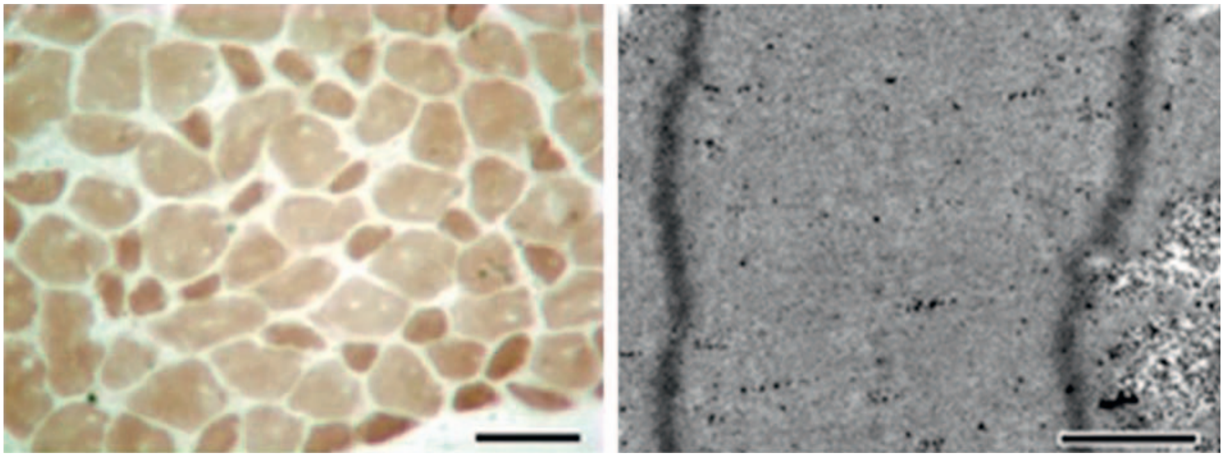

FIGURE 56-6 ■ Critical illness myopathy. (*Left*) ATPase enzyme histochemistry at pH 9.8 shows atrophy of type II (dark) fibers. Scale bar, 100 μm. (*Right*) Electron micrograph demonstrating loss of thick filaments. Scale bar, 0.5 μm. (Courtesy Susan M. Staugaitis, M.D., Ph.D., Cleveland Clinic.)

blocking agents be avoided or limited as much as possible. With recovery, there is a gradual reduction in myonecrosis and reappearance of thick myosin filaments.

RHABDOMYOLYSIS

Rhabdomyolysis is another muscle complication that can occur in the context of critical illness with corticosteroid and neuromuscular blocking agent use. It may result from many causes, presenting with myalgia, muscle tenderness, weakness, and possible swelling. It is associated with hyperkalemia and hypocalcemia, placing the patient at risk for cardiac arrhythmias. There is also a significant risk for acute renal failure, especially from marked myoglobinuria. Extensive myolysis results in serum CK levels that are frequently above 10,000 IU/L.

The electrodiagnostic findings are consistent with an acute myopathy, with motor and sensory nerve conduction studies typically being normal. The needle electrode examination usually reveals normal motor unit morphology with scant fibrillation potentials. A muscle biopsy is usually not required, but the tissue may show a variable degree of myonecrosis without inflammation or any other specific pathologic features. Rarely in bacteremic patients, muscle biopsy may confirm microabscesses (mostly seen in tropical countries or in children). With appropriate supportive therapy and treatment of the underlying condition, patients with rhabdomyolysis usually have a good functional prognosis.

ACUTE NECROTIZING MYOPATHY OF INTENSIVE CARE

This condition is considered a more “malignant” variant of rhabdomyolysis. In this subtype, there is no particular etiologic difference; however, serum CK levels are greatly elevated and there is florid myoglobinuria. Biopsy demonstrates extensively severe myonecrosis. In severe cases, the prognosis is particularly poor as significant muscle weakness may persist.

CACHECTIC MYOPATHY

This entity constitutes the weakness and atrophy related to extensive disuse or catabolic predisposition in patients with starvation and malnutrition. Patients at particular risk include those with anorexia nervosa or those following gastric bypass surgery. Cachectic myopathy is not uncommon in the ICU. The condition is characterized by normal serum CK levels and electrodiagnostic findings. The only abnormality on muscle biopsy may be type II fiber atrophy. The prognosis is quite variable and is related to the underlying disease.

Co-existing Critical Illness Polyneuropathy and Myopathy

As may be expected, the precise incidence of CIP and critical illness myopathy is difficult to ascertain because of wide variability in the study population, overlapping features, risk factors, the timing of assessment, and the diagnostic criteria used. It has been reported that in patients mechanically ventilated for 4 to 7 days or with increased risk of developing multiorgan failure, the incidence was 25 to 33 percent on clinical assessment and 30 to 58 percent with electrodiagnostic assessment.[10,11,13,14] Prospective studies have identified independent risk factors which include severity of illness, multiple (≥2) organ dysfunction, duration of vasopressor support, duration of ICU stay, hyperglycemia, female sex, renal failure and renal replacement therapy, hyperosmolality, parenteral nutrition, low serum albumin, and neurologic failure. Furthermore, aminoglycoside antibiotics, neuromuscular junction blocking agents, and corticosteroids have been implicated as risk factors in some studies.[9]

There is significant logistical difficulty in separating CIP from critical illness myopathy. Critical illness myopathy is often more challenging to diagnose since it may require more technical electrodiagnostic modalities, more sophisticated expertise, and ultimate confirmation with muscle biopsy. There is evidence to suggest that once these diagnostic methodologies are employed, critical illness myopathy is more predominant where previously mixed etiologies were diagnosed.

Nonetheless, most cases of neuromuscular weakness in the ICU may have a component of both CIP and myopathy. Accordingly, there may be overlapping clinical, laboratory, electrodiagnostic, and biopsy findings.

There is evidence that indicates that both CIP and critical illness myopathy cause limb and diaphragm weakness that persists for months or years after resolution of critical illness. Nearly one-third of patients with either or both of these conditions do not recover independent ambulation or spontaneous ventilation. CIP has been identified as the main contributor to persistent disability while critical illness myopathy is more frequently associated with complete recovery. Patients with either or both conditions are likely to benefit from fastidious treatment of infection, optimized nutrition, correction of underlying metabolic and electrolyte disturbances, deep vein thrombosis prophylaxis, chest physiotherapy and pulmonary toilet, frequent turning and pressure point padding, orthotics use, and a proactive physical therapy regimen.[15]

CONCLUDING COMMENTS

The complications of systemic inflammation in the context of critical illness affect both the central and peripheral nervous systems through a variety of mechanisms that allow inflammatory mediators among other culprits to gain access though the blood–brain or blood–nerve barrier. Optimal treatment involves early recognition and treatment of the underlying illness, with optimization of glycemic control and judicious use of corticosteroids and neuromuscular junction-blocking agents. Early mobilization and rehabilitation are proven to improve recovery time and functional independence. Electrodiagnostic tests are helpful for both diagnosis and prognostication.

CEREBRAL TRAUMA, SEIZURES, AND EPILEPSY

Seizures commonly arise in persons without epilepsy as a symptom of various general medical disorders, and they can have important implications for the treatment and prognosis of the primary disease. The occurrence and management of seizures in common medical conditions are discussed in this chapter. Attention is also directed at certain less common medical diseases in which seizures are a relatively frequent complication, and at the treatment of pre-existing epilepsy in patients with medical conditions that might complicate management. Selected therapeutic agents and recreational drugs that may cause seizures are reviewed.

Several basic points deserve emphasis. First, in persons with pre-existing epilepsy, seizures frequently worsen during an acute medical illness that typically would not result in seizures. Their occurrence may relate to a lowering of the seizure threshold by metabolic derangements, fever, impaired sleep, or other factors. Antiseizure medications (ASMs) may have to be increased, and benzodiazepines frequently are given also to prevent seizures during the acute illness. These medication changes are usually temporary and do not need to be continued.

Second, seizures provoked in persons without pre-existing epilepsy by an acute metabolic derangement or brain insult are relatively common. Such seizures do not in themselves necessitate a diagnosis of epilepsy and are termed *acute symptomatic seizures* (previously termed provoked seizures or situation-related seizures). In these patients, recognizing and treating the underlying medical illness early is imperative. Acute symptomatic seizures may occur with disorders that are transient and reversible (e.g., alcohol intoxication) or in the acute phase of an irreversible brain injury (e.g., stroke)

Aminoff's Neurology and General Medicine, Sixth Edition.

that may subsequently lead to the development of spontaneous recurrent seizures (epilepsy). Although persons experiencing acute symptomatic seizures from a brain insult may be at an increased risk for developing epilepsy in the future, this risk is clearly less than for unprovoked seizures and probably is explained by different neurophysiologic mechanisms. As a corollary, most persons with acute symptomatic seizures are started on ASMs during the acute illness, but do not require long-term ASM treatment.[1]

Finally, acute symptomatic seizures in comatose or critically ill patients can be difficult to recognize, as seizures in these patients may have only subtle or no clinical manifestations. Electroencephalography (EEG) is required in such circumstances to evaluate for seizures and to guide therapies, as discussed in a later section.

RENAL FAILURE

Seizures are common in acute uremia, typically developing between 7 and 10 days after the onset of renal failure, while the patient is anuric or oliguric. By contrast, seizures are relatively unusual in chronic renal insufficiency, and usually only occur if a significant encephalopathy is present. Risk factors for acute symptomatic seizures in renal failure include metabolic disturbances, especially hypocalcemia and hypomagnesemia, which may increase the risk for convulsive status epilepticus, and impaired renal clearance of proconvulsant medications (e.g., penicillin).

Hypertensive encephalopathy is a classic disorder associated with renal failure and blood pressure fluctuations (with the level usually exceeding 180/120 mmHg) that presents with altered mental status and headache. Generalized convulsive seizures are seen in most patients and may be the presenting symptom. Treatment is with intravenous antihypertensive medications to reduce blood pressure by 25 percent within the first hour and then to less than 160/110 mmHg by 6 hours.[2]

Hemodialysis also increases the risk for generalized convulsive seizures, usually toward the end of a hemodialysis session and for several hours thereafter, as part of the *dialysis disequilibrium syndrome.* Fluid shifts may be responsible, leading to cerebral edema from increased brain osmolality in the uremic state. Improved dialysis techniques have reduced the incidence of seizures. The dialysis encephalopathy (dementia) syndrome of myoclonus, asterixis, a distinctive speech disorder, psychiatric disturbances, and seizures due to increased aluminum levels in the brain has largely disappeared in clinical practice in response to removing aluminum from the dialysate.

Prominent myoclonus as well as asterixis (in which the hands flap due to momentary "negative" myoclonus) is often seen in renal failure. Usually, myoclonus occurs in the context of encephalopathy, and may or may not be epileptic. Cephalosporins, amlodipine, verapamil, diltiazem, and nifedipine may induce acute myoclonic jerking without convulsive seizures. Metformin in the presence of end-stage renal disease and pregabalin (frequently prescribed for diabetic neuropathic pain) may also induce myoclonus in patients receiving hemodialysis.

Use of Antiseizure Medications in Renal Disease

The treatment of seizures in renal failure requires both the correction of metabolic abnormalities and the use of ASMs. Several points regarding ASMs in renal impairment are important to remember. First, newer third- and fourth-generation ASMs tend to be cleared renally and should be used cautiously in patients with renal impairment or failure. If used, these newer ASMs usually require dose adjustments in the setting of reduced renal function. Conversely, earlier first- and second-generation ASMs do not usually require dose adjustments for renal function. However, uremic molecules may downregulate the expression of cytochrome P-450 enzymes, thereby decreasing hepatic metabolism and increasing the risks of drug toxicities for these earlier first- and second-generation ASMs that are hepatically metabolized (Table 57-1).

Second, many ASMs bind extensively to serum albumin (Table 57-1). Patients with chronic renal disease are hypoalbuminemic, so protein binding is decreased; a larger amount of free drug is therefore available to exert a pharmacologic effect. Uremic molecules may also bind to plasma proteins, displacing drugs. For these reasons, the free serum level—where available—should guide therapy.

Third, some ASMs are cleared by dialysis. As molecular size decreases, solubility increases such that the fraction removed increases. Conversely, as protein binding increases and the volume of distribution decreases, the fraction removed declines. Highly lipophilic ASMs with large volume and tissue distribution are less available for removal by dialysis. This volume is independent of renal clearance, and usually is not modified in renal impairment (Table 57-1). For this reason, ASMs that are cleared significantly by hemodialysis should be taken after the dialysis session or supplemental doses should be prescribed.

TABLE 57-1 ■ Selected Pharmacokinetics of Antiseizure Medications

		Volume of Distribution (V_d L/kg) (0.6 = V_d for H_2O)	Renal Elimination	Hepatic Metabolism	Molecular Weight (Hemodialysis More Effective if Low)
First- and Second-Generation ASMs					
Minimal or no protein binding	Ethosuximide[*]	0.6–0.7	Minimal	High	141
	Primidone	0.4–1.0	Minimal	High	218
Moderate protein binding	Phenobarbital	0.5–1.0	Minimal	High	232
High protein binding	Benzodiazepines, including Clobazam	1.4–1.8(CLZ), 1.1–3.4(DZP), 1.3(LZP)	Minimal	High	300(CLZ), 284(DZP), 321(LZP)
	Carbamazepine	0.8–2.0	Minimal	High	236
	Phenytoin	0.5–1.0	Minimal	High	252
	Valproic acid	0.14–0.23	Minimal	High	144
Third- and Fourth-Generation ASMs					
Minimal or no protein binding	Eslicarbazepine	–	Minimal	High	296
	Felbamate	0.7–1.0	Moderate	Moderate	238
	Gabapentin[*]	0.8–1.8	High	None	171
	Lacosamide	0.6	Minimal	Moderate	250
	Levetiracetam[*]	0.7	Moderate	None	170
	Pregabalin[*]	0.5	High	Minimal	159
	Rufinamide	0.7	Minimal	High	238
	Topiramate	0.6–0.8	Moderate	Moderate	339
	Vigabatrin[*]	1.1	High	None	129
Moderate protein binding	Lamotrigine	0.9–1.3	Minimal	High	256
	Oxcarbazepine[†]	0.7	Minimal	High	252
	Zonisamide	0.8–1.6	Minimal	Moderate	212
	Brivaracetam	0.5	High	High	212
High protein binding	Stiripentol[§]	3.2	Minimal	High	234
	Perampanel[¶]	1.1	Moderate	High	363

ASM, antiseizure medication; CLZ, clobazam; DZP, diazepam; LZP, lorazepam.

[*] Is not protein bound.

[†] The active metabolite 10-OH-carbamazepine is 40% bound (minimal-moderate).

[§] Approved in Europe for SMEI (Dravet syndrome).

[¶] The mean t(1/2) of perampanel is about 105 h, and steady state is achieved in 2–3 weeks; but t(1/2) increases to 305 h in mild hepatic impairment. Dosage adjustments are required in patients with mild or moderate hepatic impairment.

Data from: Israni RK, Kasbekar N, Haynes K, et al: Use of antiepileptic drugs in patients with kidney disease. Semin Dial 19:408, 2006; Diaz A, Deliz B, Benbadis SR: The use of newer antiepileptic drugs in patients with renal failure. Expert Rev Neurother 12:99, 2012; Johannessen Landmark C, Patsalos PN: Drug interactions involving the new second- and third-generation antiepileptic drugs, Expert Rev Neurother 10:119, 2010; and individual product monographs in: Micromedex® Healthcare Series [Internet database]. Thomson Reuters (Healthcare) Inc., Greenwood Village, CO. Updated periodically.

There are few data or systematic reviews on the use of third- and fourth-generation ASMs in renal failure, including patients on dialysis.[3] Data for the pharmacokinetics of individual ASMs and recommended dosing adjustments for newer ASMs are summarized in Tables 57-1 and 57-2, respectively.

HEPATIC DISEASE

Seizures are relatively uncommon in patients with acute hepatic encephalopathy, if seizures related to alcohol withdrawal are excluded. Either focal or generalized seizures may occur, usually in severe hepatic

TABLE 57-2 ■ Dose Adjustments for Selected Newer Antiseizure Medications in Renal Disease

	ASM Dose				
	GFR 60–90 mL/min	**GFR 30–60 mL/min**	**GFR 15–30 mL/min**	**GFR ≤15 mL/min**	**Hemodialysis**
Third- and Fourth-Generation ASMs					
Gabapentin	300–1,200 mg t.i.d	200–700 mg b.i.d	200–700 mg/day	100–300 mg/day	Plus 125–350 mg after HD
Levetiracetam	500–1,000 mg b.i.d	250–750 mg b.i.d	250–500 mg b.i.d	500–1,000 mg/day	Plus 250–500 mg after HD
Topiramate	50% decrease for ≤70 mL/min	50% decrease	50% decrease		Plus 50–100 mg after HD
Zonisamide	100–400 mg/day	100–400 mg/day			
Oxcarbazepine	300–600 mg b.i.d	300–600 mg b.i.d	300 mg/day (starting dose)		
Felbamate	None	50% decrease			
Lamotrigine*	None	None	None	None	
Brivaracetam	None	None	None	None	Not recommended (not studied)
Vigabatrin	25% decrease	50% decrease	75% decrease		
Rufinamide	None	None	None		Plus 30% of dose after HD
Lacosamide	None	None	300 mg/day		Plus ≤50% replacement dose
Perampanel	None	Close monitoring	Not recommended		Not recommended (not studied)
Eslicarbazepine	None	400–600 mg/day	400–600 mg/day		
Clobazam	None	None	None		None
Pregabalin	None	50% decrease	25–150 mg/day	25–75 mg/day	Plus 25–150 mg after HD

*The product monograph for Lamictal XR recommends reduced maintenance doses in patients with significant renal impairment, and caution in patients with severe renal impairment. Lamotrigine pharmacokinetics were essentially unchanged in a study comparing 10 subjects with renal failure (estimated creatine clearance of 10 to 25 mL/min) to 11 healthy subjects (Wootton R, Soul-Lawton J, Rolan PE, et al: Comparison of the pharmacokinetics of lamotrigine in patients with chronic renal failure and healthy volunteers. Br J Clin Pharmacol 43:23, 1997).

Blanks indicate inadequate data, and individual ASMs should be used with caution or avoided in these circumstances. "None" indicates that no change in dose is recommended.

ASM, antiseizure medication; b.i.d, two times daily; t.i.d, three times daily.

Data from: Israni RK, Kasbekar N, Haynes K. et al.: Use of antiepileptic drugs in patients with kidney disease. Semin. Dial. 19:408, 2006; Diaz A, Deliz B, Benbadis SR: The use of newer antiepileptic drugs in patients with renal failure. Expert Rev. Neurother. 12:99, 2012; and individual product monographs in: Micromedex® Healthcare Series [Internet database]. Thomson Reuters (Healthcare) Inc., Greenwood Village, CO. (Updated periodically.)

encephalopathy. Treatment involves management of the hepatic dysfunction and hepatic encephalopathy.

Chronic liver disease does not usually cause convulsions. The occurrence of seizures in alcoholics with hepatic cirrhosis is usually related to alcohol withdrawal. Seizures are common in Reye syndrome and rare in Wilson disease. Convulsions in patients with acute hepatic necrosis are frequently associated with severe hypoglycemia. In these patients, ASM therapy often is not required except when an underlying cause of epilepsy (e.g., prior trauma in an alcoholic) is present.

Antiseizure Medications and Hepatic Injury

Gabapentin, vigabatrin, and levetiracetam are the only ASMs not hepatically metabolized. Certain ASMs, including selected newer agents, undergo extensive hepatic metabolism (Table 57-1), but unless hepatic dysfunction is severe its effects on their pharmacokinetics are difficult to predict. Barbiturates, and benzodiazepines, as well as other central nervous system (CNS) depressants, may unmask hepatic encephalopathy in patients with compensated liver disease, and are relatively contraindicated. Valproic acid is potentially hepatotoxic and should be used with care in patients with pre-existing liver disease. The free fraction of highly protein-bound ASMs may increase due to hypoalbuminemia, and (as for renal impairment) the free serum level—where available—should guide therapy.

In persons without hepatic disease, ASMs may cause drug-induced hepatic injury. In most cases, these reactions are reversible by stopping the ASM but, occasionally, acute hepatic failure may necessitate transplantation. ASMs (as a class) were the third most-common cause (phenytoin, $n = 10$; valproic acid, $n = 10$) of acute drug-induced liver failure requiring liver transplantation in the United States between 1990 and 2002 ($n = 270$).

Overall, the incidence of clinically important hepatotoxicity seems less for third- and fourth-generation ASMs than for older ASMs, but cases of severe hepatotoxicity have been reported for newer ASMs, including lamotrigine, levetiracetam, gabapentin, pregabalin, and oxcarbazepine. Felbamate specifically has been associated with multiple cases of aplastic anemia and acute liver failure, and has a “black box warning” label that restricts its use.

Two types of hepatic injury by ASMs are described. First, ASMs may induce one of several systemic immune-mediated drug hypersensitivity syndromes that may cause hepatic injury and are potentially life-threatening. These syndromes are characterized by fever, rash, and increased serum levels of aminotransferases several weeks after starting an ASM. The risk for these hypersensitivity reactions is highest for first- and second-generation ASMs, and is estimated to be 1 to 10 per 10,000 for phenytoin, carbamazepine, and phenobarbital, but also for lamotrigine (third-generation).[4] For carbamazepine specifically, the *HLA-B* 15:02* allele is strongly associated with Stevens–Johnson syndrome/toxic epidermal necrolysis in Southeast Asia. For this reason, the U.S. Food and Drug Administration (FDA)–approved drug label for carbamazepine now recommends testing for *HLA-B* 15:02* for all patients with ancestry in populations having an increased frequency of *HLA-B* 15:02*, prior to initiating carbamazepine therapy.

Second, first- and second-generation ASMs may cause hepatic injury as a direct effect of hepatic metabolism, and not as a systemic hypersensitivity syndrome. This is a concern specifically for felbamate and (especially in children) valproic acid.[5] For valproic acid, the risk for hepatic injury in young children less than 2 years old and on multiple ASMs is as high as 1 in 800, and the drug is relatively contraindicated in this population. In adults and children, hyperammonemia may be seen with normal liver function tests in the majority of persons on valproic acid, usually with no associated clinical symptoms. Topiramate may increase this risk of hyperammonemic encephalopathy and hepatic injury from valproic acid.

Cannabidiols (CBD) derived from *Cannabis sativa* have become very popular in recent years for a variety of conditions, particularly pain. In June 2018, the first CBD-based drug, Epidiolex, was approved by the FDA for treatment of selected severe epilepsy syndromes (Dravet and Lennox–Gastaut syndromes). In the trials on which approval was based, CBD was associated with elevated serum levels of aminotransferases. Except for Epidiolex, CBD products are not regulated and the risks for hepatic injury are unclear.

CARDIAC DISEASE

Epidemiologic studies have consistently shown that people with epilepsy have a higher prevalence of structural cardiac disease than those without epilepsy, possibly reflecting shared genetic risk factors that affect the heart and brain. Cardiovascular disease also seems to be a significant contributor to the increased mortality of people with epilepsy, compared with the general population. As a group, patients with epilepsy have lower heart rate variability than normal, a finding that predicts arrhythmias and mortality in cardiac patients but is of uncertain significance in epilepsy.

Cardiac disease may also cause epilepsy indirectly due to stroke or from global cerebral ischemia after cardiac arrest. Stroke accounts for about one-third of newly diagnosed seizures in people over the age of 60 years.

The use of first- and second-generation ASMs may also increase cardiovascular disease risks in persons with epilepsy. The enzyme-inducing ASMs phenytoin or carbamazepine may lead to elevated serologic vascular risk markers (e.g., total cholesterol, low-density lipoproteins, homocysteine) and atherosclerosis. Some first- and second-generation ASMs (e.g., valproic acid, carbamazepine) cause weight gain and may increase the risk of developing nonalcoholic fatty liver disease and metabolic syndrome.

Use of Antiseizure Medications in Cardiac Disease

Cardiovascular disease and epilepsy may co-exist, especially in the elderly, persons with congenital cardiac disease, and persons with alcohol and polysubstance use. This complicates treatment of acute seizures and status epilepticus. Intravenous benzodiazepines may cause hypotension in medically ill or elderly patients. Rapid intravenous administration of phenytoin may cause sinus arrest and hypotension; fosphenytoin, a water-soluble prodrug of phenytoin that does not require propylene glycol as a diluent, is generally preferred for treating status epilepticus as its infusion rate is faster and there is a lesser risk of arrhythmia than with phenytoin. In these patient populations, valproic acid, levetiracetam, or lacosamide are preferred if fosphenytoin is not available.

Various cardiac arrhythmias have been described in persons with epilepsy, including ictal asystole (usually self-limiting), postictal asystole (not self-limiting), ventricular tachycardia/ventricular fibrillation, bradycardia, and atrioventricular block. In some epilepsies, these abnormalities may reflect genetic ion channel mutations expressed in the brain as well as in the heart, and may in part explain the increased risk for sudden unexplained death in epilepsy (SUDEP). The most recognized example of this is Dravet syndrome, a severe epilepsy syndrome with high premature mortality, caused by an *SCN1A* mutation. Biomarkers associated with the risk of sudden cardiac death (e.g., decreased heart rate variability) have been found in patients with this syndrome. In mutant *SCN1A* knock-out mice, postictal bradycardia and seizure-triggered ventricular fibrillation have been recorded before a death resembling SUDEP.[6]

ASMs that affect sodium channels may influence cardiac excitability and conduction, but clinically relevant arrhythmias are usually related to ASM overdose. Long-term ASM use has been associated only rarely with significant cardiovascular complications. A prolonged PR interval is seen in patients on lacosamide and carbamazepine. Symptomatic arrhythmias have been reported in patients receiving lacosamide and carbamazepine in therapeutic dosages, but underlying cardiac abnormalities or the use of multiple sodium channel-blocking ASMs usually (but not always) have been present. Shortening of the QT interval is seen in patients on rufinamide. Routine electrocardiograms should be considered in all patients started on these ASMs and in all patients with pre-existing cardiac arrhythmias.[7]

Anticonvulsant agents may also interact with certain cardiac medications. The concomitant use of phenytoin and quinidine may increase ectopy in patients with ventricular arrhythmias. The metabolism of quinidine, digoxin, lidocaine, and mexiletine may be increased by phenytoin and phenobarbital because of induction of hepatic microsomal enzymes. Amiodarone increases phenytoin levels, and calcium-channel blocking agents, such as verapamil, may increase serum carbamazepine concentrations. For these reasons, serum ASM levels and cardiovascular function should be followed closely when either antiseizure or cardiac medications are introduced or altered.

SEIZURES IN CRITICALLY ILL PATIENTS

Nonconvulsive Seizures and Status Epilepticus

Acute symptomatic seizures in patients who are critically ill are detected typically on continuous EEG monitoring, may have subtle or no clinical signs, and are probably under-recognized. The published incidence of seizures in critically ill patients is highly variable but is nonetheless impressive, ranging from 8 percent to as high as 48 percent in various studies. The possibility of nonconvulsive seizures and status epilepticus should be suspected in any critically ill patient with altered mental status of unknown cause. Subtle motor activity, such as rhythmic twitching of the fingers or eye movements, should raise suspicion of seizure activity in this setting. Diagnosis depends on the EEG findings. Prompt recognition and treatment are essential because delay is associated with a poor outcome.

Continuous EEG monitoring of brain function in critically ill patients usually includes simultaneous video recording and quantitative analysis of EEG trends (Fig. 57-1). The guideline recommendation of the American Clinical Neurophysiology Society for recording for at least 24 to 48 hours using continuous EEG enables the identification of 80 to 95 percent of patients with nonconvulsive seizures.[8] Monitoring should be initiated as soon as possible when nonconvulsive seizures are suspected, and is required in newly admitted critically ill patients with altered mental status and observed seizures.

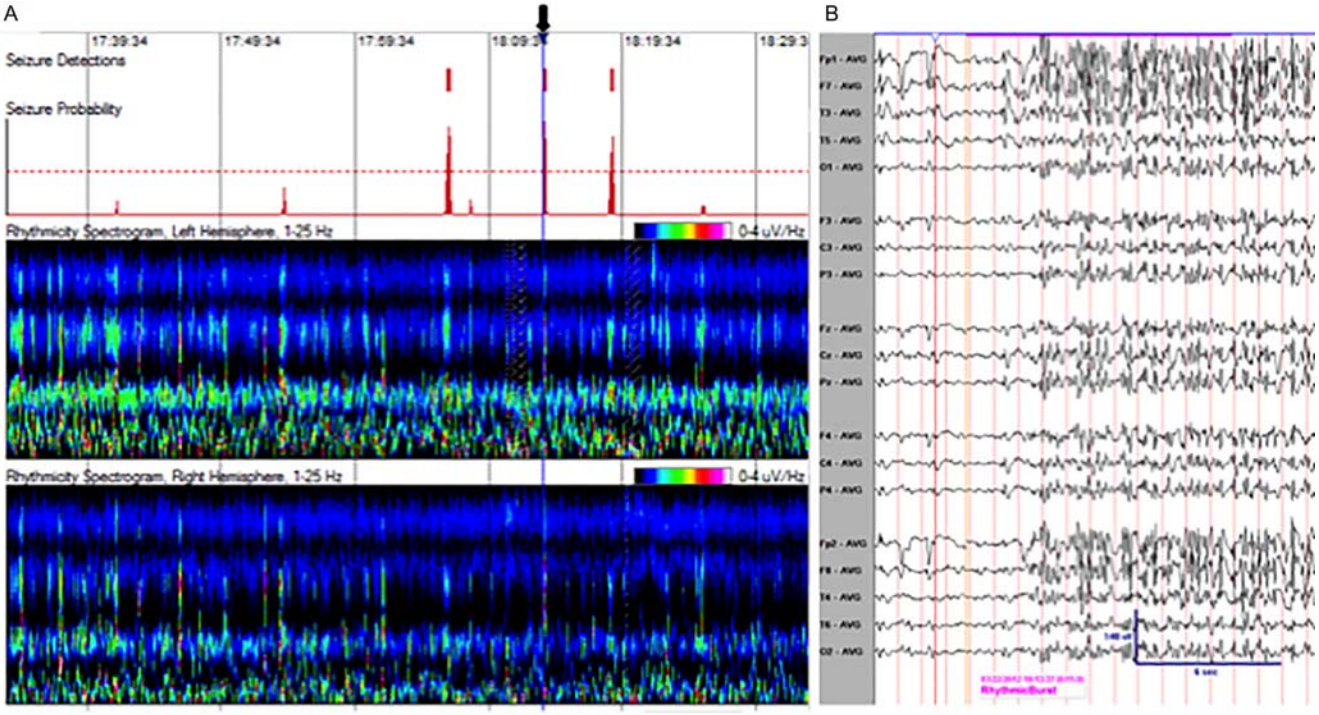

FIGURE 57-1 ■ *A*, Quantitative EEG. EEG for 1 h in a young man intubated for respiratory failure with symptomatic generalized epilepsy and subtle tonic seizures. The upper two panels use a proprietary algorithm to calculate the probability of seizures over time (Persyst seizure detection, Persyst Corporation, San Diego, CA). The lower two panels show time along the *x*-axis, frequency on the *y*-axis (0–25 Hz) and EEG on a color scale. Most power is in the delta range for most of the tracing. There is an asymmetry in faster frequencies, increased over the left hemisphere. Intermittent bursts of power in higher frequencies represent brief electrographic seizures, with subtle or no clinical correlate on video. *B*, EEG recorded using an average reference and corresponding to the arrow in *A*.

Treatment of Seizures in Critically Ill Patients

When evaluating the causes of seizures in critically ill patients, various metabolic derangements must be considered; if detected, therapy is directed at their correction. The electrolyte abnormalities contributing most frequently to seizures are reviewed in a later section. Reversible causes, such as medications (or acute withdrawal of them, including anticonvulsants, benzodiazepines, and barbiturates) and substance abuse are important (Table 57-3).

When ASM treatment is necessary, the increased potential for complex drug interactions in patients receiving numerous other medications and the possibility of altered pharmacokinetics (e.g., due to renal or hepatic impairment) and of adverse systemic effects must be considered. For example, in hypoalbuminemic patients, it may be necessary to monitor free drug levels when using a first- or second-generation ASM (e.g., phenytoin) that exhibits significant serum protein binding. Many first- or second-generation ASMs that are inhibitors or inducers of certain metabolic enzymes may also affect the serum concentration of other medications taken concurrently.

Ideally, ASMs should initially be administered parenterally as loading doses to attain therapeutic serum concentrations, especially in patients with gastrointestinal dysfunction, so limiting the selection of ASMs to those with intravenous formulations.

The use of continuous renal replacement therapy (CRRT) in critically ill patients complicates the use of the third- and fourth-generation ASMs, as most of these are cleared renally. There are as yet no data available for ASM dosing in patients on CRRT. For this reason, ASMs with readily measured serum levels are preferred to guide dosing in patients on CRRT. In general, an ASM that is eliminated renally or affected by dialysis will be removed using CRRT, but the degree of removal will depend largely on the replacement parameters and the specific ASM.

The use of extracorporeal membrane oxygenation (ECMO) is also increasing in critically ill patients, but as for CRRT, no data are available for evaluating specific ASM dosing. The biggest impact of ECMO on drug

TABLE 57-3 ■ Common Medications That May Lower Seizure Threshold

Class	Examples	Notes
Antimicrobials		
β-Lactams	Penicillins, cephalosporins, carbapenems	β-Lactams interact with the $GABA_A$ receptors, interfering with inhibitory effects of GABA in a concentration-dependent manner.
Antituberculous agents	Isoniazid	Isoniazid inhibits pyridoxine phosphokinase, the enzyme that converts pyridoxine for the synthesis of GABA from glutamate, reducing GABA. Give pyridoxine and benzodiazepine.
Antimalarials	Mefloquine, chloroquine	
Fluoroquinolones	Ciprofloxacin	May inhibit the $GABA_A$ receptor; seizures are rare but have been reported.
Analgesics		
Opioids	Morphine, tramadol, codeine, fentanyl	All opioids appear capable of lowering the seizure threshold.
Methylxanthines	Theophylline, aminophylline	Interacts with adenosine A1-receptor; also interferes with activity of BZD.
Antipsychotics	Clozapine (and to a lesser extent, other antipsychotics including risperidone, olanzapine)	Seizures affect 3–6% of clozapine-treated patients.
Antidepressants	Buproprion	A recent systematic review found no evidence for an increase in seizure frequency with other classes of antidepressants. Seizures may be seen in toxicity with other antidepressants.
Antiseizure medications	All	Most can induce paradoxical seizures in overdose; carbamazepine and oxcarbamazepine can exacerbate generalized epilepsies. Stopping them without taper seems invariably to lower seizure threshold.

BZD, benzodiazepines; GABA, γ-aminobutyric acid.
Adapted from Hitchings AW: Drugs that lower the seizure threshold. Adverse Drug React Bull 298:1151, 2016.

dosing lies in the propensity for the ECMO circuit to sequester drugs, resulting in a larger than expected volume of distribution. This phenomenon may decrease over time with continued dosing due to saturation of binding sites. In general, medications with higher volumes of distribution/lipophilicity and higher protein binding tend to be sequestered more. Patients on ECMO frequently receive concomitant CRRT, further complicating dosing. For these reasons, ASMs that have readily available serum levels are strongly preferred.

Seizures Caused by Anoxic-Ischemic Encephalopathy

A high proportion of patients who have been resuscitated after a cardiac arrest go on to develop seizures due to global anoxic-ischemic cerebral injury. Seizures typically commence within 24 hours of cardiopulmonary arrest and may consist of generalized tonic-clonic, tonic, myoclonic, or partial seizures, as well as tonic-clonic or myoclonic status epilepticus. Electrographic status epilepticus with restricted clinical manifestations (usually limited to extraocular or facial muscles) is also well described after cardiopulmonary arrest, occurring in 12 to 22 percent of patients, but may be difficult to recognize.

Published guidelines have emphasized the importance of neurocritical care for patients with brain injury after cardiac arrest, including EEG monitoring for the detection and treatment of seizures.[9] Certain EEG patterns are associated with poor outcome. Thus, generalized background suppression to 20 μV, a burst-suppression pattern with generalized epileptiform activity, or generalized periodic complexes on a flat background are strongly but not invariably associated with poor outcome.[10]

The occurrence of focal seizures or even of generalized tonic-clonic status epilepticus does not determine the eventual clinical outcome of patients in postanoxic coma. By contrast, myoclonic status epilepticus (defined as spontaneous, repetitive, unrelenting, generalized multifocal myoclonus in comatose patients) seems invariably associated with poor outcome and may well represent a marker of severe anoxic-ischemic brain injury. Although hypothermia has antiseizure effects, seizures in resuscitated patients after cardiac arrest may occur during therapeutic hypothermia and, in many patients with nonconvulsive status epilepticus, seizures first appear on EEG during therapeutic hypothermia.

The available evidence does not support the use of prophylactic ASMs in these patients. The same ASMs used for the treatment of status epilepticus from other causes may be considered for seizures and status epilepticus after cardiac arrest, but bearing in mind the potential cardiac effects of selected ASMs reviewed earlier. The neurologic complications of anoxic-ischemic encephalopathy are reviewed in detail in Chapter 9.

INFLAMMATORY AND AUTOIMMUNE DISEASES AND EPILEPSY

Limbic Encephalitis

Limbic encephalitis is the prototype for an autoimmune disease presenting with acute neurologic symptoms, including seizures. Clinical features include the subacute onset of impaired short-term memory, confusion, hallucinations, and sleep disturbances; patients are anxious, irritable, or paranoid. Seizures are not always the presenting symptom but are seen in nearly all cases during the acute or early stages of the illness. They usually do not respond to ASMs. Diagnosis is by autoantibodies to intracellular antigens or extracellular (cell surface) antigens involved in synaptic transmission (Table 57-4). Paraneoplastic etiologies for limbic encephalitis must be excluded. These syndromes are discussed in detail in Chapter 27.

TABLE 57-4 ■ Antigens for Autoantibodies Associated With Seizures

Intracellular Antigens
ANNA-1, CRMP-5, GAD65, Ma-2
Extracellular Antigens (Cell Surface or Synapse)
AMPA receptor, $GABA_B$ receptor, ganglionic ACh receptor, NMDA receptor, VGKC complex (Caspr2, Lgi1)

ACh, acetylcholine; ANNA-1, antineuronal nuclear antibody-type 1; Caspr2, contactin-associated protein-like 2; CRMP-5, collapsing response-mediator protein 5; $GABA_B$, γ-aminobutyric acid subtype B; GAD65, glutamic acid decarboxylase 65; Lgi1, leucine-rich glioma inactivated 1; NMDA, N-methyl-D-aspartate; VGKC, voltage-gated potassium channel antibody.

Selected autoimmune encephalopathies have characteristic clinical or EEG features that are helpful to recognize. Faciobrachial dystonic seizures are brief (1 to 2 seconds) motor seizures, affecting the limbs and face, that can occur over 100 times per day, do not have an EEG correlate, and typically precede the development of anti-LGI1 encephalitis (i.e., encephalitis with antibodies to leucine-rich glioma inactivated 1). Patients with anti-NMDA (N-methyl-D-aspartate) receptor encephalitis may have a unique EEG pattern termed "extreme delta brush" because of its resemblance to waveforms seen in premature infants.

In the majority ($>70\%$) of patients with limbic encephalitis the associated seizures are successfully treated with immunotherapy and ASMs acutely, and most do not require chronic antiseizure therapy. The risk for developing epilepsy in these patients appears low (10 to 15%) and is dependent on the antigen. Disorders with antibodies to cell membrane antigens (VGKC, NMDA-R, AMPA-R, and GABA) tend to be less severe and complete recovery is possible. Conversely, patients with antibodies to an intracellular antigen (e.g., GAD65) frequently develop epilepsy and have a suboptimal response to treatment.

Connective Tissue Diseases and Cerebral Vasculitis

The connective tissue diseases are discussed in detail in Chapter 50. Of these, systemic lupus erythematosus (SLE) probably has the highest incidence of neuropsychiatric symptoms. Seizures are frequent both at the time of diagnosis and during disease flares, seen in 40 to 85 percent of persons with SLE. The prevalence of epilepsy in the SLE population is also increased, variably reported in larger series from 3 to 29 percent.[11] Neuropsychiatric manifestations imply a poorer prognosis for SLE than otherwise, but the presence of seizures or psychosis without other neurologic features or significant renal disease does not reduce survival.

Seizures in SLE may be due to a hypertensive or metabolic encephalopathy, especially in the context of lupus nephritis and uremia (discussed earlier) or as a complication of immunosuppressive therapy (discussed in the next section on seizures in transplant patients). Seizures in SLE may also reflect direct brain involvement by various antibodies that have been implicated in the pathogenesis of neuropsychiatric SLE. Of these, antiphospholipid antibodies are important as these may have a direct neuromodulatory effect. The frequency of seizures and epilepsy may correlate with the presence of these antibodies, although this is not clear. Cerebral microinfarcts and, less often, subarachnoid and intracerebral hemorrhages are found on pathologic examination and may relate to an immunologically mediated vasculopathy.

Treatment of CNS lupus is discussed in Chapter 50. ASMs are frequently started for a limited period (e.g., 3 months) while immunosuppression is used to treat the SLE flare. Drug-induced lupus may occur with various ASMs (including phenytoin, carbamazepine, valproic acid, and lamotrigine), but there is no evidence that ASMs exacerbate idiopathic SLE.

Cerebral vasculitis or vasculopathy from other causes may lead to seizures. Antiphospholipid antibody syndrome may occur without SLE. In Sjögren or Behçet syndrome, convulsions may be associated with a flare of disease activity. Seizures rarely are described due to cerebral involvement in rheumatoid arthritis, scleroderma, or mixed connective tissue disease. The one exception to this is linear scleroderma with hemifacial atrophy of the face, or Parry–Romberg syndrome, in which intractable epilepsy can be part of the spectrum of disease.

Thyroid Disease and Hashimoto Encephalopathy

Hashimoto encephalopathy is a relapsing encephalopathy occurring in association with Hashimoto thyroiditis, with high titers of antithyroid peroxidase antibodies, antithyroid microsomal antibodies, and antithyroglobulin antibodies. Thyroid hormone levels are usually decreased, but 30 percent of persons may be euthyroid or hyperthyroid. Seizures occur in the majority of these patients. A subset of patients responds to intravenous methylprednisolone (termed steroid-responsive encephalopathy associated with autoimmune thyroiditis, or SREAT). ASMs are required to treat seizures acutely; seizures tend to remit as the encephalopathy improves. The disorder is discussed in detail in Chapter 18.

Inflammatory Bowel Disease

Both ulcerative colitis and Crohn disease are chronic relapsing inflammatory diseases of the gut. They are associated with neurologic and systemic complications, possibly including an increased incidence of epilepsy—but this is not quite clear. The epidemiologic association of celiac disease with epilepsy is clearer, seen in between 3.5 and 5.5 percent of patients with celiac disease.

Diabetes and GAD65 Antibodies

Antibodies to glutamic acid decarboxylase 65-kDa isoform (GAD65) have been found in 2 to 3 percent of adults and 6 to 7 percent of children with chronic epilepsy. GAD65 antibodies also occur in 80 percent of patients with type 1 diabetes (and interestingly, epilepsy is increased in this population compared with controls). Very high titers of GAD65 antibodies are seen in patients with seizures in the context of limbic encephalitis. Compared with GAD65 antibodies in epilepsy or in patients with diabetes, patients with limbic encephalitis have substantially higher titers of serum antibodies (~100 to 1,000 times higher), and the antibodies are detectable in CSF. Patients with epilepsy and GAD65 antibodies show a poor response to immunotherapy and tend to be refractory to medical treatment.

Multiple Sclerosis and Other Demyelinating Diseases

Seizures are occasionally the first presentation of multiple sclerosis. The incidence of seizures in multiple sclerosis is quite low, but varies in different series to as high as 8 percent. One-third of seizures occur in the context of an acute flare of the disease and occasionally present as focal status epilepticus. Seizures usually stop with disease remission. The reason for the occurrence of seizures (a cortical disturbance) in demyelinating disease is not clear, but specialized magnetic resonance imaging sequences demonstrate intracortical lesions in patients with seizures.

Seizures also occur in 11 to 43 percent of patients with acute disseminated encephalomyelitis. Antibodies against myelin oligodendrocyte glycoprotein have been identified in about 40 percent of these patients, but such antibodies are also found in other demyelinating disorders (including clinically isolated syndromes) that do not manifest with seizures. There is no information about the risk of developing epilepsy in these patients.

HEPATIC PORPHYRIAS

Porphyrias are named from the Greek word *porphura*, meaning purple, and this refers to the discoloration of the urine that may be seen due to red and purple pigments produced in these disorders. Porphyrias are caused by deficiencies in enzymes of the heme biosynthetic pathway that lead to the accumulation of heme precursors (porphyrins). The inherited conditions are classified into the acute porphyrias (hepatic porphyrias) and cutaneous (erythropoietic) porphyrias, reflecting the location of the accumulation of porphyrins. Three of the acute porphyrias may present with epilepsy and neuropsychiatric symptoms: acute intermittent porphyria (AIP), hereditary coproporphyria, and variegate porphyria.

AIP is the most common hepatic porphyria, and the most commonly associated with seizures and epilepsy. The clinical features of variegate porphyria are identical to AIP, except for cutaneous photosensitivity that is seen in 30 percent. Persons are asymptomatic until exposed to circumstances that demonstrate the deficiency, including infection, hormonal cycles, diet, and medications. The classic symptoms are due to an acute neuropathy and evolve over hours or days. They include abdominal pain, nausea, vomiting, weakness, and severe neuropathic pain. Laboratory studies demonstrate increased δ-aminolevulinic acid (ALA), and porphobilinogen (PBG) in the urine.

Encephalopathy, coma, or seizures are seen in 5 to 20 percent of persons during acute attacks and may be the presenting feature in AIP. These seizures may reflect a direct neurologic effect of ALA binding to GABA receptors. Defects in hepatic heme synthesis may alter brain levels of neurotransmitters. Seizures may also be symptomatic of metabolic disturbances from excessive vomiting or inappropriate secretion of antidiuretic hormone.

All the enzyme-inducing ASMs, valproic acid, and benzodiazepines may exacerbate or precipitate attacks by stimulating hepatic ALA synthase activity, and ideally these drugs should be avoided. Experimental studies suggest that lamotrigine, felbamate, and topiramate may also exacerbate hepatic porphyrias. These studies are supported clinically in the case of lamotrigine. Gabapentin, pregabalin, and levetiracetam are probably safe and have been used successfully. The use of intravenous benzodiazepines also seems relatively safe despite evidence that they may be porphyrinogenic. If seizures are medically refractory, magnesium sulfate (a noncompetitive NMDA receptor antagonist that may enhance the effect of ASMs) may be used intravenously as an ASM to keep serum magnesium concentrations between 2.5 and 7.5 mmol/L. Urine ALA and PBG levels must be monitored closely during therapy.

SEIZURES IN TRANSPLANT RECIPIENTS

The neurologic complications of organ transplantation are summarized in Chapter 44. Transplant recipients are at high risk for seizures that may relate to their underlying illness, irradiation, or chemotherapy, and to perioperative metabolic abnormalities or complications such as cerebral ischemia. After surgery, the effects of immunosuppression, therapeutic agents, and rejection are also important causes.

Immunosuppressive agents, especially cyclosporine, have been associated with seizures. These may occur with serum levels of cyclosporine within or exceeding the therapeutic range and may relate to a cyclosporine metabolite. Other immunosuppressive agents may also cause post-transplantation seizures. Tacrolimus (FK506) has neurologic complications similar to cyclosporine, including seizures and encephalopathy. The antirejection agent muromonab-CD3 (OKT3) can cause seizures as part of a cytokine encephalopathy. Sirolimus (rapamycin), one of the newer immunosuppressive agents, did not cause seizures or other neurotoxicity in at least one series consisting of kidney and liver transplant recipients. In bone marrow recipients, busulfan, either alone or in combination with cyclophosphamide, may cause seizures.

Seizures may also result from CNS infections or other brain insults (e.g., stroke or cerebral hemorrhage), or from metabolic abnormalities including hyponatremia, hyperosmolar states, hypoglycemia, or multiorgan system failure. Finally, transplant rejection may lead to an encephalopathy syndrome that includes seizures, sometimes as the first manifestation of rejection.

Options for ASMs in transplant recipients are constrained by the type of transplantation procedure undergone by the patient and the immunosuppressive drugs in use. Valproic acid is contraindicated in liver recipients because of its potential hepatotoxicity. Carbamazepine should not be used in bone marrow recipients because it may cause myelosuppression. Bone marrow engraftment occurs 2 to 6 weeks after transplantation, and phenytoin, phenobarbital, and valproic acid are best avoided over this period in favor of a newer ASM. The enzyme-inducing first- and second-generation ASMs may affect the metabolism of immunosuppressive agents. Thus, the clearance of cyclosporine and corticosteroids is increased by phenobarbital, phenytoin, and carbamazepine, necessitating increased dosages of corticosteroids by 25 to 30 percent and of cyclosporine depending on serum cyclosporine levels.

Levetiracetam does not appear to influence immunosuppressive drug levels and is not hepatically metabolized. There seems to be a consensus that levetiracetam is a good initial choice for ASM therapy in all transplant populations. Gabapentin may also be a reasonable choice in liver transplant recipients (not hepatically metabolized), but in practice is not used.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND SEIZURES

Seizures occur in perhaps 10 percent of persons infected with human immunodeficiency virus (HIV). They may occur at any stage of HIV infection or acquired immunodeficiency syndrome (AIDS) and are sometimes the presenting symptom of HIV infection. Involvement of the nervous system is present at autopsy in 85 percent of persons with HIV infection. The introduction of combination antiretroviral therapy using protease inhibitors has reduced brain involvement by opportunistic infections in these autopsy series, but also corresponds to an increase in HIV encephalopathy of from 34 to 60 percent, perhaps reflecting the dramatic improvement of survival in patients with HIV infection. Variants of HIV encephalitis with intense perivascular inflammation have also emerged, presumably due to an exaggerated response from a reconstituted immune system.

In nearly half of patients with HIV/AIDS and seizures, no cause except HIV infection is found and in these persons direct cerebral HIV infection seems the correct explanation. Other important CNS disorders that may be responsible and are associated with HIV/AIDS include CNS toxoplasmosis, cryptococcal meningitis, neurotuberculosis, progressive multifocal leukoencephalopathy, and CNS lymphoma. Systemic illness, alcohol or drug use (especially cocaine), and even antiretroviral agents are also important causes of acute symptomatic seizures. A detailed diagnostic evaluation is therefore required when HIV-infected patients experience the new onset of seizures.

The risk for subsequent seizures following a first one is relatively high in HIV-infected persons, and for this reason ASMs are usually started following a first seizure. The use of newer ASMs that do not induce hepatic enzymes is preferable as first-line therapy. On balance, the older enzyme-inducing antiepileptic agents are best avoided in patients with HIV/AIDS due to concern for drug–drug interactions. For example, phenytoin interacts with protease inhibitors, affecting viral load, and may cause intoxication in patients treated concurrently with fluconazole, commonly prescribed in AIDS patients.

SEIZURES ASSOCIATED WITH SYSTEMIC CANCER

Seizures are a relatively common neurologic complication of systemic cancer in children and adults. Different potential etiologies must be considered when seizures occur in this context. First, seizures may be due to direct brain effects including CNS metastasis in 10 to 20 percent of persons with systemic cancer. Metastases are especially frequent for melanoma, lung, breast, renal cell, gastrointestinal, and germ cell tumors, as well as when leptomeningeal seeding occurs by malignant tumor cells (carcinomatous meningitis). Guidelines for the treatment of patients with single metastatic lesions recommend surgery (if possible) followed by whole-brain radiation therapy.[12] In patients operated for CNS metastases but who have never had seizures, ASMs are recommended perioperatively for 7 days only (levetiracetam is preferred for this by neurosurgical services) and then discontinued.

Second, seizures may be symptomatic of an associated diagnosis or condition occurring as a consequence of the systemic cancer. Examples include stroke due to hypercoagulable states or nonbacterial thrombotic endocarditis. CNS infections, including fungal or parasitic abscesses, may result from immunosuppression after chemotherapy and produce seizures.

Third, seizures are an uncommon but described complication of chemotherapy, including etoposide, L-asparaginase, alkylating agents such as chlorambucil or busulfan, immunotherapies, methotrexate, and cytosine arabinoside.

Fourth, acute seizures may be secondary to cancer-related metabolic disturbances, paraneoplastic encephalitis, or drugs used to treat complications, such as pain medications and antibiotics.

In patients who have had a seizure and are considered to be at increased risk for future seizures, ASMs should be started. There are no specific recommendations regarding the type of ASM, dose, or length of therapy.[13] Chemotherapy used to treat systemic cancers may complicate the selection of an ASM. For example, corticosteroids are indicated for patients with symptoms secondary to elevated intracranial pressure. Phenobarbital and phenytoin shorten the half-life of corticosteroids, and increased or decreased serum concentrations of phenytoin have been described in patients receiving corticosteroids. A second concern is that many chemotherapeutic agents undergo hepatic metabolism or induce or interfere with hepatic enzymes. Consequently, first- and second-generation ASMs that induce hepatic enzymes may lower the effectiveness of cancer chemotherapy. Because of the potential for drug–drug interactions, ASMs that do not induce hepatic enzymes, including levetiracetam, gabapentin, pregabalin, or lacosamide, are preferred in individuals undergoing cancer chemotherapy.

ENDOCRINE OR METABOLIC DISORDERS

Disorders of Glucose Metabolism

Abnormal glucose levels, whether too high or too low, can cause seizures. Experimental studies suggest that a threshold glucose concentration is necessary to support synaptic transmission and that elevated extracellular glucose levels are associated with neuronal hyperexcitability. The problem is especially pertinent to individuals with diabetes, whose blood glucose levels can fluctuate widely over the course of a day as a result of intercurrent illness, variations in insulin levels, or other metabolic factors.

Hypoglycemia must be considered and excluded as a possible cause in any patient with seizures. It is treated by intravenous administration of dextrose and correction of any other metabolic abnormalities. Patients usually do well but are best hospitalized for observation because hypoglycemia may recur hours after initial treatment.

Seizures are also relatively common in nonketotic hyperglycemia and may be of any type. They are typically refractory to ASMs but respond to correction of hyperglycemia with insulin and intravenous fluid replacement. Associated focal neurologic abnormalities are usually transient, and recovery is typically complete if treatment is initiated before coma occurs. ASMs are not indicated for seizures related to nonketotic hyperglycemia. Phenytoin must specifically be avoided because it can exacerbate hyperglycemia by inhibiting insulin release.

Thyroid Disease

Seizures are not uncommon in hypothyroidism, are usually generalized, and remit with treatment of the hypothyroidism. ASMs such as phenytoin and carbamazepine may reduce serum thyroxine and triiodothyronine levels because of competition for serum-binding proteins; however, patients remain clinically euthyroid because free thyroxine and triiodothyronine fractions are increased.

Seizures are uncommon in thyrotoxicosis, but hyperthyroidism or excess thyroxine may occasionally cause seizures or exacerbate pre-existing epilepsy. When seizures occur in the setting of thyrotoxicosis, the hyperthyroid state should be corrected; ASMs usually are not required except occasionally in the acute setting.

Disorders of Sodium Homeostasis

The neurologic manifestations of disorders of sodium homeostasis are reviewed in Chapter 17. Symptoms reflect the rate of development of hyponatremia rather than absolute serum sodium levels, and chronic hyponatremia is surprisingly well tolerated. Seizures are usually seen in the context of acute hyponatremia with concentrations less than 115 mEq/L, but seizures may occur at higher levels if the decrease is rapid. Children are at high risk for cerebral edema in hyponatremia. Both partial and generalized seizures may occur.

Seizures in hyponatremia require careful correction using intravenous hypertonic (3%) saline, and increases in serum sodium concentration cannot exceed 1 mmol/L (1 mEq/L) per hour or 12 mmol/L (12 mEq/L) over 24 hours. More rapid correction of hyponatremia may cause osmotic demyelination (previously termed pontine and extrapontine myelinolysis), as well as seizures due to too rapid correction.

Hypernatremia if severe (>160 mEq/L) causes an encephalopathy. The aim of treatment is to replace body water. Seizures may occur, especially during rehydration.

Calcium and Magnesium Imbalance

The neurologic manifestations of hypocalcemia are reviewed in Chapter 17. Hypocalcemic seizures are quite common, affecting 30 to 70 percent of patients with hypoparathyroidism, often accompanied by an altered sensorium and tetany. Treatment of hypocalcemic seizures involves correction of serum calcium levels and treatment of any underlying cause. Hypercalcemia only infrequently causes seizures.

Seizures may also be provoked by hypomagnesemia, especially when the serum magnesium concentration decreases below 0.8 mEq/L (see Chapter 17). Convulsions in such circumstances are treated with

TABLE 57-5 ■ Proposed Cut-Off Values in Biochemical Parameters in Patients With Symptomatic Seizures from Common Metabolic Disorders

Biochemical Parameter	Cut-Off Value
Serum glucose	>450 mg/dL associated with ketoacidosis whether or not diabetes exists
Serum sodium	<115 mg/dL
Serum calcium	<5.0 mg/dL
Serum magnesium	<0.8 mg/dL
Serum urea nitrogen	>100 mg/dL
Plasma creatinine	>10.0 mg/dL

Adapted from Beghi E, Carpio A, Forsgren L, et al: Recommendation for a definition of acute symptomatic seizure. Epilepsia 51:671, 2010.

intravenous magnesium; calcium gluconate should be available to counteract transient hypermagnesemia. Seizures are not seen in hypermagnesemia (Table 57-5).

SEIZURES RELATED TO ALCOHOL, MEDICATIONS, AND RECREATIONAL DRUGS

Alcohol

Seizures are a common consequence of alcohol use, as discussed in Chapter 33. Alcohol potentiates the activity of $GABA_A$ receptors, and chronic alcohol use results in a compensatory downregulation of these receptors. As a consequence, when alcohol is stopped, neuronal inhibition is decreased and this can result in seizures. Usually, alcohol-related seizures are self-limited generalized convulsions that happen within 48 hours after stopping alcohol, often accompanied by other signs and symptoms of alcohol withdrawal. Convulsive status epilepticus may occur uncommonly after alcohol withdrawal. The brain substrates responsible for these seizures are largely in the brainstem, and the ASMs effective for generalized epilepsies seem to be the most helpful in this context. In the United States, benzodiazepines are preferred to treat alcohol withdrawal and to prevent seizures.[14]

Patients with seizures solely in the setting of alcohol or drug abuse do not, by definition, have epilepsy. Because seizures are self-limited, long-term ASM therapy is not indicated. These patients should be advised against chronic alcohol use or binge drinking.

Cocaine and Other Recreational Drugs

Seizures may be induced by acute intoxication with recreational drugs, especially cocaine and other stimulants. Less frequently, seizures may appear as a withdrawal phenomenon. Seizures are typically convulsions and do not require acute or chronic treatment with ASMs.

Between 2 and 8 percent of patients presenting to the emergency department for cocaine toxicity will also have seizures, usually generalized convulsive in type. This risk is highest with intravenous or inhaled crack cocaine and may reflect a direct CNS stimulant effect through blockage of neurotransmitter reuptake at dopaminergic and noradrenergic nerve terminals. Other proposed mechanisms include a kindling effect with chronic use, cerebrovascular or systemic effects, or a terminal event in massive cocaine overdose.

Amphetamines are an uncommon cause of generalized convulsions; as for cocaine, this happens more commonly after intravenous use and administration of high doses. Seizures are also uncommon with phencyclidine. Heroin use has been associated with convulsions, although this may relate to anoxia and chemical adulterants rather than to a convulsant effect of heroin itself.

Complications of intravenous drug abuse that may cause seizures, including infectious endocarditis and HIV infection, should be sought in patients with convulsions associated with the use of heroin or other intravenous drugs. Marijuana is often used concurrently with heroin and other recreational drugs but seems independently to lower the risk of a first seizure.

Medications

ANTIDEPRESSANT DRUGS

The most commonly implicated drugs in causing seizures are the tricyclic antidepressants (TCAs) and bupropion. The absolute risk of TCAs at usual therapeutic doses is actually quite low, but overdose may cause seizures. Bupropion is a monocyclic inhibitor of dopamine and has a clear dose-related risk of seizures, with a seizure incidence of 0.4 percent at doses of 450 mg/day or less, increasing to 2.2 percent at doses exceeding 450 mg/day. Conversely, selective serotonin reuptake inhibitors (SSRIs) appear to have low seizure risk even in overdose, with no seizures in a series of 234 cases of fluoxetine overdose. The seizure risk with SSRIs is generally quoted as 0.2 percent, based on premarketing data for sertraline. Importantly, antidepressants as a class may actually reduce the risk for seizures compared to placebo, consistent with the observation that low levels of pre/postserotonergic transmission in depressed persons may be a risk factor for seizures.

Antipsychotics and Lithium

Clozapine, an atypical antipsychotic, demonstrates a clear dose-related risk of seizures of 0.9 percent for doses less than 600 mg/day and 1.5 percent for higher doses, and has the highest seizure risk of all the antipsychotic medications. An increased risk of seizures has also been reported with olanzapine and quetiapine, but the other atypical antipsychotics (ziprasidone, aripiprazole, and risperidone) as a group do not seem to be associated with an increased incidence of seizures. Seizures with lithium intoxication are common when levels exceed 3.0 mEq/L although seizures have been reported in patients on lithium at therapeutic levels.

Antibiotics

Seizures have been reported with penicillins, cephalosporins, carbapanems (β-lactam antibiotics), and fluoroquinolones. They are believed to be due to direct or indirect binding to $GABA_A$ receptors. Of these antibiotics, the risk is highest for imipenem, from 0.2 to 0.9 percent, although acute seizures were seen in one series in 11 of 200 patients on imipenem. Risk is increased in the very young or very old and with renal insufficiency, focal neurologic deficits, and severity of illness, and when given intravenously or intrathecally.

Other Medications That May Cause Seizures

Tramadol is a weak μ-opioid receptor agonist that also induces serotonin release and inhibits the reuptake of norepinephrine. Seizures have been reported with tramadol at therapeutic doses, but are very frequent at supratherapeutic levels, seen in 14 percent of overdoses in one series.

Isoniazid is a common cause of drug-induced seizures, particularly in intentional overdose, believed to be due to inhibition of pyridoxine (vitamin B_6) metabolism that is required to synthesize GABA. For this reason, isoniazid-induced seizures may be refractory to ASMs and should be treated with intravenous pyridoxine.

Seizures may result from theophylline. This is most likely due to the inhibition of phosphodiesterase, which may reduce adenosine-mediated CNS inhibition. Status epilepticus may be seen in acute overdose; it does not respond to ASMs and requires hemodialysis or hemoperfusion therapy. Theophylline is best avoided in persons with epilepsy for these reasons.

Seizures have been reported with the anesthetic agents propofol, sevolfurane, and lidocaine. Propofol, which acts on the $GABA_A$ receptors and is used in the treatment of refractory status epilepticus, has also been associated with seizures during induction or recovery from anesthesia. Seizures can occur in the setting of abruptly stopping benzodiazepines and barbiturates, and also baclofen, which may cause nonconvulsive status epilepticus.

CEREBRAL TRAUMA, SEIZURES, AND EPILEPSY

Traumatic brain injuries (TBIs) are an important cause of seizures and epilepsy, especially in young adults, and may also increase seizures in persons with pre-existing epilepsy. Seizures caused by TBI are classified as immediate (at the moment of injury, or within minutes), early (within the first 7 days), and late (beyond the first week after injury). The incidence of immediate seizures following TBI is 1 to 4 percent; they are usually generalized convulsions and do not imply that the patient will develop epilepsy. Conversely, early seizures (occurring more than 1 hour after injury) do seem to present an increased risk of post-traumatic epilepsy. These seizures are symptomatic for the physics of the initial brain injury, including shearing injury to fiber tracts and blood vessels, bleeding, and brain swelling. The incidence of early seizures (within the first 7 days) is 2 to 9 percent, depending on the severity of the brain injury.[15]

The latency from the initial TBI to a first unprovoked seizure can be up to several years. Approximately 80 percent of patients with post-traumatic epilepsy experience their first (late) seizure within the first 12 months after injury and more than 90 percent do so before the end of the second year. However, the risk for a first late seizure is increased more than 10 years after the traumatic event. The presence of early seizures is the most important risk factor for the development of late seizures and epilepsy, and the incidence for late seizures in persons with early seizures is high, from 25 to 75 percent. Other risk factors include open or penetrating brain injury, focal lesions (hematoma, contusion) or neurologic signs, and prolonged coma or amnesia. The EEG is disappointing as a predictor of the risk for development of post-traumatic epilepsy, as many patients who eventually develop post-traumatic epilepsy have normal recordings early after injury. MRI of the brain is the imaging modality of choice, and has shown some promise for improving prediction of post-traumatic seizure risk.[15]

The precise mechanisms of epileptogenesis that leads to late seizures are poorly understood. Treatment of early-onset seizures with ASMs decreases early seizures, but prospective clinical trials have failed to demonstrate that preventing early seizures using ASMs affects mortality, morbidity, or the development of late epilepsy. These include randomized or quasi-randomized monotherapy studies using phenytoin, phenobarbital, carbamazepine, and valproic acid. Glucocorticoids also appear to have no benefit in preventing the development of seizures after TBI.

Movement disorders may complicate a variety of general medical diseases. Evaluation of patients with involuntary movements or postures requires a detailed history, including an account of perinatal events, ethnicity, parental consanguinity, psychiatric disorders, past medications, exposure to infectious agents, immunologic status, substance abuse, and exposures to toxins. The age of onset and pattern of progression further direct the evaluation. Clinical examination should be directed at determining the character and distribution of the abnormal movements and excluding non-neurologic causes.

CHOREA, BALLISM, AND DYSTONIA

Dystonia or chorea occurs in a wide variety of medical contexts. Although chorea is typically a more fluid, “dance-like” undulation of a limb, and dystonia is a slower movement or a sustained abnormal posture of a limb or the trunk, it is sometimes difficult to distinguish between them. Many cases of dystonia or chorea are secondary to a neurodegenerative disorder or an hereditary metabolic defect, which are not the subject of this review. The focus here is on movement disorders (other than ataxias) that arise in the context of a systemic medical disorder.

Aminoff's Neurology and General Medicine, Sixth Edition.

In a series of 51 cases of chorea from Italy, vascular causes were identified in 40 percent, drug-induced causes in 14 percent, acquired immunodeficiency syndrome (AIDS)–related causes in 10 percent, Huntington disease in 10 percent, hyperglycemia in 4 percent, and hyponatremia in 4 percent; single cases (2% each) of borreliosis (Lyme disease), Sydenham chorea, and acanthocytosis were also identified.[1] The epidemiology will differ in regions where AIDS or other infectious conditions are more prevalent.

Chorea is usually associated with dysfunction of the thalamus or basal ganglia. In most cases, the physiologic effect of the disorder reduces inhibitory input from the globus pallidus interna to the motor thalamus, resulting in excessive thalamocortical motor facilitation.

Dystonia is characterized by impaired inhibition at multiple levels of the central nervous system (CNS), and altered levels of several neurotransmitters have been reported in various diencephalic nuclei, as well as the putamen, globus pallidus, red nucleus, and subthalamic nucleus. Nonetheless, the generation of dystonia remains poorly understood.

Hypoxic-Ischemic Disorders

Chorea and dystonia due to hypoxia-ischemia may result from global or focal cerebral hypoperfusion as well as cellular hypoxia, such as in mitochondrial toxicity.

STROKE

Stroke may cause a variety of movement disorders depending on the location of the lesion and age of the patient. The abnormal movements may develop during the acute phase of a stroke or after a variable delay, and can be transient or permanent. Dystonia, especially, is rare in the acute phase but tends to occur at a time when patients are recovering from the initial motor deficit.

In a series of 1,500 patients with stroke, Alarcon and colleagues found that movement disorders occurred in about 56 (approximately 4%) over the following year; chorea occurred in 20, whereas dystonia, tremor, and parkinsonism were less common, occurring in 16, 14, and 6, respectively.[2] The average age at onset of chorea was 75 years, whereas that for dystonia was 48. Patients with deep (rather than isolated surface) vascular lesions were more likely to develop a movement disorder. *Hemichorea* occurred most commonly with contralateral thalamic strokes but also occurred with other lesions of the basal ganglia (putamen and subthalamic nucleus), white matter tracts (corona radiata, internal and external capsule), and pons. *Hemiballism* was caused most often by a lesion of the contralateral subthalamic nucleus but also occurred with lesions of the frontal and parietal lobes or the corona radiata. Putamenal strokes caused *focal* or *hemidystonia* most frequently, although lesions of the pons or globus pallidus and larger strokes of the frontal or parietal lobe were also sometimes responsible.

Thus, lesions in different parts of the brain may produce the same movement disorder, perhaps because they are interrupting the same motor networks but at different levels. The time to onset of the movement disorder is shorter for chorea—usually within 1 week of the stroke—than for dystonia and tremor, which typically developed 2 to 3 weeks after the stroke in the study by Alarcon and associates.[2] Hemorrhagic strokes are responsible for many movement disorders developing after 6 months or more, and especially for dystonia developing in young patients.[3] Most patients with these poststroke movement disorders improve over time.

Various points deserve emphasis. Severe pathologic involvement of the basal ganglia, as by an infarct, does not always lead to the development of a movement disorder, and many movement disorders relate to diffuse changes at multiple rather than single sites. A movement disorder may emerge immediately or soon after a stroke or—particularly with vascular parkinsonism—after many months or years, and can be progressive, evolving in severity and also in the character of the abnormal involuntary movements. The pathophysiologic basis of this progression is unclear.

Treatment is symptomatic. Chorea or ballismus may respond to tetrabenazine, deutetrabenazine, or valbenazine, or to haloperidol or other neuroleptics, and there are anecdotal reports of benefit with clonazepam, topiramate, and valproate. In severe and refractory cases, ablative surgery or deep brain stimulation may be indicated. Poststroke dystonia may respond to tetrabenazine, anticholinergic drugs, benzodiazepines, or baclofen. Botulinum toxin may help focal and segmental dystonias. Severe hemidystonia may be helped by deep brain stimulation of the globus pallidus or thalamus.

GLOBAL HYPOXIA-ISCHEMIA

The time course of a movement disorder resulting from global hypoxic-ischemic injury differs in infants, children, and adults. In infants and children, the movement disorder takes longer to develop and the abnormal movements are more likely to generalize. In adults, chorea or dystonia becomes manifest as any hemiparesis resolves and usually remains localized. Only in young children with postpump chorea and adults with postthalamotomy syndrome does the movement disorder commonly begin within a week of injury. The basis of such differences is not clear.

The age of patients at the time of anoxia influences the outcome. Patients developing an akinetic-rigid parkinsonian syndrome are typically in middle or later life, whereas those developing pure dystonia are usually younger than 20 years. The site of injury is also important. Involvement of the putamen is more likely to cause dystonia, whereas lesions of the globus pallidus are usually associated with parkinsonism. Perinatal hypoxic-ischemic injury may lead to any pattern of dystonia, often after a long interval. At onset the dystonia is focal or, rarely, segmental, and commonly spreads over a variable period that may be as short as a few months or as long as 20 to 30 years, resulting in segmental dystonia, hemidystonia, or generalized dystonia.

Postoperative encephalopathy with chorea, also known as *postpump chorea*, consists of chorea, athetosis, or ballismus, episodic eye deviations, and hypotonia. It occurs in infants or children within 12 days of cardiac surgery involving hypothermia, cardiopulmonary bypass, and often complete circulatory arrest, and may be severe. Although this surgical complication was previously common, occurring in up to 20 percent of children, current techniques have drastically reduced its incidence. Risk factors include age at time of surgery (higher risk between 6 months and 5 years), rapid cooling during cardiopulmonary bypass, lower body temperature, and the duration of hypothermic circulatory arrest. Infants younger than 6 weeks are less susceptible; in older infants, the chorea is often mild and reversible. The pathophysiology is poorly understood, although it seems likely that hypoxic-ischemic mechanisms secondary to surgical technique (including deep hypothermia) play a role.

Children and young adults sustaining acute hypoxic injury may also develop dystonia. They usually have focal or unilateral findings clinically and on imaging studies, despite the global insult. Dystonia may develop after 1 week to 3 years and typically generalizes over the following months or years; imaging shows abnormalities especially in the putamen.

Polycythemic chorea occurs for uncertain reasons. Polycythemia rubra vera has a male predominance, but polycythemic chorea is more common in women. Neurologic manifestations of polycythemia are common, occurring in 50 to 80 percent of patients, and include headache, vertigo, stroke, visual symptoms, tinnitus, and paresthesias. Chorea is a rare complication, occurring in 0.5 to 5 percent of patients. Examination may also show a plethoric complexion and splenomegaly. The chorea may be the presenting symptom of polycythemia, may begin suddenly or gradually, is sometimes episodic, and typically becomes generalized but affects particularly the facial, lingual, and brachial muscles. The limbs are hypotonic, with pendular patellar tendon reflexes. The chorea may persist for up to several years, with spontaneous remissions and recurrences. Treatment is of the underlying polycythemia but additional symptomatic control with dopamine-depleting or dopamine-blocking agents may be necessary.

Toxins

Exposure to certain gases and heavy metals is a rare cause of encephalopathy, parkinsonism, and dystonia, probably as a result of cellular hypoxia from mitochondrial dysfunction or the generation of free radicals. *Carbon monoxide* toxicity appears to result from a combination of tissue hypoxia and direct cellular toxicity. After initial recovery, about 10 percent of survivors will develop parkinsonism several weeks to months later; approximately 80 percent recover within 6 months. Imaging often reveals focal injury particularly to the pallidum and diffuse white matter changes, and the findings on magnetic resonance spectroscopy of white matter lesions are consistent with demyelination. Treatment with levodopa and anticholinergic agents usually is unhelpful.

Parkinsonism and dystonia are common among survivors of *cyanide poisoning*. The movement abnormalities may initially improve, only to worsen days to months later, followed by stabilization and gradual but incomplete recovery. Cyanide reacts with cytochrome-*c* oxidase, causing cellular hypoxia. Imaging studies show lesions in the caudate and lentiform nuclei, precentral cortex, and cerebellum. Functional imaging shows reduced dopamine transporter uptake suggestive of nigral neuronal loss.

Ingestion of *methanol* results in the production of formaldehyde by the liver; the liver and erythrocytes synthesize formic acid, which inhibits cytochrome-*c* oxidase and, thus, mitochondrial electron transport and tissue adenosine triphosphate production. Metabolic acidosis injures the retina and optic nerves and leads to necrosis of the putamen, subcortical white matter, cerebellum, brainstem, and spinal cord, resulting in parkinsonism, dystonia, tremor, and blindness. Initial treatment relies on correction of the metabolic acidosis with ethanol and elimination of methanol with hemodialysis. Gradual improvement may occur with time, and treatment with amantadine and dopaminergic medications sometimes helps.

Manganese toxicity may occur as an occupational exposure (e.g., in miners of the ore or with chronic exposure to metal alloys, batteries, paint, varnish, enamel, or colored glass), or as a consequence of liver failure. Manganese increases free radical formation, inhibits antioxidant function, may reduce mitochondrial energy production, and perhaps increases glutamate neurotoxicity. In addition to foot dystonia, parkinsonism, early freezing of gait, a distinct gait disturbance (cock gait), hyperreflexia, and Babinski signs may occur. Remission may occur in mild cases if further exposure is prevented, but the course is otherwise progressive. There are reports of improvement after chelation. Pathologic examination reveals damage to the globus pallidus and substantia nigra pars reticulata (which are downstream from the nigrostriatal dopaminergic pathway), consistent with the failure to respond to levodopa. Magnetic resonance imaging (MRI) may show hyperintensity of the putamen on T1-weighted images. A similar syndrome (with elevated serum manganese and putamen T1 hyperintensity) has been described in methcathinone users when the drug was produced using potassium permanganate oxidation of ephedrine or pseudoephedrine.

Organic *mercury* poisoning, as seen formerly with the ingestion of certain fungicides and shellfish (Minamata disease), causes visual loss, ataxia, paresthesias, and cognitive dysfunction. Choreoathetosis, parkinsonism, and tremor also occur, and dystonic posturing is occasionally seen. Inorganic mercury poisoning, seen in glass blowers, hatters, and battery workers, produces a psychotic encephalopathy and tremor.

Dystonia secondary to copper accumulation occurs in *Wilson disease*. If hepatic damage is mild, significant improvement follows chelation therapy with penicillamine or trientine and zinc, which reduces dietary absorption of copper. Liver transplantation may be required for nonresponders and patients with severe liver dysfunction. The movement disorder may respond to trihexyphenidyl, levodopa, dopamine agonists, or amantadine.

Cellular and global hypoxia-ischemia have been implicated in *disulfiram* overdose. In one such case, psychomotor slowing and parkinsonism were evident several days after awakening from coma, and over 10 years progressed to include dystonia of a lower limb, the eyelids, and speech. Brain computed tomography (CT) shows hypodense lesions, and MRI shows hyperintense lesions in the pallidum and inferior putamen. Chorea has also been described as a consequence of toluene (glue sniffing) and thallium exposures.

Drug-Induced Dystonia and Chorea

Medications may cause dystonia (Chapter 32) and chorea (Table 58-1). Acute iatrogenic dystonic reactions are idiosyncratic, reversible, and common. They may occur almost immediately (minutes to hours) after the first dose of a medication, or days to weeks later. For dystonia, the most common offenders include antipsychotics (both typical and atypical), benzodiazepines, anticonvulsants, dopamine agonists, and tricyclic antidepressants.[4] Reactions have been encountered less often with calcium-channel blockers, propranolol, histamine-blocking drugs (cimetidine, ranitidine, cetirizine), and substituted benzamides (metoclopramide, sulpiride, clebopride, and domperidone). Patients with AIDS dementia complex are particularly sensitive to neuroleptic-related acute dystonic reactions because of underlying dopaminergic dysfunction. Dystonia may occur soon after starting antidepressants or develop after chronic use. Many agents (and medication classes) may be responsible including tetracyclics (trazodone and amoxipine), tricyclics (clomipramine, amitriptyline, and imipramine), selective serotonin reuptake inhibitors (including fluoxetine, paroxetine, fluvoxamine, escalopram, citalopram, and sertraline), and serotonin-norepinephine reuptake inhibitor (duloxetine).[4]

If dystonia develops acutely, treatment involves discontinuation of the offending agent and administration of an anticholinergic drug or benzodiazepine. Diphenhydramine, benztropine mesylate, chlorpheniramine, diazepam, or lorazepam may be given orally or intravenously; treatment for several days is sometimes necessary, especially if the causal agent was taken regularly or in depot form. If dystonia is mild or develops slowly, gradual down-titration of the medication is appropriate.

Chorea has been reported secondary to a variety of medications including anticonvulsants (phenytoin, carbamazepine, valproate, and gabapentin), stimulants (amphetamine, cocaine, methylphenidate, pemoline), benzodiazepines, estrogens, lithium, levodopa (with or without catechol-*O*-methyltransferase inhibitors), dopamine agonists, tricyclic antidepressants, and antihistamines, as well as other agents such as baclofen, cimetidine, thyroxine, cyclosporine, and aminophylline.[4] Chorea and encephalopathy has been associated with ciprofloxacin use and also with 4-aminopyridine overdose. Disulfiram overdose or poisoning (discussed

TABLE 58-1 ■ Selected Drugs and Toxins Inducing Chorea and Dystonia

Drug or Toxin	Chorea	Dystonia
Anticholinergics	Benzhexol, trihexyphenidyl	–
Antiepileptics	Carbamazepine, felbamate, gabapentin, lamotrigine, phenytoin, valproic acid	–
Anti-infectious agents	Ciprofloxacin	–
Antidepressants and anxiolytics	Tricyclic agents	Selective serotonin reuptake inhibitors, tricyclic agents, benzodiazepines
Cardiac medications	Flecainide	Flecainide
Calcium-channel blockers	–	Cinnarizine, flunarizine, verapamil
Dopamine agonists and levodopa	Apomorphine, bromocriptine, pergolide, pramipexole, ropinirole, lisuride, cabergoline, levodopa	Apomorphine, bromocriptine, pergolide, pramipexole, ropinirole, lisuride, cabergoline, levodopa
Dopamine-receptor blocking drugs	Antipsychotics, metoclopramide, antiemetics	Antipsychotics, metoclopramide, antiemetics
Histamine-receptor blocking drugs	Cyproheptadine	Cimetidine, ranitidine, cetirizine
Hormones	Oral contraceptives, estrogens, thyroxine	–
Immunosuppressants	Corticosteroids, cyclosporine	–
Stimulants	Amphetamine, cocaine, methylphenidate, pemoline	–
Serotonin receptor antagonists	Ondansetron	Ondansetron
Miscellaneous drugs	Baclofen, digoxin, lithium, theophylline, 4-aminopyridine	Clebopride, disulfiram, domperidone, metoclopramide, sulpiride
Toxins/metals	Mercury, organophosphates, thallium, toluene	Carbon monoxide, cyanide, disulfiram, manganese, methanol, mercury, thallium

earlier) may present clinically with encephalopathy, ketotic hyperglycemia, and dystonia.

Tardive syndromes develop after the introduction of the provoking medication, usually a dopamine receptor blocking drug. Most patients have been on the medication for at least 3 months; the disorder may first manifest after the causal agent has been discontinued, but typically does so within 6 months of withdrawal. The syndrome may involve dyskinesias, typically repetitive orolingual facial movements or repetitive movements of the head, trunk, and extremities. Older patients seem more susceptible than young persons. A tardive syndrome also may take the form of dystonia, chorea, akathisia, tremor, or myoclonus.

A number of medications have been associated with the development of tardive dyskinesia. It occurs most commonly with haloperidol or typical antipsychotics, but it is also common with the atypical antipsychotic drugs and with prolonged use (i.e., for more than 3 months) of metoclopramide. Other dopamine-blocking agents such as the antiemetics prochlorperazine and promethazine may cause tardive syndromes. Less commonly, certain calcium-channel blockers (especially cinnarizine and flunarizine) and rarely serotonin reuptake inhibitors have been associated with its development. The causal agent should be discontinued if feasible; otherwise, patients requiring antipsychotic medication should be switched to an atypical antipsychotic drug such as quetiapine. The withdrawal of dopamine-blocking agents may initially exacerbate the dyskinesia, but the movement disorder ultimately decreases or disappears in up to 50 percent of patients, persisting unchanged in the remainder. Dopamine-depleting agents (valbenazine, tetrabenazine, reserpine) are the most useful adjunctive treatments, followed by benzodiazepines such as clonazepam; GABA agonists such as baclofen and sodium valproate also have been used, but evidence of benefit is sparse. Anticholinergic drugs may exacerbate the syndrome.

Tardive dystonia may be indistinguishable from idiopathic dystonia and may respond to sensory tricks. It may be focal, segmental, or generalized; however, the head and neck region are most commonly affected, resulting in torticollis, blepharospasm, or oromandibular dystonia. Orobuccal-lingual dyskinesia or other tardive movements may occur in tardive dystonia, unlike in idiopathic dystonia. The onset is insidious, typically after several years of antipsychotic use, but may occur with exposures shorter than 1 year. Tapering the antipsychotic occasionally produces gradual or partial remission of tardive dystonia, often after an initial worsening. An increase in dose of the antipsychotic or its continuation may lead to temporary benefit, but probably worsens the long-term outlook. If treatment with an antipsychotic is necessary, replacement of the original neuroleptic with clozapine or quetiapine has been helpful. Approximately 50 percent of patients benefit from dopamine-depleting or -blocking agents and anticholinergic treatment. For patients with focal or segmental dystonia, botulinum toxin injections are beneficial. Stereotactic surgery, including pallidotomy and pallidal deep brain stimulation, has been successful for severe tardive dystonia unresponsive to other measures.

Some medications appear to cause chorea in the setting of pre-existing basal ganglia injury. For example, dose-related dyskinesias develop in a large proportion of parkinsonian patients taking carbidopa-levodopa. Similarly, many patients who develop chorea while taking oral contraceptives have had striatal abnormalities on imaging studies or have a past history of Sydenham chorea, chorea gravidarum, or chorea with Henoch–Schönlein purpura.

Among illicit drugs, cocaine and amphetamines have been most frequently associated with dyskinesias. Both influence central dopaminergic mechanisms, and cocaine also decreases serotonin turnover and degradation. Both may lead to choreoathetoid movements of the extremities, less often the head or trunk, or buccolingual dyskinesias within 24 hours of use; these typically resolve without treatment in 2 to 6 days. However, in chronic users, chorea persisting for more than 1 year after discontinuation of these stimulants has been described.

Infectious Disorders

Infections may cause the full spectrum of movement disorders (Table 58-2). Movement abnormalities usually develop during the acute illness and are transient, but abnormal movements sometimes begin or persist after the infection has cleared. One mechanism is vasculitic ischemia of the basal ganglia, although direct neuronal injury by the organism or a toxin, and autoimmune cross-reactivity with basal ganglia epitopes are also postulated to play a role.

BACTERIAL INFECTIONS

Sydenham chorea is a transient chorea that develops in about one-quarter of patients with rheumatic fever, an autoimmune complication of infection with group A β-hemolytic streptococci. It is the most common cause of acute chorea in children, typically affecting those between ages of 7 and 12 (with a range of 3 to 17) years. After 10 years of age, it is more common in girls. The chorea is usually generalized (80% of cases), and may be the presenting feature of rheumatic fever; cardiac involvement is present in the majority. An encephalopathy occurs in 10 percent. Dysarthria and behavioral abnormalities are common; obsessive-compulsive disorder and attention deficit and hyperactivity occur in about 25 percent of patients. The pathogenesis of Sydenham chorea may be related to the development of antineuronal antibodies. Although the condition usually improves over months, residual chorea has been observed in 50 percent of patients 2 years after onset, and behavioral abnormalities may persist. Symptomatic treatment with valproic acid, carbamazepine, or clonidine may be considered in those with troublesome chorea. Dopamine-receptor blocking drugs are reserved for those who do not respond to these other agents, and brief case reports suggest that tetrabenazine may also be helpful. In severe cases a brief course of prednisone has been prescribed to shorten the course of the disease, and there are also anecdotal reports of benefit from intravenous immunoglobulins (IVIg) or plasmapheresis. In about half of affected patients, chorea recurs within 2 years of the initial episode in the absence of infection. A course of penicillin is usually initiated at the time of diagnosis and continuous prophylaxis with penicillin is often advised to prevent further streptococcal infections until adulthood. Neuroimaging studies may be normal or show contralateral or bilateral striatal abnormalities that resolve as the chorea settles. Positron emission tomography (PET) scanning shows reversible striatal hypermetabolism.

Tuberculous meningitis may cause dystonia or chorea. Brain imaging may be normal or show ischemic or hemorrhagic infarcts. Direct infection or infarction of the basal ganglia may account for the development of the movement disorder. Treatment is with antituberculous therapy. Most patients improve over several weeks.

Mycoplasma pneumoniae causes pneumonia but also affects the CNS in approximately 5 percent of patients

requiring hospitalization. Aseptic meningitis, cranial neuritis, transverse myelitis, or encephalitis may occur, and neurologic symptoms may precede pulmonary ones. Generalized choreoathetosis and dystonia have been described. Cerebral imaging may be unremarkable or show abnormalities in the caudate, putamen, and globus pallidus. The cerebrospinal fluid (CSF) is normal or exhibits a mild lymphocytosis with elevated protein concentration. The diagnosis is made by respiratory cultures and tests for serum and CSF complement-fixing and cold agglutinin antibodies.

In Legionnaire disease (*Legionella pneumophila*), high fevers and pulmonary involvement may be accompanied in approximately 20 percent of cases by headache and, rarely, by chorea. The CSF and head CT scan are normal, and the diagnosis is made by serologic studies. The chorea may persist for up to 2 years.

Chorea has also been reported uncommonly in patients with Lyme encephalitis or neurosyphilis and rarely with other infections.

VIRAL INFECTIONS

Viral encephalitis (including Japanese encephalitis, West Nile, St. Louis, herpes simplex, dengue, mumps, and measles) may be accompanied by movement disorders. Japanese encephalitis, endemic to much of Asia, causes dystonia or parkinsonism several weeks after infection. Brain MRI typically shows abnormalities in the thalamus, globus pallidus, or putamen. Varicella has been associated with transient chorea and dystonia. Chorea can be an early feature of herpes simplex encephalitis but more frequently signals a relapse. In adults, human immunodeficiency virus (HIV) infection may present with hemichorea-hemiballism or with generalized chorea, usually in the presence of dementia. Most AIDS-related cases are secondary to toxoplasmosis but may also relate to HIV encephalitis, cryptococcal infection, or progressive multifocal leukoencephalopathy.

FUNGAL AND PARASITIC INFECTIONS

In HIV-seropositive patients, cerebral toxoplasmosis is the most common cause of dyskinesia. *Toxoplasma* abscesses in various diencephalic structures have been associated with contralateral limb ballism, choreoathetosis, and dystonia. Treatment of the infection is usually successful, but improvement in the dyskinesia is seen in only approximately 25 percent of instances, suggesting irreversible injury to the basal ganglia. Improvement of the dyskinesia may occur with dopamine-blocking agents or dopamine depleters such as tetrabenazine. Hemichorea and hemiballismus have been reported only rarely in cryptococcal meningitis and may respond to antifungal treatment.

Autoimmune, Inflammatory, and Paraneoplastic Disorders

In systemic lupus erythematosus (SLE), choreoathetosis develops in 1 to 2 percent of patients and may be the presenting feature.[5] Women are affected more commonly than men. The chorea typically occurs before the age of 30 years and tends to manifest during a lupus flare, often accompanied by behavioral disorders. It may be generalized or lateralized and is usually transient, lasting for a few days up to 3 years; recurrence occurs in approximately 25 percent of cases. Rarely, the chorea is permanent. The chorea may be self-limited or respond to corticosteroid or symptomatic treatment. Imaging studies may be abnormal, but the location of lesions does not usually explain the chorea.

Patients with SLE and chorea may possess antiphospholipid antibodies (lupus anticoagulant or anticardiolipin antibody) that predispose to endovascular thrombosis and cerebral infarction.[6] Approximately 30 percent of patients with SLE and these antibodies have thrombotic events. Laboratory studies reveal that whole-blood clotting time is prolonged, and the prothrombin time and the Russell viper venom time may be abnormal. Chorea in several patients with SLE and antiphospholipid antibodies has improved within days on aspirin therapy or warfarin, consistent with a vascular mechanism. Thus, chorea in SLE may result from autoimmune vasculopathy or direct antibody-mediated basal ganglia dysfunction, or both.[6]

The antiphospholipid syndrome may occur in the absence of SLE or other autoimmune conditions, the so-called primary antiphospholipid syndrome. Clinically and pathophysiologically, this condition is indistinguishable from that associated with SLE. In addition to lupus anticoagulant and an IgG anticardiolipin antibody, many patients have a low titer of antinuclear antibody, 30 percent have a false-positive Venereal Disease Research Laboratory test, and some have antithyroid antibodies. Chorea (either lateralized or generalized) has been the most frequently reported movement disorder, occurring in 1 to 4 percent of patients with primary or secondary antiphospholipid syndrome, although tics, dystonia, myoclonus, and corticobasal syndrome may occur. Brain MRI shows lesions of the basal ganglia in 6 to 16 percent of patients; labeled glucose PET imaging has revealed increased uptake contralateral to the hemichorea. For patients with no vascular events, treatment may consist of discontinuation of estrogen or progesterone (if applicable) and immunosuppressant treatment. For patients who have had a vascular event, anticoagulation may reduce the risk of recurrent thrombosis.

Chorea is a rare complication of polyarteritis nodosa and isolated angiitis of the CNS, and athetoid movements have been noted as the initial manifestation of primary Sjögren syndrome. Patients with Behçet syndrome (recurrent oral and genital ulcers, uveitis, and skin lesions) may present with chorea, jaw-opening dystonia, or paroxysmal dystonia. Typically, these patients have had an increased CSF protein concentration and lymphocytosis. They respond to immunosuppression but may require other agents to control abnormal movements. Chorea may also develop in Churg–Strauss syndrome.

Chorea sometimes occurs in Hashimoto encephalopathy. The CSF protein concentration is usually elevated, and some samples have oligoclonal bands or a mononuclear pleocytosis. Characteristically, the electroencephalogram (EEG) shows epileptiform activity, and transient or permanent areas of increased T2 signal are seen on brain MRI, particularly in the frontal and temporal lobes. Patients respond to prednisone, with a slow taper once improvement is stable. Complete remissions can be anticipated, although relapses sometimes occur or a deficit remains. Spontaneous remissions are rare.

Dystonia and tremor or chorea may be part of a movement disorder associated with celiac disease. Abdominal pain, ataxia, diarrhea, and myoclonus may also occur. Diagnosis is supported by demonstration of gliadin antibodies and characteristic findings on small bowel biopsy. The condition may respond to a gluten-free diet.

Chorea and dystonia are rare complications of paraneoplastic syndromes. In a series of 979 patients with paraneoplastic diseases, 9 presented with chorea and 3 had dystonia or dyskinesia.[7] Most had small-cell cancer of the lung, and one each had nonsmall cell lung cancer, renal cancer, and colon cancer. Most of these patients had CV2/collapsing response-mediator protein (CRMP)-5 antibodies, but ANNA-1 (anti-Hu) antibodies were found in four. In many patients, chorea was the initial symptom. CSF was abnormal in some patients. Brain imaging was abnormal in four of the nine patients, with diffuse hyperintensity of the white matter in T2-weighted MRI; two showed basal ganglia hyperintensity. Improvement may occur with cancer treatment or symptomatic medications (dopamine-blocking or -depleting medications or benzodiazepines). Laryngospasm, jaw-opening dystonia, and cervical dystonia have been described in paraneoplastic syndromes associated with antineuronal nuclear antibody type 2 (ANNA-2, also known as anti-Ri antibodies, associated most commonly with breast or lung cancer).[8]

Patients with anti–*N*-methyl-D-aspartate receptor encephalitis are usually women and many have ovarian cancers; various other cancers have also been reported. Patients commonly present with behavioral changes and seizures, and have dyskinesias (chorea, dystonia) involving the face, trunk, abdomen, and extremities in 80 percent of cases; orobuccolingual dyskinesias are most common. The dyskinesias usually respond to tetrabenazine, deutetrabenazine, or valbenazine.

Metabolic Disorders

The association between thyrotoxicosis and choreoathetosis or dystonic posturing was recognized by Gowers in 1893, particularly in young women, but patients of either sex may be affected. Chorea occurs in about 1 to 2 percent of those with *hyperthyroidism* and its course usually parallels that of the thyroid disorder. Abnormal movements typically involve the limbs, sometimes unilaterally, and are most conspicuous distally; the neck and face may also be affected. Paroxysmal (rather than more continuous) choreoathetosis may occur in rare instances; paroxysmal and kinesigenic choreoathetosis have also been reported with iatrogenic hyperthyroidism. No cerebral lesions have been noted on MRI or at autopsy. Treatment consists primarily in normalization of thyroid function (antithyroid drugs, radioiodine, or thyroidectomy). Chorea may respond to dopamine receptor blockers or propranolol even before hyperthyroidism has resolved. Altered dopamine turnover or increased dopamine receptor sensitivity may be responsible for the dyskinesia. Since chorea may occur in both hyperthyroidism secondary to Graves disease and iatrogenic thyrotoxicosis, it is hypothesized that the disorder results from a direct effect of thyroxine on the basal ganglia, perhaps by increasing dopamine receptor sensitivity.

Hypocalcemia from idiopathic hypoparathyroidism rarely may cause dystonia or choreoathetosis.[9] The abnormal movements may be the presenting complaint, may be asymmetric, are usually paroxysmal, and rarely are kinesigenic. Patients are usually younger than 30 years, with calcium levels of 4 to 6 mg/dL, elevated serum phosphorus levels (5 to 12 mg/dL), and low serum magnesium. Brain imaging frequently reveals basal ganglia calcification that persists after treatment of hypocalcemia and resolution of chorea or dystonia.

Generalized chorea or hemiballism-hemichorea may occur in *nonketotic hyperosmolar hyperglycemia*. Brain CT may show high-density lesions, and MRI often shows high T1 signal and hypoperfusion in the caudate or putamen contralateral to the side involved clinically. These imaging findings are considered to be a consequence of hyperviscosity and cytotoxic edema, not petechial hemorrhage. The chorea may resolve with correction of hyperglycemia; however, dopamine-depleting or -blocking agents may be useful treatments until the condition resolves. Severe *hypoglycemia* may be accompanied by either generalized chorea or hemichorea that resolves as blood glucose normalizes.

Dystonia or chorea has rarely been noted in hypernatremic dehydration, hyponatremia, and hypomagnesemia and also after central pontine myelinolysis. In addition, many inherited metabolic disorders or inborn errors of metabolism can cause chorea or dystonia, as is reviewed elsewhere.[10]

Other Causes

Post-traumatic focal and hemidystonia may occur rarely as a long-term consequence of severe head injury or following peripheral injury. Chorea-ballism may also follow head injury, as may functional movement disorders.

Approach to Diagnosis

The evaluation of patients with involuntary movements or postures requires a detailed history, as outlined earlier. Characterization of the movement disorder and its distribution, together with findings such as organomegaly, skin lesions, retinal or optic nerve disease, or neurologic deficits, narrows the differential diagnosis. The relaxed patient must be observed carefully while lying, sitting, standing, and walking to determine whether any abnormality is exacerbated by movement or rest. The patient should perform tasks that are particularly impaired because certain movement disorders are solely task specific.

The age of onset and the pattern of involvement and progression vary with the etiology. Focal or task-specific dystonias, often associated with a dystonic or essential-type tremor, onset in adulthood, a benign history, and no other abnormalities on examination are usually idiopathic. Limb dystonia beginning as action dystonia is usually idiopathic, whereas dystonia beginning at rest is sometimes symptomatic. Dystonia with onset in the legs is usually idiopathic in children but symptomatic in adults. Chorea or dystonia of acute or subacute onset or having a rapidly progressive course is more likely to be symptomatic. Hemidystonia at any age suggests a secondary etiology, and approximately 75 percent of patients have contralateral basal ganglia abnormalities on imaging, a history of hemiparesis, or both. One-third of hemidystonic patients have infarction or hemorrhage of the contralateral basal ganglia, especially the putamen. Generalized dystonia beginning at an early age may be idiopathic or symptomatic, but it is more often symptomatic when onset is in adulthood. Childhood-onset dystonias tend to become generalized, whereas those commencing in adulthood often remain focal or segmental. Similarly, tardive dystonia may be generalized in children, but it usually remains focal or multifocal in adults. Thus, dystonia of sudden onset, rapid progression, onset in infancy, cranial onset in children, lower-extremity onset in adults, or hemidystonia at any age is more likely symptomatic and requires full evaluation.

A large number of factors contribute to decision-making in the evaluation of chorea and dystonia. Brain MRI has a high yield, and basic laboratory studies include a complete blood count and blood electrolytes, calcium, phosphorus, uric acid, and liver and thyroid function tests. Any patient with chorea or dystonia younger than 40 years must be evaluated for Wilson disease. Evaluation for vascular disease, a hypercoagulable state, connective tissue disorders, and antiphospholipid antibodies may be required. Serum antistreptolysin O or antihyaluronidase titers and an electrocardiogram are useful when Sydenham chorea is suspected. Neurodegenerative and hereditary metabolic disorders require a separate battery of studies, which are described elsewhere.

Treatment

The treatment of secondary dystonia or chorea is difficult. In symptomatic cases, the underlying pathologic process should be treated first, as discussed earlier. General therapeutic measures may provide symptomatic benefit when specific treatments of the underlying lesion have failed to temper the movement disorder satisfactorily. Anticholinergics, dopaminergics, antidopaminergics, benzodiazepines, anticonvulsants, and certain other medications (discussed later) are used, based on patient age, tolerance, co-existing medical illnesses, and interactions with other medications taken concomitantly. All of these medications are disappointingly variable in their efficacy. Unfortunately, there is a paucity of adequate trials demonstrating therapeutic benefit or comparative efficacy because patient numbers are small, common side effects make double-blinding difficult, and nonspecific effects such as sedation can diminish abnormal movements. Moreover, spontaneous remissions, partial or complete, and transient or permanent, may occur unpredictably.

Anticholinergic medication, of which trihexyphenidyl is the best studied, is more effective in mild dystonia and in younger patients. Approximately one-third of patients with secondary dystonia benefit, and up to 50 percent of those with perinatal hypoxic injury improve. The selected agent is started at a low dose, which is increased slowly, depending on response and tolerance. (A particular daily dose may take several weeks to produce maximal benefit.) Side effects can be dose-limiting, particularly with advancing age. Tricyclic antidepressants and diphenhydramine are also sometimes used for their anticholinergic effects.

The useful antidopaminergic medications include dopamine depleters (reserpine, tetrabenazine, deutetrabenazine, valbenazine) or dopamine receptor antagonists. Valbenazine is particularly helpful for tardive dyskinesia.

Dopaminergic supplementation using levodopa is singularly effective in patients with dopamine-responsive dystonia, which may be present in 5 to 10 percent of patients with childhood-onset hereditary dystonia beginning in the legs, with or without diurnal fluctuations. It is less useful in treating symptomatic dystonias. In some instances, levodopa actually worsens symptomatic dystonia, whereas improvement may occur with dopamine agonists or amantadine.

Anticonvulsants have been tried and sometimes help, but usually the results are disappointing. Baclofen, a presynaptic γ-aminobutyric acid agonist, is also frequently tried and occasionally is effective, either orally or intrathecally. Other medications that have been tried alone or in combination, with variable benefit, include benzodiazepines, particularly clonazepam (which helps perhaps one-quarter of patients with secondary dystonia), muscle relaxants, cyproheptadine, and lithium. Adult-onset cranial or focal limb dystonias are best treated with intramuscular botulinum toxin.

Surgical approaches are sometimes warranted. Deep brain stimulation of the globus pallidus is effective for primary dystonia, myoclonus dystonia, and tardive dystonia. Selective peripheral denervation is sometimes successful for blepharospasm and cervical dystonia, but is now generally reserved for cases refractory to botulinum toxin. The use of deep brain stimulation for refractory chorea is being explored.

MYOCLONUS

Myoclonus is an acute, brief, involuntary jerk caused by a sudden muscle contraction (positive myoclonus) or relaxation (negative myoclonus). It can be classified by distribution, the location of the generator, or the underlying etiology. It may recur in the same muscle groups (focal or segmental myoclonus) or asynchronously and asymmetrically in different muscle groups (multifocal or generalized myoclonus), and it may occur at rest (spontaneous), on movement (action or intentional myoclonus), or in response to specific stimuli (reflex myoclonus).

Myoclonus occurs in healthy individuals (hiccups, hypnic jerks) or as a movement disorder with an idiopathic (essential), epileptic, or symptomatic etiology. Symptomatic myoclonus is the most common variety and may be due to primary neurologic causes, but it is more commonly seen in a general medical setting, to which this section is devoted. Myoclonus may be generated from spinal, subcortical, or cortical circuits and involves the somatotopically organized dorsal column/lemniscal and corticospinal systems superimposed on the spinoreticular and reticulospinal circuits.

Hypoxia-Ischemia

STROKE

Strokes involving the thalamus or brainstem may cause focal or segmental myoclonus that sometimes responds to levetiracetam, clonazepam, valproate, zonisamide, or primidone. Local injection of botulinum toxin may also be worthwhile.

GLOBAL HYPOXIA-ISCHEMIA

Posthypoxic action myoclonus may occur in survivors of cardiopulmonary arrest. Two forms of myoclonus are recognized in this context.

Acute posthypoxic myoclonus is characterized by severe, generalized myoclonus in comatose patients. The jerk-like movements develop within the first day after hypoxia and are characterized by violent flexion movements. If myoclonus persists for more than 30 minutes or for most of the resuscitation day, it is often called myoclonus status epilepticus, despite the lack of evidence that the myoclonus is epileptic in nature. In most patients with posthypoxic myoclonus, an EEG performed on the first hospital day demonstrates a burst-suppression pattern, alpha-pattern coma, or polyspike-wave activity. Myoclonus status epilepticus occurs in 30 to 40 percent of comatose adult survivors of cardiopulmonary resuscitation, is difficult to control, and has a poor prognosis. Approximately 90 percent of patients with myoclonus status epilepticus have a fatal outcome, a few survive but in a persistent vegetative state, and only 2 to 3 percent survive with a good outcome.

Chronic posthypoxic myoclonus (Lance–Adams syndrome) occurs within days to weeks after hypoxic injury, often while the patient is still comatose or is beginning to recover consciousness. The myoclonus predominantly involves the limbs and is precipitated by active or passive movement; it occasionally spreads to other portions of the body. It may be stimulus sensitive, and negative myoclonus may also occur, predisposing patients to falls. Cerebellar ataxia and cognitive impairment are often associated. Treatment of chronic posthypoxic myoclonus is not satisfactory. However, levetiracetam, clonazepam, valproate, zonisamide, and piracetam (not available in the United States) are often helpful. Treatment with 5-hydroxytryptophan (often with carbidopa to limit nausea) or with sodium oxybate may also be worthwhile, based on anecdotal reports or pilot studies.

Metabolic Disorders

Metabolic disorders are commonly associated with mental status changes and negative myoclonus (asterixis), which is usually of brainstem reticular origin. Renal failure and its treatment may both be associated with neurologic dysfunction. Generalized and multifocal positive and negative myoclonus occur in *uremic encephalopathy* (Chapter 16). It may occur at rest, with movement, or in response to a stimulus. Myoclonus also occurs in patients with *dialysis dementia* (Chapter 16). The myoclonus is exacerbated during and after dialysis and is most prominent in the face and upper limbs.

In *hepatic insufficiency* of any cause, asterixis is typical, but multifocal positive myoclonus also occurs. Treatment requires addressing the underlying disorder. In rare instances, Wilson disease may present with progressive myoclonus.

Hyperglycemia is the most common metabolic disturbance causing focal motor phenomena. In nonketotic hyperglycemia, severe hyperglycemia, hyperosmolality, and dehydration are accompanied by segmental or generalized myoclonic seizures in up to 20 percent of patients. Asterixis or negative myoclonus is also seen. EEG shows diffuse slowing, sometimes with a spike-wave pattern. The glucose level is typically over 600 mg/dL and osmolality above 300 mOsm/kg H_2O, with mild or absent ketoacidosis. Treatment is by fluid and electrolyte replacement and correction of hyperglycemia. The myoclonus resolves with treatment of the hyperosmolality, and not with anticonvulsants.

Vitamin B_{12} deficiency may cause myoclonus in children and adults. The myoclonus resolves after treatment with vitamin B_{12}. Myoclonus may also occur after intramuscular vitamin B_{12} administration.

Pellagra (niacin deficiency) is characterized by the triad of myoclonus, altered mental status, and generalized hypertonicity; a dermatitis is sometimes present. It typically occurs in alcoholism but can be seen in malabsorption conditions and after treatment with certain medications (5-fluorouracil, isoniazid, pyrazinamide, ethionamide, 6-mercaptopurine, hydantoins, phenobarbital, and chloramphenicol). Early replacement of niacin is required. Hypernatremic dehydration has also been associated with transient myoclonus and chorea in chronic alcoholism.

Finally, myoclonus may occur in a number of inborn errors of metabolism, as is reviewed elsewhere.[10]

Autoimmune and Inflammatory Disorders

Myoclonus occurs in about 40 percent of patients with *Hashimoto encephalopathy* (also called encephalopathy associated with autoimmune thyroid disease). Any combination of cognitive impairment, encephalopathy, psychosis, transient neurologic deficits, myoclonus or tremor, seizures, somnolence, or coma develops and fluctuates over weeks to months. The myoclonus may be generalized or multifocal and spontaneous or reflex-evoked, and is without EEG correlates. Patients are clinically euthyroid, with elevated antithyroid antibodies, the levels of which correlate poorly with the clinical state. Further clinical and laboratory details are provided in Chapter 18.

Myoclonus has been described in the *antiphospholipid syndrome*. Nonvasculitic *autoimmune inflammatory meningoencephalitis* may present with the rapid onset of dementia, parkinsonism, and myoclonus. In rare instances, the EEG shows persistent periodic sharp waves suggestive of Creutzfeldt–Jakob disease; dramatic clinical improvement has occurred with corticosteroids.

A myoclonic syndrome often accompanied by ataxia may occur in *celiac disease*, despite normal vitamin B_{12} and E levels. Typically, patients have a gastrointestinal syndrome that may include chronic diarrhea and abdominal pain, although gastrointestinal complaints may be subtle (only nausea and vomiting episodes during infection in one report). Action or reflex myoclonus may occur in patients with established celiac disease, but whether this relates to inadequate dietary restriction or poor compliance is uncertain. The myoclonus initially may be focal but usually becomes multifocal; generalized convulsions may develop. The jerks are usually preceded by a time-locked polyspike EEG discharge, supporting a cortical origin. In some cases improvement occurs after a gluten-free diet is instituted. Anticonvulsant or benzodiazepine therapy is commonly required but is incompletely effective. Opsoclonus-myoclonus has also been described in a child with celiac disease and responded to a gluten-free diet.

Drug- and Toxin-Induced Myoclonus

Neuroleptic malignant syndrome may complicate neuroleptic treatment but also occurs with dopamine-depleting agents and on withdrawal of dopaminergic treatments.

It is primarily due to functional dopamine deficiency, which leads to disinhibition of cortical and subcortical excitatory pathways; norepinephrine and serotonin may also be involved. Its incidence is 0.2 percent of patients exposed to neuroleptic agents. The disorder occurs within a month of starting the neuroleptic agent. Fever, rigidity, and an elevated serum creatine kinase (the major criteria) and tachycardia, labile blood pressure, tachypnea, diaphoresis (autonomic instability), altered mental status, and leukocytosis (the minor criteria) develop over 24 to 72 hours. Altered mental status and rigidity are often the first signs and are each present in over 95 percent of instances. The presence of all three major or two major and four minor criteria is highly predictive of the syndrome. The movement disorder is primarily an axial rigidity with tremor, choreoathetosis, dystonia, or myoclonus in the limbs. Rhabdomyolysis, renal insufficiency, respiratory failure, adult respiratory distress syndrome, disseminated intravascular coagulation, myocardial infarction, pulmonary embolism, and coma may complicate the picture.

The patient is best managed in the intensive care unit. Treatment involves discontinuing the offending neuroleptic or other precipitating drug (or reinstituting dopaminergic medication) and supportive therapy, including rehydration and reduction of body temperature by antipyretics or with artificial cooling if warranted. It may require administering the muscle excitation–contraction uncoupler dantrolene sodium at 1 to 2.5 mg/kg intravenously four times daily (maximum 10 mg/kg per day) and the dopamine agonist bromocriptine at 2.5 mg orally or via nasogastric tube four times daily (titrated up to 45 mg/day as required). Other dopamine agonists, amantadine, or carbidopa-levodopa can also be used in place of bromocriptine. Dopaminergic treatment should continue for 7 to 10 days, which is the usual duration of the disorder, and then slowly tapered. Rhabdomyolysis and renal failure are the greatest predictors of poor outcome. The mortality rate is between 10 and 20 percent. Survivors almost always achieve complete recovery.

The *serotonin syndrome* is a potential complication of treatment with antidepressants and related medications that increase cerebral serotonin neurotransmission. It is characterized by mental status changes, autonomic hyperactivity and neuromuscular abnormalities. The prerequisite is a recent increase in the dosage of a serotonergic agent or the addition of a new one. Cognitive and behavioral changes include confusion, hypomania, and agitation; myoclonus, ataxia, hyperreflexia, or tremor may also be present. Autonomic disturbances include nausea, vomiting, diarrhea, labile blood pressure, fever, shivering, and diaphoresis. Seizures may occur. The symptoms may begin as early as 2 hours after the medication is taken and usually resolve within 24 hours on discontinuation of the offending agent. When severe, serotonin syndrome may be indistinguishable from neuroleptic malignant syndrome and has a similar risk of multiple organ failure and death. Treatment requires discontinuation of precipitating drugs, supportive care, treatment for agitation with benzodiazepines and for hyperthermia with cooling measures and—if necessary—neuromuscular paralysis. Despite these measures, administration of a 5-HT$_{2A}$ antagonist such as cyproheptadine (4 to 8 mg, followed by 4 mg six times daily to a total of 0.5 mg/kg daily) may be necessary. Chlorpromazine (50 to 100 mg intramuscularly) has also been used for this purpose, but evidence of efficacy is lacking.

Of the non-neuroleptic psychiatric medications capable of causing myoclonus, *lithium* toxicity is well described. A variety of presentations occur including action, spontaneous, or stimulus-sensitive myoclonus, sometimes with opsoclonus. The myoclonus is of cortical origin but is not associated with epileptiform EEG abnormalities. Vomiting and a decreased level of consciousness may also be present; in rare instances the presence of cognitive changes and characteristic EEG findings suggests the erroneous diagnosis of Creutzfeldt–Jakob disease. Full recovery is usual. Overdose with *tricyclic antidepressants* may result in myoclonus because of their ability to inhibit reuptake of serotonin and norepinephrine. Myoclonus may occur with *levodopa* treatment. Reducing the levodopa dosage may diminish the myoclonus.

Tardive myoclonus due to neuroleptic medications is the least common of the tardive syndromes. It usually affects the face, neck, or upper limbs and responds to withdrawal of the neuroleptic treatment, but the movements may take several months to resolve. Benzodiazepines are sometimes useful.

A number of other medications and toxins have occasionally been associated with myoclonus and are summarized in Table 58-3. A pharmocovigilance study in 423 patients found drug-induced myoclonus was associated with anti-infectious agents (15%), antidepressants (15%), anxiolytics (14%), opiate agents (12%), antiparkinsonian medications (7%), and neurolepics (12%).[11]

Among illicit drugs, *cocaine* most commonly causes movement disorders. Myoclonus can be seen in the setting of a cocaine-induced disorder resembling neuroleptic malignant syndrome or as multifocal rest and action myoclonus together with opsoclonus and ataxia.

Myoclonus may develop in *gasoline sniffers* as a result of lead toxicity; it may be segmental or generalized and occurs spontaneously, with movement, or in response

TABLE 58-3 ■ Selected Drugs and Toxins Inducing Myoclonus

Anesthetics

Etomidate, enflurane, chloralose, methohexital, propofol, thiopental, spinal anesthesia

Anticonvulsants

Carbamazepine, gabapentin, phenytoin, lamotrigine, primidone, topiramate, valproic acid, vigabatrin

Antihistamines

Promethazine, omeprazole, oxatomide

Anti-infectious Agents

Carbenicillin, cephalosporins, ciprofloxacin, cefmetazole, gatifloxacin, imipenem, isoniazid, pefloxacin, piperazine, penicillin, (quinolones), ticarcillin, trimethoprim-sulfamethoxazole

Cardiac Medications

Diltiazem, flecainide, propafenone

Chemotherapeutic Agents

Busulfan, chlorambucil, ifosfamide, prednimustine

Dopaminergic Agents

Levodopa, dopamine agonists

Miscellaneous Medications

Amantadine, carisoprodol, cimetidine, metoclopramide, opiates, physostigmine, L-tryptophan

Narcotics

Diamorphine, fentanyl, hydrocodone, hydromorphone, methadone, meperidine, morphine, tramadol

Nonsteroidal Anti-inflammatory Drugs

Diclofenac

Psychiatric Medications

Antipsychotic medications, tricyclic antidepressants, lithium, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, clozapine, buspirone, lorazepam, methaqualone, midazolam, mirtazapine, sedative-hypnotics

Solvents and Gases

Acetone, carbon disulfide, ethyl benzene, methanol, ethylene oxide, formaldehyde, hydrogen sulfide, nitrous oxide, methyl chloride, methyl ethyl ketone, toluene

Heavy Metals

Aluminum, arsenic, bismuth salts, lead, manganese, organic mercury, thallium

Illicit Drugs

Cocaine, marijuana, methaqualone (Quaalude), methylenedioxymethamphetamine

Miscellaneous Agents and Toxins

Carbon monoxide poisoning, dichloroethane (used in dry cleaning), intrathecal water-soluble contrast media, tetraethyl lead

Pesticides

Aldrin, chlordane, chlordecone, cyclodienes, DDT, lindane, methyl bromide, organophosphate compounds, pyrethroids

Withdrawal Syndromes

Benzodiazepines, carbamazepine, dopaminergics

to an external stimulus. The condition may respond to chelation treatment with dimercaprol and calcium disodium edetate, although repeated exposures may result in a permanent encephalopathy. High serum levels of *bismuth*, used for treatment of certain gastrointestinal symptoms, may result in confusion followed by severe myoclonus, truncal ataxia, dysarthria, tremor, and sometimes generalized convulsions and coma. The syndrome can evolve slowly over months or acutely over days and has sometimes been confused with Creutzfeldt–Jakob disease or rapid-onset Alzheimer disease. The myoclonus may be multifocal or a massive generalized movement, and may occur spontaneously, on action, and in response to stimuli. Recovery over 3 to 12 weeks is the rule when the bismuth intake is discontinued early; chelation with dimercaprol may enhance renal clearance but has been associated with clinical deterioration in one patient. Diazepam, clonazepam, or valproic acid may reduce myoclonus.

Paraneoplastic Disorders

Multifocal myoclonus with opsoclonus is most commonly seen as a paraneoplastic syndrome. In children, 50 percent have an underlying neuroblastoma, whereas in adults it is more frequently associated with breast, ovarian, or small cell lung cancers. The most common antibody associated with paraneoplastic myoclonus is anti-Ri (ANNA-2) but myoclonus has also been associated with anti-Ma2, anti-Hu, and antiamphiphysin antibodies. PET with CT may be useful if initial radiologic screening is negative and early detection and treatment of the tumor appears to be useful. Occasionally the myoclonus improves with treatment of the underlying malignancy or prednisone, rarely with plasmapheresis, IVIg, cyclophosphamide, or immunoadsorption therapy with a protein A column. Myoclonus may respond to antiepileptic drugs.

Action and postural myoclonus has been reported in the setting of carcinomatous meningitis. It has also been described in a child with a rare cerebellar ganglioglioma, resolving with successful removal of the tumor.

Infections

Viral encephalopathies are the most common infectious cause of myoclonus (Table 58-2). In subacute sclerosing panencephalitis, myoclonus is time-locked to generalized bursts of high-voltage slow waves (periodic complexes) occurring approximately every 5 to 15 seconds on EEG. The myoclonus is relatively resistant to treatment, but sodium valproate, phenobarbital, carbamazepine, clonazepam, or levetiracetam may be tried. Herpes simplex virus encephalitis and postviral acute demyelinating encephalomyelopathy may also cause myoclonus. Segmental spinal myoclonus has occurred as a late complication of herpes myelitis.

Myoclonus occurs rarely with HIV infection. In a study of 2,460 inpatients with HIV infection, only 4 had myoclonus (2 with spinal myoclonus and 2 with generalized myoclonus).[12] Evaluation suggested four different causes: toxoplasmosis, HIV encephalopathy, tuberculous radiculomyelopathy, and herpes zoster. The myoclonus tends to be most prominent in the face, trunk, and proximal limbs and may be spontaneous or stimulated. Rarely, the myoclonus occurs with seroconversion, but usually the affected patients are significantly ill, often taking multiple medications. Treatment depends on the underlying cause; in some cases, myoclonus has resolved with antimicrobial treatment for opportunistic infections, retroviral therapy, or additional symptomatic medications. Other rare viral causes of myoclonus include mumps, chickenpox, parainfluenza virus type 3, coxsackievirus B3, poliovirus, St. Louis encephalitis, JC virus causing progressive multifocal leukoencephalitis, and encephalitis lethargica. Myoclonus or opsoclonus-myoclonus may also be the presenting symptom of West Nile virus infection.

Bacterial infections associated with myoclonus are less common than viral infections. Spinal myoclonus and opsoclonus-myoclonus have been reported in Lyme neuroborreliosis and in typhoid (enteric fever). Opsoclonus-myoclonus has also been described as a sequela of group A β-hemolytic streptococcal infection and responds to corticosteroid treatment. Multifocal myoclonus may be a rare feature of tuberculous meningitis or cerebral tuberculomas. Approximately 25 percent of patients with Whipple disease (discussed in Chapter 13) due to the gram-positive bacillus *Tropheryma whipplei* have myoclonus, although oculofacial and oculomasticatory myorrhythmias are the most characteristic movement disorders described.

Multifocal myoclonus may occur in the postmalaria neurologic syndrome, which also includes encephalopathy, tremor, and ataxia, beginning days to weeks after treatment of malaria. It responds rapidly to corticosteroids. Multifocal and oculopalatal myoclonus have also been reported in neurocysticercosis.

Injury by Physical Agents

Spinal myoclonus may develop as a late complication of spine irradiation for cancer. The high-pressure neurologic syndrome, which occurs on diving beyond a depth of 100 meters, consists of cognitive impairment and hyperkinesis. Myoclonus occurs at a depth of 300 to 500 meters or 50 to 60 atmospheres. Segmental myoclonus has been reported in the setting of electrical injury. Finally, myoclonus may occur as a long-term consequence of severe head injury.

Approach to Diagnosis

As mentioned earlier, the clinical approach to evaluation of myoclonus requires a detailed history and full neurologic and general medical examination. If the myoclonus is considered pathologic and no offending drug or toxin is appreciated, screening blood studies may include a complete blood count and erythrocyte sedimentation rate; determination of electrolyte and glucose levels; thyroid, renal, and hepatic function tests; and drug and toxin testing. An EEG to exclude an epileptic basis and brain and spine MRI to exclude structural causes are important. Paraneoplastic antibody testing may also be helpful.

Treatment

When possible, myoclonus should be treated by addressing the underlying medical disorder. Immunotherapy may help when postinfectious or paraneoplastic causes are responsible. The location of the generator of the myoclonus can guide treatment. Cortical myoclonus responds best to anticonvulsants, particularly sodium valproate (0.6 to 3 g daily), clonazepam (0.5 to 12 mg daily), levetiracetam (1,000 to 3,000 mg daily), primidone (50 to 1,000 mg daily), and piracetam (2 to 20 g daily). Reticular reflex myoclonus and spinal myoclonus may respond to clonazepam. Other medications that have been anecdotally useful include anticholinergic agents, baclofen, tetrabenazine, acetazolamide, and opiates; γ-aminobutyric acid receptor agonists may also be effective. Combinations of two or three medications may be more effective than monotherapy.

TREMOR

Tremor is the most common of all involuntary movements and is defined as an involuntary, rhythmic oscillation of a body part. It can be physiologic (normal) or pathologic, and is characterized by its frequency, amplitude, and distribution, and the position in which it occurs. Tremor is most easily classified as rest or action tremor.

Some forms of tremor are generated primarily by a central oscillator, as in essential tremor, and others, such as physiologic tremor, are mainly mechanical in origin. Central tremor is generated in the cerebellothalamocortical and dentatorubro-olivary pathways, with a poorly understood contribution from basal ganglia circuits. Rest tremor is characteristic of *parkinsonism*, which itself may occur secondary to a variety of causes. Such rest tremor is often accompanied by rigidity, bradykinesia, or postural instability, but may occur in isolation. Mechanical tremors decrease in amplitude and frequency with a load, whereas centrally generated tremors decrease only in amplitude.

Stroke

Tremor may occur as a consequence of stroke. The most common lesions involve the thalamus, mesencephalon, rubro-olivary tract, and cerebellar tracts. Limb tremor may occur with lesions of the cerebral cortex. Poststroke tremor is often unilateral or segmental rather than generalized, and may be associated with other movement disorders. It is usually an action tremor (i.e., postural or kinetic, or both). It often fails to respond to primidone or propranolol or to other symptomatic agents such as clonazepam, valproate, or anticholinergic agents, and, in severe cases, may necessitate thalamic deep brain stimulation.

Medications

It may be difficult to determine whether a tremor has been caused or simply enhanced by a particular medication.[13] Tremor is common and may be a normal finding (physiologic tremor). Other causes must be excluded before a tremor can be ascribed to medication. The timing of tremor onset in relation to the introduction of a medication or to dose adjustments may be suggestive, as may the symmetry of the tremor and its failure to progress other than with dose adjustments. Patients often take more than one medication, so that identification of the offending drug may be difficult. Drug interactions may confound recognition. Medications can cause the full spectrum of tremor subtypes (rest, postural, or kinetic), although postural tremor is most common (Table 58-4). Intention tremor refers to the subtype of kinetic tremor that becomes more prominent as the limb approaches the target. Most medication-induced tremors respond to dose reductions or discontinuation of the responsible agent.

Commonly used medications such as adrenergic agonists, including all β-agonists, lithium, caffeine, corticosteroids, tricyclic antidepressants, cyclosporine, and thyroid excess usually cause postural tremor. Dopaminergic and anticonvulsant medications also cause an enhanced physiologic tremor. Lithium- or valproate-induced tremor may be present at rest and is enhanced with posture or action.

Tremor is particularly common with lithium, valproate, and amiodarone. Lithium-related tremor occurs most often in the elderly, mainly affects the hands, and is usually mild. It may be enhanced by concomitant treatment with tricyclic antidepressants or selective serotonin reuptake inhibitors and alleviated by propranolol. The tremor induced by valproate is dose related and is more marked with immediate-release than controlled-release preparations. It may be ameliorated by propranolol, acetazolamide, or amantadine. The antiarrhythmic amiodarone may cause a postural and terminal movement tremor in up to 20 to 30 percent of patients. The tremor is dose dependent, may become apparent at any time during treatment, and usually improves or settles within weeks of dose adjustment or discontinuation of the medication. The mechanisms by which tremors are induced by these medications are unknown.[13]

Central monoaminergic stimulation by neuroleptics, phenylethylamines, and indoles may result in a parkinsonian rest tremor and a postural tremor. Specifically, tremor is seen in neuroleptic malignant syndrome and serotonin syndrome (discussed earlier). Dopamine receptor-blocking drugs and dopamine-depleting agents such as tetrabenazine and reserpine may also trigger a rest tremor.

Toxins and Recreational Agents

A variety of toxins cause tremor directly or as part of a withdrawal syndrome (Table 58-4). Tremor may occur with acute cocaine intoxication, and persists in abstinent cocaine-, alcohol-, and opiate-dependent subjects for months after the last use; rest tremor is reportedly more common in those with prior cocaine use. Alcohol and other drug withdrawal states enhance, sometimes asymmetrically, postural physiologic tremor, which decreases with time but can be treated with propranolol or benzodiazepines. The intention tremor of chronic alcohol abuse, however, is the result of cerebellar injury by alcohol. With cannabis use, withdrawal symptoms may occur after as little as 7 days of use and include tremor, irritability, restlessness, anorexia, fever, and other sympathetic effects.

Intoxication with heavy metals and organic compounds may produce a rest or action tremor, and

TABLE 58-4 ■ Drugs and Toxins Causing Tremor

Drug or Toxin	Kinetic or Postural Tremor	Intention Tremor	Rest Tremor
Anticonvulsants	Carbamazepine, felbamate, lamotrigine, phenytoin, tiagabine, topiramate, valproate, vigabatrin	—	Valproate
Antidepressants and mood stabilizers	Amitriptyline, lithium, MAOIs, SSRIs, valproate	Lithium	Lithium, SSRIs, valproate
Anti-infectious agents	Trimethoprim-sulfamethoxazole	Vidarabine	Trimethoprim-sulfamethoxazole, amphotericin
β-Adrenergic agonists	Salbutamol, salmeterol	Salbutamol, salmeterol	
Cardiac medications	Amiodarone, mexiletine, procainamide		
Chemotherapy	Cytarabine, ifosfamide, tacromilus, vincristine	Cytarabine, ifosfamide	Thalidomide
Dopamine-blocking and -depleting agents	Cinnarizine, haloperidol, metoclopramide, thioridazine, reserpine, tetrabenazine	—	Cinnarizine, metoclopramide, neuroleptics (e.g., haloperidol, thioridazine), reserpine, tetrabenazine
Recreational agents	Cocaine, ethanol, MDMA, nicotine	—	Cocaine, ethanol, MDMA, MPTP
Hormone treatments	Calcitonin, sex steroids, thyroxine, (medroxy)progesterone, tamoxifen	Epinephrine	(Medroxy)progesterone
Immunosuppressants	Cyclosporine, tacrolimus, interferon-alpha	Cyclosporine, tacrolimus	Cyclosporine
Metals	Arsenic, lead, mercury	—	Lead, manganese, mercury
Miscellaneous agents	Metoclopramide, cimetidine, theophylline, caffeine, cyanide	—	Metoclopramide
Toxins	Organochlorine pesticides	—	Methanol
Withdrawal syndromes	Cannabis, ethanol	—	—

MAOI, monoamine oxidase inhibitor; MDMA, methylenedioxymethamphetamine; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropryidine; SSRI, selective serotonin reuptake inhibitor.

improvement after withdrawal of the toxin depends on the severity and duration of exposure.

Metabolic Disorders

Almost any metabolic derangement may be associated with tremor. Thyrotoxicosis is the most common, producing an enhanced physiologic tremor. It affects any age group and responds to treatment of the underlying disorder, but it can also be ameliorated by propranolol. Tremor and myoclonus are seen frequently in Hashimoto encephalopathy. Tremor is one of the first and most prevalent signs of hypoglycemia and may be seen in nonketotic hyperglycemia along with myoclonus, chorea, and dystonia. In renal insufficiency, a postural and action tremor is often evident before asterixis develops, and may foreshadow encephalopathy. The tremor in Wilson disease may be postural, kinetic, or at rest. A coarser movement of the upper limb ("wing beating" tremor) also occurs. It is present in the proximal arms and occasionally the head in the flexion–extension plane, and is due to thalamocapsular and cerebellar system pathologic processes. Chelation therapy and liver transplantation can reverse the neuropathologic process, but there is no effective symptomatic treatment. Hemochromatosis is associated with tremor, parkinsonism, and dementia due to iron deposits in the basal ganglia; progression may be forestalled by phlebotomy or liver transplantation. Variegate porphyria and the hyperadrenergic state associated with pheochromocytoma may also cause tremor, as can striatal injury in the setting of hypoxic-ischemic encephalopathy.

Hypomagnesemia and hypocalcemia may lead to tremor, muscle twitching, and irritability, and a severe, movement-associated, distal flapping tremor may occur in hypercalcemia due to hyperparathyroidism. Tremor has been reported with hyponatremia and its correction. Severe vitamin E deficiency may cause tremor in addition to spinocerebellar findings and peripheral neuropathy, and tremors may respond to vitamin E supplementation. In infants, vitamin B_{12} deficiency can produce a generalized tremor syndrome and mental retardation, which are partially reversible with supplementation, although the abnormal movements may transiently increase with treatment before resolving.

Infections

Viral encephalitides are probably the most common infections to cause tremor (Table 58-2). Generalized tremors have also been described with poliovirus infection, St. Louis encephalitis, and the rhombencephalitis that sometimes complicates hand-foot-and-mouth disease (due to enterovirus 71). Respiratory syncytial virus encephalitis and mumps, with a predilection for the cerebellum, manifest as intention tremor and ataxia. Echovirus 21 encephalitis and Japanese encephalitis result in tremor through basal ganglia and cerebellar involvement. Herpes zoster–related vasculitis affecting the midbrain may result in an ipsilateral cerebellar syndrome with intention tremor. Congenital cytomegalovirus infection and rubella and adult tickborne meningoencephalitis result in longlasting neurologic dysfunction, including tremor. The encephalopathy sometimes present with Lassa fever may be accompanied by tremor, seizures, and coma. Meningoencephalitic involvement with flaviviruses may cause tremor in addition to the typical dengue hemorrhagic fever. A similar picture is seen in Bolivian hemorrhagic fever caused by Machupo virus (family Arenaviridae), which responds to ribavirin.

Tremor disorders occur rarely in early HIV infection but occur in 5 to 44 percent of those with HIV-associated dementia. Tremor may be part of an HIV-related parkinsonian syndrome or may occur in isolation. Typically, there is a symmetric postural tremor but there may be a rest component; kinetic components are rare. Holmes (rubral) tremor, in which rest, postural, and kinetic components are present, has been reported in AIDS and often results from opportunistic infections such as tuberculosis or toxoplasmosis. In addition to drug-induced tremor from dopamine-blocking drugs such as neuroleptics and antiemetics, AIDS patients may develop a reversible rest or postural tremor from trimethoprim-sulfamethoxazole. Treatment of tremor in HIV infection depends on etiology; drug-induced tremor and tremor secondary to opportunistic infection may be reversible.

Tremor occurs in up to 17 percent of those with tuberculous meningitis and 30 percent of those with tuberculomas and is usually of the postural variety. It may respond to antituberculous therapy over several weeks; if not, symptomatic treatment may be considered.

Recovery from *Plasmodium falciparum* malaria is occasionally followed by a corticosteroid-responsive encephalopathy with postural tremor, cerebellar ataxia, myoclonus, seizures, and motor aphasia. In neurocysticercosis, tremor and parkinsonism are the most frequent movement disorders. Tremor is also seen in typhoid, together with altered bowel habits. Unilateral postural, kinetic, and Holmes tremor have been reported with thalamic toxoplasmosis in HIV-positive patients.

Immune Disorders

CNS lupus may include tremor among its many features. Waldenström macroglobulinemia has been associated with an asymmetric tremor and peripheral neuropathy. Basal ganglia and brainstem involvement in Behçet syndrome may result in postural tremor, and pyramidal and extrapyramidal findings. Tremor may occur as a complication of celiac disease.

In Hashimoto encephalopathy, in which myoclonus and seizures are common, 80 percent of patients have postural tremor. In patients older than 50 years with cerebellar degeneration, the etiology is paraneoplastic in about half. Intention tremor, ataxia, and dysarthria are particularly associated with anti-Yo antibodies in gynecologic cancers and anti-Hu antibodies in small cell lung cancers.

Some immune-mediated polyneuropathies, particularly those associated with IgM monoclonal gammopathy, are accompanied by a distally predominant action and postural tremor. In a case-control study, 29 percent of subjects with IgM monoclonal gammopathy of undetermined significance had tremor compared to 9 percent of controls; among the 60 with tremor, 49 had postural and kinetic tremor, 8 had rest tremor, and 3 had mixed rest and action tremor.[14] The tremor sometimes responds to immunosuppressive therapy or propranolol. A postural and kinetic tremor may follow Guillain–Barré syndrome and occur in chronic inflammatory demyelinating polyneuropathy.

Other Causes of Tremor

Postural and kinetic tremors may develop after head trauma and may be transient or permanent. Cerebral radiation and gamma-knife treatments cause postural or Holmes tremor in rare instances. A postural and intention tremor may develop during compression during dives to depths greater than 100 meters as part of the high-pressure neurologic syndrome. It usually remits on decompression but occasionally persists for several months.

Approach to Diagnosis

Rapid onset (over days to months) of tremor is atypical for essential tremor but may occur when drug induced or related to an underlying medical disorder. If no offending drug or toxin is recognized, screening blood studies should include determination of electrolyte and glucose concentrations as well as thyroid, renal, and hepatic function tests. Testing for serum cortisol, parathyroid hormone, and ceruloplasmin; 24-hour urinary copper excretion; and toxicology assays may also be necessary in individual instances. Brain MRI may be required to exclude structural causes, particularly when there are other neurologic findings or the tremor is asymmetric.

Treatment

In all cases of tremor, an underlying disorder should be sought and treated while symptomatic treatment is contemplated. Action tremor, and particularly aggravated physiologic tremor, usually responds to adrenergic blockade or primidone. Other agents, including alprazolam, atenolol, gabapentin, sotolol, and topiramate, are also useful. Benefit may also occur with nadolol, nimodipine, clonazepam, botulinum toxin A, deep brain stimulation, thalamotomy and gamma-knife or ultrasound thalamotomy. Pregabalin is sometimes helpful. Rest tremor is treated by anticholinergic agents, amantadine, and dopaminergic medications; deep brain stimulation of the globus pallidus or subthalamic nucleus may be used in patients with severe parkinsonian tremor that is refractory to medications.

Cerebellar tremor is the most difficult to treat and only occasionally improves with the treatments described above. Holmes (rubral) tremor is poorly responsive to treatment but sometimes improves with levodopa, dopamine agonists, trihexyphenidyl, or some of the medications used for essential tremor; in other instances, deep brain stimulation may be necessary.

PARKINSONISM

Parkinson disease is the most common cause of parkinsonism, but there are a number of other causes that relate to systemic disease and therefore merit discussion here.

Vascular Causes

An akinetic-rigid syndrome may occur acutely, usually after infarcts of the basal ganglia, or may develop in a delayed manner, months to years after focal, multifocal, or global ischemic events. Patients may have multiple risk factors for vascular parkinsonism, such as hypertension, diabetes, hyperlipidemia, and cigarette smoking. Unlike classic Parkinson disease, the clinical disorder usually occurs later in life (in the seventh or eighth decade) and symptoms develop more rapidly. Presentation may be with gait impairment, postural instability, and so-called lower-body parkinsonism. The findings may be symmetric or asymmetric, with limb rigidity or spasticity, hyperreflexia, and extensor plantar responses; a pseudobulbar palsy and cognitive deficits may also be present. Rest tremor is uncommon but postural tremor may occur. Brain imaging commonly shows bilateral lesions often involving the external capsule, corona radiate, thalamus, basal ganglia, substantia nigra, and pons, and there may be extensive periventricular white matter lesions. Unilateral parkinsonism may occur with infarcts of the lenticulostriate arteries involving the contralateral basal ganglia.

Only a limited number of studies have explored the treatment of vascular parkinsonism. About one-third of patients—usually those with involvement of the nigrostriatal pathways—respond to levodopa, but the level of benefit is often disappointing. Medication for secondary stroke prevention may arrest progression of parkinsonian deficits and improve the long-term prognosis.

Other vascular events such as a midbrain hemorrhage, subdural hematoma, cortical venous thrombosis, arteriovenous malformations, and giant cerebral artery aneurysm may cause parkinsonism. It has also been reported in patients with vasculitis related to various connective tissue diseases.

Medications and Bone Marrow Transplantation

Drug-induced parkinsonism is common; one population-based study found that parkinsonism was likely drug induced in 20 percent of cases. Drug-induced parkinsonism differs from Parkinson disease in that symptom onset may be rapid, often over weeks, bradykinesia is more symmetric, and tremor and postural instability are less common.[15] However, individual cases may be clinically indistinguishable from Parkinson disease. Drug-induced parkinsonism occurs most often in patients treated with D2 dopamine receptor blockers (e.g., antipsychotics and metoclopramide), monoamine depleters (reserpine or tetrabenazine), and certain calcium-channel blockers (especially cinnarizine and flunarizine). A French pharmacovigilance center reported 155 cases of drug-induced or -worsened parkinsonism between 1993 and 2009.[15] About 70 percent of the cases were observed in the first 3 months after introduction of the suspect drug, whereas 30 percent occurred after 1 year. Rigidity was the most common symptom. Antipsychotic treatment (including haloperidol, risperidone, and olanzapine) was cited in 113 cases, diazepines in 15, selective serotonin reuptake inhibitors in 12, calcium-channel blockers (flunarizine, cinnarizine, verapamil and diltiazem) in 13, H1 antihistamines in 12, valproate in 10, metoclopramide in 9, and lithium in 4. Improvement occurred after stopping the medication in 89 percent of cases. Abrupt discontinuation of dopamine-blocking medications should be avoided. In our experience, reversal of symptoms may take months or even up to a year.

Acute or subacute parkinsonism has developed from disulfiram treatment or overdose. Encephalopathy, hyperglycemia, ketosis, bradykinesia, and rest tremor may develop and may improve after disulfiram is discontinued and with supportive therapy. CT may show hypodensity and MRI shows increased T2 signal in the putamen and globus pallidus.

After bone marrow or organ transplantation, parkinsonism has developed in several patients after starting cyclosporine and resolved after discontinuing it.

Toxins

Since the recognition that 1-methyl-4-phenyl-1,2,3,6-tetrahydropryidine caused rapid-onset parkinsonism, a great deal of research has shown that factors adversely affecting energy metabolism and disposal of damaged proteins in dopaminergic neurons may cause parkinsonism. In most epidemiologic studies, prolonged exposure to pesticides (particularly insecticides and herbicides) is a risk factor for Parkinson disease.

Other toxins that have been associated with parkinsonism include polychlorinated biphenyls, carbon monoxide, cyanide, some metals (mercury and manganese), and some organic solvents (carbon disulfide, trichloroethylene, and methanol). Several of these were discussed earlier in this chapter. A disorder similar to manganism may follow intravenous methcathinone use for recreational purposes (discussed on p. 1025). Carbon monoxide toxicity results from a combination of tissue hypoxia and direct cellular toxicity especially affecting the basal ganglia. Several weeks to months after initial recovery, about 10 percent of survivors will develop parkinsonism (hypomimia, rigidity, bradykinesia but without rest tremor) that is unresponsive to antiparkinsonian medications but often regresses spontaneously within 6 months.

Methanol poisoning may cause an acute parkinsonian state, but chronic exposure has also been associated with the development of parkinsonism. Acute intoxication may cause coma. Upon recovery, visual impairment, hypophonia, rigidity, and bradykinesia develop and may respond to dopaminergic agents. Brain imaging shows hypointensity of the putamen on CT scan and hyperintense lesions of the putamen on T2-weighted MRI.

Welders are frequently exposed to manganese-containing fumes, but it remains unclear whether this is associated with the development of parkinsonism. In other circumstances, chronic manganese exposure alone or in combination with liver failure has caused extrapyramidal, parkinsonian-like syndrome. Brain MRI often shows increased signal in the globus pallidus on T1-weighted images. In some cases there is improvement after chelation therapy. This form of parkinsonism is poorly responsive to dopaminergic treatment.

Metabolic Disorders

Several metabolic conditions may mimic Parkinson disease including hypothyroidism, extrapontine myelinolysis, chronic liver failure, hemochromatosis, and Wilson disease. In Wilson disease rigidity, bradykinesia, hypophonic speech, and tremor as well as autonomic disturbances may occur. Parkinsonism has been described in liver failure from other causes. In a prospective study, 21 percent of patients with liver failure being considered for liver transplantation had parkinsonism.[16] Clinical features included rapid progression over months, symmetric akinetic-rigid syndrome, postural but not rest tremor, and early gait impairment. Serum and CSF manganese levels were elevated, and MRI showed hyperintensities involving the globus pallidus and substantia nigra resembling that seen in patients with manganese exposure (Fig. 58-1). Some of these patients responded to levodopa.

Although Goswami and colleagues found that idiopathic hypoparathyroidism was associated with basal ganglia calcifications in 107 of 145 patients, parkinsonism occurred in only 2.[9] Treatment with calcium, parathyroid hormone, and levodopa may be helpful, but treatment with vitamin D is also sometimes required. In rare instances, parkinsonism has developed in patients with hyperparathyroidism and resolved after surgery.

Acute parkinsonism has been described in patients with diabetes and uremia requiring dialysis. Cognitive impairment, dysarthria, bradykinesia, and rigidity develop over days to weeks. There is typically an elevated serum creatinine, uremia, and a metabolic acidosis. Brain CT shows hypodense lenticular nuclei, and MRI shows T1 hypointense and T2 hyperintense lesions in the putamen and globus pallidus (Fig. 58-2). The condition and imaging abnormalities may resolve with hemodialysis. Development of this syndrome has been related to preceding hypoglycemia.

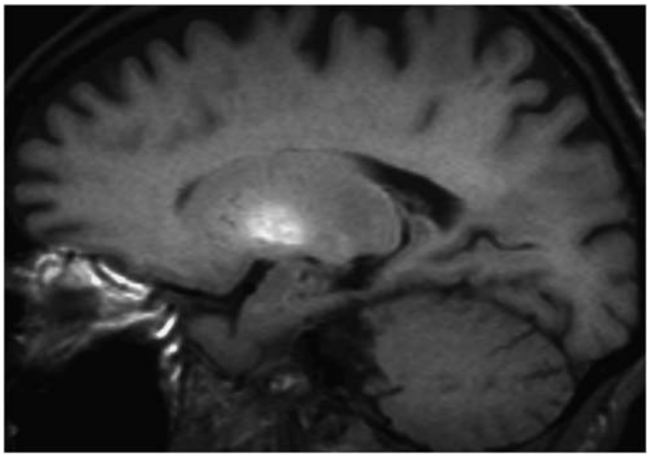

FIGURE 58-1 ■ Sagittal T1-weighted magnetic resonance image showing increased signal in the globus pallidus in a 39-year-old man with advanced liver disease due to hepatitis with a 1-year history of a gait disturbance and intermittent tremulousness. Examination showed subtle tremulousness and slowing of rapid repetitive movements in all limbs. Laboratory evaluation revealed elevated serum manganese.

Infections

Various infections may cause parkinsonism acutely or as a long-term complication (Table 58-2). Viral infections that have been associated with this phenotype include herpes simplex, HIV, Japanese encephalitis, coxsackie B, influenza A, measles (and related subacute sclerosing panencephalitis), mumps, polio, Western equine encephalitis, dengue, and St. Louis encephalitis.[17] Japanese encephalitis, prevalent in most Southeast Asian countries, is estimated to be the most common viral cause of parkinsonism. Parkinsonism or other movement disorders develop 1 to 4 weeks after the acute phase and may persist for months to years. Patients with chronic hepatitis C infection have a higher incidence of Parkinson disease than uninfected subjects.

HIV infection may cause parkinsonism by direct injury to the basal ganglia or as a consequence of immunodeficiency. AIDS-associated parkinsonism is characterized by symmetric bradykinesia, rigidity, postural instability and gait impairment; tremor is often absent. Postural and gait instability may occur early. The parkinsonism may be secondary to opportunistic infection, drug induced, or related more directly to the HIV infection. There is evidence of early involvement of the basal ganglia in HIV infection: anatomic neuroimaging reveals selective basal ganglia atrophy, and functional imaging shows relative hypermetabolism in the basal ganglia and thalamus. Neuropathologic examination frequently

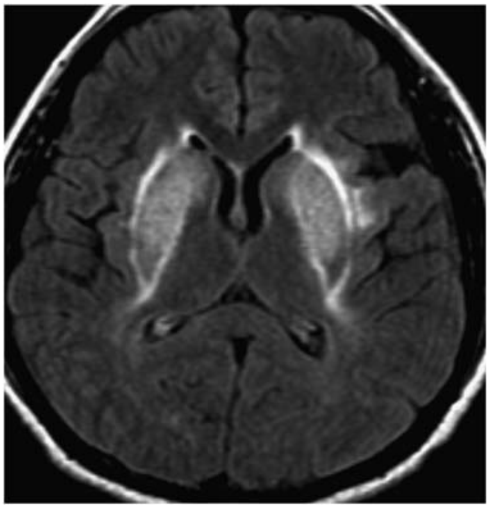

FIGURE 58-2 ■ This axial fluid-attenuated inversion recovery-weighted MRI was obtained from a 41-year-old woman with a long history of diabetes and dialysis-dependent renal failure with rapid-onset encephalopathy, dysarthria, tremor, rigidity, and bradykinesia. It shows increased signal in the putamen and globus pallidus bilaterally. Her condition improved with dialysis.

shows evidence of HIV infection with microglial nodule encephalitis affecting the putamen and caudate nuclei. Both lymphoma and opportunistic infections with *Toxoplasma* and *Cryptococcus* show an affinity for the basal ganglia. Progressive multifocal leukoencephalopathy caused by JC virus in immunosuppressed individuals may also cause parkinsonism. Perhaps because of the early involvement of the basal ganglia, HIV-infected patients develop drug-induced parkinsonism at lower doses of antipsychotic treatments.

When evaluating patients with HIV-related parkinsonism, opportunistic infection and drug-induced causes require exclusion. Treatment with dopaminergic medications may help. In some AIDS patients, parkinsonism has improved after initiation of combination antiretroviral therapy. Another patient, whose initial presentation was parkinsonism with supranuclear gaze paresis and postural instability and who did not have an AIDS-defining diagnosis but had a CD4 count of 266, reportedly improved on treatment with combined antiretroviral therapy after obtaining no benefit with levodopa.

Since the epidemic of 1916 to 1927, only sporadic cases of parkinsonism following encephalitis lethargica have been described. CSF shows a lymphocytic pleocytosis and oligoclonal bands, but bacterial and viral studies are unrevealing. Brain imaging may show inflammatory changes in the basal ganglia or brainstem. Dale and colleagues found elevated basal ganglia antibodies in 20 patients who developed parkinsonism, a sleep disorder, dyskinesia, and neuropsychiatric symptoms that were attributed to encephalitis lethargica. In 65 percent, antistreptolysin-O titers were elevated and 95 percent had basal ganglia antibodies, raising the possibility that encephalitis lethargica is an autoimmune condition possibly triggered by bacterial infection such as in Sydenham chorea.[18] In a subsequent study in children with clinical features of encephalitis lethargica, NMDA receptor antibodies were found in those with dyskinesias, agitation, and seizures but not in those with parkinsonism and somnolence.[19] Atypical cases of parkinsonism associated with NMDA receptor antibodies have been described, with amelioration by immunotherapy. Improvement may occur with methylprednisolone, with or without IVIg.

Tuberculous meningitis is a rare cause of parkinsonism. Infection with *Mycoplasma pneumoniae* is another rare cause of parkinsonism. The condition begins with a flu-like illness, and bradykinesia follows; T2-weighted MRI shows increased signal of the basal ganglia, which resolves several months after treatment of the infection. Reversible parkinsonism has been reported in Lyme disease. Other infections associated with parkinsonism, generally in association with other neurologic abnormalities, include prion disease and neurosyphilis.

Malaria and neurocysticercosis (both parasitic conditions) may cause parkinsonism and tremor. In neurocysticercosis, improvement may occur with albendazole and, when hydrocephalus is present, placement of a CSF shunt.

Autoimmune and Paraneoplastic Disorders

Parkinsonism may occur as a complication of systemic lupus erythematosus; rigidity and akinesia are more common than tremor, and pyramidal signs may be present. In a case series of 41 patients with CNS lupus, 2 presented with parkinsonism and responded to immunosuppressant (but not dopaminergic) treatment.[5] In addition to the common findings of recurrent oral and genital ulcerations, bilateral posterior uveitis and retinal vasculitis, skin papules, parkinsonism, and postural tremor have been observed in Behçet syndrome. Nonvasculitic autoimmune inflammatory meningoencephalitis may present with rapidly progressive myoclonus, dementia, and parkinsonism that improves with high-dose corticosteroids. The EEG may show persistent periodic sharp waves reminiscent of Creutzfeldt–Jakob disease. Parkinsonism has been described as a rare complication of the antiphospholipid antibody syndrome. The brain MRI shows periventricular white matter changes and the condition responds poorly to levodopa.

Paraneoplastic parkinsonism (with bradykinesia, rigidity, and tremor) and eye-movement abnormalities have been described in patients with anti-Ma2 antibodies, which are often associated with paraneoplastic limbic or brainstem encephalitis. Parkinsonism has been reported in association with the CRMP-5 antibody (although chorea is more common) and the antineuronal nuclear autoantibody type 2, and rarely with NMDA receptor antibodies as discussed earlier. Finally, parkinsonism occurs in approximately 10 percent of patients with voltage-gated potassium channel antibodies.

Trauma

Development of parkinsonism after a single head injury is rare; it typically follows severe injury with loss of consciousness. Symptoms may develop over several months. Neuroimaging usually demonstrates a lesion of the globus pallidus or substantia nigra. Parkinsonism may be secondary to chronic subdural hematoma, typically developing within weeks of the causal injury. Complete or near-complete remission of parkinsonism often follows drainage of the hematoma.

Parkinsonism may occur after repeated head injury, as in boxing. A variable spectrum of signs and symptoms may be present, including behavioral changes, dementia, and corticospinal and cerebellar deficits; dysarthria is especially common, and parkinsonism occurred in 18 of 48 subjects with recurrent head injury in one series.[20] Pathologic examination revealed atrophy of the cerebral hemispheres, medial temporal lobe, thalamus, mammillary bodies, and brainstem. Histologic examination showed extensive tau-immunoreactive neurofibrillary tangles, astrocytic tangles, and spindle-shaped neuritis. The disorder was distinguished from other tauopathies by its patchy distribution and the preferential involvement of the superficial cortical layers.[20] Patients often respond to dopaminergic treatment. The relationship of nonrepetitive remote head trauma to Parkinson disease is controversial and unsettled.

Other Causes of Parkinsonism

Some aspects of parkinsonism may be simulated by communicating or noncommunicating hydrocephalus or a subdural hematoma. In normal-pressure hydrocephalus, gait abnormalities predominate. Mass lesions are rare causes of parkinsonism. Parkinsonism resulting from focal irradiation of the brain or brainstem may respond to dopaminergic treatment and is sometimes partially reversible.

Approach to Diagnosis

Rapid onset of parkinsonism over days to months is atypical of Parkinson disease but occurs when drug induced, after infection, due to a structural brain injury (subdural hematoma, stroke, or hydrocephalus), or secondary to an underlying medical condition. If no offending drug or toxin can be identified, screening blood tests should be performed (blood electrolyte and glucose levels, erythrocyte sedimentation rate, and antinuclear antibody, as well as thyroid, renal, and hepatic function tests). Testing for 24-hour urinary copper excretion and serum ceruloplasmin determination should be considered in patients younger than 40 years. Toxicologic screening tests may be necessary in individuals for whom no cause is found. Brain imaging, particularly MRI, may be helpful.

Treatment

The management of secondary parkinsonism depends on the cause but generally includes symptomatic measures. The most common cause is medication related. When possible, the offending medication should be tapered to prevent worsening of any underlying psychiatric disorder for which it may have been prescribed and also to reduce the risk of precipitating a tardive movement disorder. When a behavioral disorder requires a dopamine-blocking agent, it is sometimes possible to switch to an antipsychotic medication with less affinity for the D2 receptor, such as clozapine or quetiapine. It may take weeks to many months for the full effect of a dopamine-blocking drug such as haloperidol to resolve.

In other cases of secondary parkinsonism, management of the underlying medical disorder may take precedence. In many cases, however, treatment of the primary disorder is inadequate and symptomatic therapy is appropriate. In general, treatment of parkinsonism with levodopa, dopamine agonists, or both, may improve bradykinesia, rigidity, or tremor. The effectiveness of dopaminergic treatment varies considerably between conditions. Other agents that may be particularly useful for tremor include amantadine and anticholinergic agents. Deep brain stimulation of the globus pallidus or subthalamic nucleus may be considered in selected patients who are refractory to medications.

GENERAL CONSIDERATIONS IN ADDRESSING HEADACHES IN THE ELDERLY
CONCLUDING COMMENTS

Headache disorders are very common, and therefore they often co-exist with one or more significant medical illnesses. This pairing can complicate the diagnosis of both the headache disorder and general medical conditions, while raising a number of treatment conflicts. In patients with multiple complex medical conditions, management decisions can be difficult. However, if the clinician is armed with an understanding of the key features of common headache disorders as well as a good basic background in clinical pharmacology, a successful approach to managing headaches in these patients is possible. This chapter will summarize epidemiologic observations regarding the co-occurrence of headaches and medical illnesses, explore the ways in which medical illness and headaches co-exist, and describe specific considerations regarding treatment of headaches in particular medical disease states.

ASSOCIATION OF HEADACHE AND GENERAL MEDICAL ILLNESS

Headache is the most common category of neurologic disease, and it has been estimated that around half of the world's adult population have experienced head pain in the last 12 months. Therefore, the comorbidity of headache with other medical illnesses is not surprising. For example, migraine has significant comorbidity with asthma and allergic conditions such as rhinitis, food allergies, hay fever, and bronchitis (Table 59-1). Migraine also seems to be more prevalent in people with gastrointestinal (GI) conditions such as peptic ulcer disease, hiatal hernia, and colitis, but the confounding factor of analgesic medication effects on the GI tract may complicate this relationship. There is suggestive evidence that hyperthyroidism and hypothyroidism are more commonly associated with migraine than would be predicted, and these patients should be screened for headaches at regular medical visits. All headache disorders are likely more prevalent in obesity, and worsening migraine frequency ("migraine chronification") is more common in those who are obese. Among the autoimmune disorders, celiac disease, Raynaud phenomenon, and systemic lupus erythematosus (SLE) are comorbid with migraine, as are chronic fatigue syndrome and fibromyalgia.[1,2]

Migraine, especially with aura, increases the risk of stroke, although evidence tends to be conflicting, with substantial differences seen across age groups and genders.[3] There is no clear epidemiologic association between migraine and epilepsy, although spells of each can be mistaken for one another. Recent data suggest

Systemic lupus erythematosus
Rheumatoid arthritis
Psychiatric disease including depression, anxiety, and bipolar affective disorder

that migraine is an independent risk factor for developing multiple sclerosis, but the pathophysiology that would link these two conditions is uncertain. Psychiatric comorbidity with migraine and other headache disorders has long been noted and there do seem to be significant bidirectional risks in patients with anxiety, depression, and bipolar disorder. There is a well-established increased co-occurrence of headache disorders in patients with sleep disorders, with probable bidirectional causality, since pain certainly can disrupt sleep, and sleep deprivation is a common trigger for headaches. Interestingly, little evidence exists for a higher prevalence of migraine in people with hypertension despite this common belief. There is an unclear association between migraine and ischemic heart disease, with the best evidence for an association being found in young women and in those who have migraine with aura.[4] The association between migraine and patent foramen ovale (PFO) has been noted, especially in patients with migraine with aura, although there is no evidence that PFO closure improves the severity or frequency of migraine.

In children, similar associations between headache disorders and medical illness have been noted. In particular, depression, anxiety, and sleep disorders are more common in children and adolescents with migraine and there does seem to be, unlike in adult populations, an increase in headache disorders in patients with epilepsy. In children and adolescents, attention deficit hyperactivity disorder (ADHD) and Tourette syndrome are comorbid with migraine, as are PFO, cardiovascular disease, and stroke.[5]

Underlying mechanisms by which medical illnesses might cause headaches include: (1) activation of dormant migraine or other primary headache disorders; (2) production of painful cranial or pericranial inflammation as a component of the underlying medical condition; (3) irritation or compression of cranial or pericranial nociceptive nerves; and (4) medication or other treatments causing headache as an adverse effect (Table 59-2).

In the other causal direction, headache conditions can lead to or exacerbate medical illnesses via the use

TABLE 59-2 ■ Common Medications and Substances Known to Cause Headache

Alcohol
Amantadine, levodopa
Antihypertensive medications including nifedipine, enalapril, hydralazine
Carbon monoxide
Cyclophosphamide
Estrogen, progesterone, tamoxifen
Food additives (monosodium glutamate, aspartame)
Illicit drugs including cocaine, marijuana, amphetamines
Interferons
Interleukin inhibitors
Monoamine oxidase inhibitors (e.g., phenelzine)
Nitric oxide donors (e.g., isosorbide, nitroglycerin)
Nonsteroidal anti-inflammatory analgesics (NSAIDs)
Phenothiazines
Pseudoephedrine, sympathomimetics
Ranitidine, famotidine, cimetidine
Selective serotonin reuptake inhibitors
Sildenafil, vardenafil, tardalafil
Tetracyclines, trimethoprim
Theophylline
Medication overuse of opioids, barbiturates, NSAIDS, simple analgesics, and combinations such as aspirin, acetaminophen
Substance withdrawal from opioids, barbiturates, benzodiazepines, cannabis, caffeine, estrogen

(or overuse) of medications employed in preventing or alleviating headache attacks. Examples include nonsteroidal anti-inflammatory drugs (NSAIDs) leading to GI irritation, ulceration, and bleeding; corticosteroid-induced complications such as bone necrosis; exacerbation of vascular disease by ergot medications; worsening of asthma by β-blockers; renal and hepatic toxicity from a number of headache prophylactic medications; and dependency and addiction to opioids and other analgesics. Medication interactions that result from simultaneously treating headache and general medical disorders are also common and can lead to systemic illness. Headache disorders can lead to a deterioration in general health by reducing activity, worsening sleep function, limiting social involvement, and causing financial stress.

SPECIFIC MEDICAL DISEASES AND HEADACHES

Cardiovascular Disease

Patients with coronary artery disease commonly experience headaches as a consequence of vasodilating medications used for cardiovascular benefit. Attempting to reduce the dose and frequency of these drugs can improve headache control. Treating primary headache disorders in patients with cardiovascular disease poses unique challenges. Ergots are contraindicated due to their vasoconstrictive effects, which are especially prominent in patients with co-existing peripheral vascular disease. NSAIDs used for headache can reduce the benefits of antithrombotics used to treat coronary artery disease and may also lead to an increased risk of myocardial infarction via unclear mechanisms.

A number of medications used in headache management can prolong the QT interval, leading to a risk of torsade de pointes. Commonly used agents in headache treatment that share this propensity include tricyclic antidepressants, dopamine blocking agents (including prochlorperazine, metoclopramide, chlorpromazine, and promethazine), and ondansetron. Patients with a tendency for palpitations and tachyarrhythmias should probably avoid tricyclic antidepressants, and patients with bradyarrhythmias should avoid β-blockers. All patients with cardiac conduction issues should use β-blockers and calcium-channel blockers carefully and only after careful consideration by their cardiologist. In the appropriate patient, β-blockers may be useful for both migraine prophylaxis and angina reduction.

A headache type termed "cardiac cephalalgia" is a relatively rare but important entity, as it can signal the onset of acute coronary disease. The mechanism for the head pain is not clear, although it is perhaps related to an unusual pattern of referred pain. The headache is notable that it resolves with antianginal medication.

Approximately 25 percent of the population has a PFO and the prevalence seems to be nearly double that in patients with migraine. Larger PFOs are found in persons who experience migraine with aura compared with those without aura. Based on observational data showing improvement in migraine following PFO closure for other reasons, it was suggested that PFO closure could help in preventing migraine attacks. However, a randomized controlled study examining PFO closure for migraine was negative, and people with migraine and PFO should not use closure as a means of controlling their headache frequency.

Hypertension

While hypertension alone seems not to be associated particularly with headache disorders, rapidly rising and malignant hypertension is commonly accompanied by head pain, reported by some to be posteriorly predominant. The presence of this headache can serve as an early indication for more aggressive blood pressure control to prevent hypertensive complications such as hypertensive encephalopathy, which itself is virtually always accompanied by headache in awake, communicative patients. The very small number of severely hypertensive patients who harbor an underlying pheochromocytoma will also commonly present with headaches, often highly unresponsive to treatment.

In hypertensive patients, posterior reversible encephalopathy syndrome can occur from the blood pressure rise itself, and the initial presentation may include, or even be limited to, headache. A possibly related condition, reversible cerebral vasoconstriction syndrome (RCVS) can occur in a number of settings including pregnancy and typically presents with one or more sudden severe thunderclap headaches. RCVS is diagnosed using noninvasive imaging which typically reveals multiple areas of intracerebral arteriolar narrowing, often with evidence of focal, cortical subarachnoid hemorrhage.

Some antihypertensive medications can be very useful in preventing migraine, including propranolol, atenolol, and nadolol. Angiotensin-converting enzyme inhibitors do not have significant antimigraine properties, but the angiotensin receptor blocker candesartan can be an efficient agent for patients with both hypertension and migraine. Verapamil and amlodipine are particularly useful in limiting cluster headache attacks, although the dosage used must often be high.

Some antihypertensives have the tendency to worsen headaches, including the calcium-channel blocker nifedipine and some of the angiotensin-converting enzyme inhibitors. Treatment with triptans is contraindicated in patients with severely elevated blood pressure as they can worsen hypertension, but they are considered to be generally safe in hypertensive patients with good blood pressure control by medications.

Cerebrovascular Disease

It has long been known that headache can be a common presentation for stroke, both ischemic and hemorrhagic, in addition to more traditional focal neurologic symptoms and signs. A vexing problem is the distinction between migraine aura with minor or no headache and transient ischemic attack (TIA). Positive visual phenomena are the most common migraine aura and include scintillations, oscillating "zig-zag" lines, and wavy vision; this presentation is rare in TIA. In some elderly patients with visual phenomena from migraine, there may be no history of headache, a condition termed "late-life migrainous accompaniments." While transient sensory loss, aphasia, and hemianopic loss of vision are common TIA symptoms, they also can occur as part of a migraine aura. Some of these patients are misdiagnosed as having a stroke and are commonly treated as such with the intravenous administration of thrombolytics. A progression of sensory changes beginning distally and progressively moving centrally is very suggestive of migraine aura rather than stroke, as is the short duration of most auras, which usually last less than 30 minutes. Motor auras are quite rare in migraine, and can be compelling for a TIA diagnosis. Monocular vision loss is extremely unlikely in migraine.

In patients with a history of stroke who require acute migraine treatment, ergots are contraindicated, as they are in cardiovascular and peripheral vascular disease. Triptans, as weak vasoconstrictors, are generally considered contraindicated in patients with cerebrovascular disease, but this concern is probably exaggerated and not supported by strong evidence.

Infectious Disease

Infections which lead to meningeal inflammation typically produce significant head pain. Some purely systemic infections are also known to induce headache or exacerbate primary headaches, often for unclear reasons. These patients with systemic bacterial and viral infections tend to respond to simple analgesics, or when severe, limited opioid treatment. In contrast, patients will often experience a particularly prolonged and refractory headache after successful treatment of their underlying meningitis or encephalitis.

Some headaches accompanying infectious diseases may represent an exacerbation of a pre-existing primary headache disorder such as migraine, but there are a number of secondary headaches that must be considered in this setting, including septic venous sinus thrombosis, which carries a high mortality and presents often with head pain. Intracranial abscesses may present with headache particularly when their size increases.

Human immunodeficiency virus (HIV) is known to affect the central nervous system and may induce meningeal inflammation leading to head pain, but the virus itself may also lead to chronic headaches without evidence of meningitis for unclear reasons.[6] Virtually all of the antiretroviral agents used to treat HIV can cause headache. Careful adjustment of dosing and trials of alternative agents usually allow HIV treatment to proceed without headache.

Several areas of caution must be observed when treating HIV patients for primary headache disorders. Divalproex may lead to increased replication of HIV and should be avoided. Ergots and some triptans including almotriptan, eletriptan, and naratriptan are CYP3A4 substrates, and therefore coadministration with protease inhibitors may significantly increase the risk of severe vasoconstriction. Other triptans should be safer including rizatriptan, sumatriptan, and zolmitriptan. Other agents that are CYP3A4 substrates, including calcium-channel blockers, should be used cautiously. Topiramate, an inducer of CYP3A4, could lower the concentration of protease inhibitors.

Postlumbar puncture headaches are generally managed with judicious hydration and caffeine administration followed by lumbar epidural blood patching when the pain is refractory. In severe cases, patients can present with a dramatic postural headache that is worse when sitting or standing and can even occasionally develop subdural hematomas from stretching of the bridging veins due to sagging of the brain within the cranial vault.

Focal paranasal sinus infections commonly produce headaches. Bacterial and fungal etiologies predominate, and often surgical resection is necessary for relief of pain while antimicrobial treatment is ongoing. Occasionally, headache represents intracranial extension of these infections, and the development of cranial nerve abnormalities or a particularly refractory headache should prompt neuroimaging.

Thyroid Disorders

Headaches are more common in both hypothyroid and hyperthyroid states, even when the altered thyroid status is subclinical.[7,8] These headaches can mimic migraine and often respond to treatment of the underlying thyroid condition. Graves disease can additionally lead to pain via the direct inflammation and heightened nociception produced by the ophthalmopathy it can cause from involvement of the eye muscles themselves. Hyperthyroidism has also been associated with several other neurologic conditions which themselves may present with headache including cerebral venous sinus thrombosis and intracranial hypotension.

Lithium carbonate, highly effective in some cases of cluster headache, can reduce the production of T4 as well as interfere with the deiodination of T4 to produce T3. Therefore thyroid status must be carefully monitored in any patient taking lithium for primary headache disorders, particularly in those known to have pre-existing thyroid dysfunction.

Obesity

Evidence suggests that obesity and migraine are comorbid and that women with migraine in particular are more likely to experience weight gain.[9,10] Headache preventive medications that promote additional weight gain, such as tricyclic antidepressants, gabapentin, neuroleptics, and divalproex, should be avoided in obese patients. In some cases topiramate, which leads to weight loss for many patients, might be of use for both headache prevention and body mass index reduction. This topiramate-induced weight loss can continue unabated in some patients, leading to an unhealthy reduction in weight which requires careful monitoring.

Pulmonary Disease

Headaches are observed in many patients with chronic pulmonary disease, in part because of hypoxia, a known trigger for headache. Asthma is comorbid with headache and must be identified since nonselective β-blocker medications are contraindicated for migraine prophylaxis in these patients. The cardioselective β-blockers atenolol and metoprolol are sometimes tolerated in these patients. Bronchodilators used to treat asthma can induce migraine, and new headache in the setting of a change in inhaler prescription should be a clue to this association. Sedatives such as benzodiazepines and opiates may depress respiratory drive and should be avoided in patients with pulmonary disease if possible.

Patients with obstructive sleep apnea often report morning headaches. The phenomenon was previously thought to be the result of insufficient cerebral oxygenation. However, whether hypoxia, carbon dioxide retention, or other factors lead to these headaches upon awakening is now a matter of debate. Successful treatment of the underlying sleep disorder seems to improve headache in many patients.[11] Clues to the presence of obstructive sleep apnea when evaluating a patient with headache include the three cardinal manifestations of heavy snoring, gasping during the night, and daytime somnolence; cognitive complaints can also be a useful warning sign.

Renal Disease

Headaches are common in patients with chronic kidney disease. A number of metabolic triggers have been implicated as the etiology of headache in end-stage renal disease (ESRD) including hyperkalemia and hypomagnesemia. Headache is the most common neurologic symptom reported by hemodialysis patients (~50%), generally occurring during or soon after dialysis and resolving within 72 hours after dialysis. The pain is usually bilateral and in most patients is only very brief. Factors that raise the likelihood of dialysis headache include hypertension, elevated blood urea nitrogen, low serum osmolality, and low magnesium. Caffeine withdrawal may be the cause in some patients as caffeine is removed during dialysis. Headaches are also seen in the dialysis disequilibrium syndrome (see Chapter 16) which consists of headache, cerebral swelling, seizures, stupor, and coma.

Preventing dialysis headache can be challenging. Recommendations include chlorpromazine 25 to 50 mg orally given prior to dialysis, or prophylactic nortriptyline or magnesium supplementation. Other suggested beneficial interventions include volume maintenance, blood pressure control, and avoidance of caffeine dependence.[12,13]

Treating headaches pharmacologically in patients with chronic renal failure must be performed carefully as some medications may be poorly excreted, leading to toxicity. Other medications with high protein-binding affinity are poorly dialyzable and might need to be avoided. Tricyclic antidepressants, β-blockers and anticonvulsants such as topiramate can be used within recommended guidelines in ESRD patients.

For mild head pain, acetaminophen is preferred over NSAIDs due to the latter's potentially toxic effects on the kidney. Triptans seem safe in ESRD; eletriptan or frovatriptan should be used preferentially as these are not eliminated renally. Ergots are considered contraindicated in these patients. If opioids are used, they should be used sparingly, as accumulation can lead to respiratory depression and seizures. Codeine, hydrocodone, meperidine, morphine, and tapentadol should probably be avoided. If needed, hydromorphone may be the best choice as it is relatively short acting, has safe metabolites, and is not heavily protein bound.

Hepatic Disease

Liver disease, outside of florid hepatic encephalopathy, is not known to cause headaches. However the presence of liver disease can be a contraindication to the use of some common treatments for migraine and other headache disorders due to concern regarding further hepatic injury. Potentially culprit medications include acetaminophen, tricyclic antidepressants, divalproex, topiramate, carbamazepine, oxcarbazepine, calcium-channel blockers, and neuroleptics. Patients with liver disease, including those with concomitant occult alcoholism, should have hepatic enzyme levels monitored frequently if one of these medications is selected for headache treatment in order to avoid further hepatic compromise. Medications that are metabolized by the cytochrome P-450 pathway, including benzodiazepines, calcium-channel blockers, corticosteroids, ergots, carbamazepine, ondansetron, and some triptans (primarily eletriptan and almotriptan), may build to toxic levels in patients with advanced liver disease, and patients should therefore be monitored closely for side effects.

Autoimmune Disorders

It was formerly believed that patients with SLE were much more likely to experience migraine-like headaches, termed "lupus headaches," than the general population. This phenomenon has not been demonstrated conclusively in population-based studies, so the relative prevalence of headaches in SLE is not clear.[14] The antiphospholipid syndrome has not been shown to be comorbid with migraine.

Cerebral vasculitis in SLE is rare, but when it occurs, it is very painful. Polyarteritis nodosum and other arteritides that affect the central nervous system are very likely to produce headaches, often directly related to inflammatory vascular changes. Pain can occur diffusely or focally, and usually requires strong analgesics. It has been suggested that people with Raynaud phenomenon are more likely to have migraine.

Rheumatoid arthritis commonly produces cervicogenic headaches due to its tendency for atlanto-axial deformation leading to C2 and C3 radicular pain as well as local upper cervical periosteal and ligamentous pain, all of which can produce a focal or diffuse headache via pain referral mechanisms. These headaches tend to be worsened by provocative neck maneuvers and can sometimes be ameliorated with physical therapy.

Neoplastic Disease

For a multitude of reasons, patients with noncranial cancer experience frequent headaches. Chemotherapeutic agents often are the direct causes of headaches, and anemia, thrombocytosis, leukocytosis, and erythrocytosis all produce headache whether as part of the neoplastic disease process or its treatment. Anorexia and sleep deprivation are common headache triggers, and the stress of investigations and treatments in many cancer patients triggers migraine and other underlying headache disorders. When headache is persistent and new, cranial metastases, including meningeal carcinomatosis, as well as infectious meningitis must be aggressively ruled out with imaging and likely cerebrospinal fluid sampling.

Brain and skull tumors are known to produce headaches, via either the mechanism of dural stretching due to large tumor size or due to hydrocephalus. Pituitary region tumors, even when small, may lead to migraine- or cluster-like headaches. Seizures, nausea, vomiting, and focal neurologic signs and symptoms are common with brain tumors. Surgical resection generally helps to reduce headache frequency, and radiation therapy has also been shown to be effective in controlling head pain.

Many chemotherapeutic agents are substrates for the cytochrome P-450 system and therefore a headache medication that induces this system might pose a risk for reduction in efficacy of these agents. Commonly used headache medications that potentially have this effect include carbamazepine, oxcarbazepine, topiramate, dexamethasone, and prednisone.

Transplantation

Antirejection medications tend to be metabolized by P-450 systems. Hence, migraine medications which are inducers of this system will potentially lower the levels of these antirejection drugs and inhibitors may raise them to toxic ranges. Renal transplant recipients should probably avoid NSAIDs and hepatic transplant patients might want to avoid divalproex, topiramate, tricyclic antidepressants, and calcium-channel blockers given their organ-specific deleterious effects.

Psychiatric Disorders

There is a complex interplay between head pain and mood disorders. The increased co-occurrence of migraine and depression, anxiety, and bipolar disorder

TABLE 59-3 ■ Common Migraine and Other Headache Medications that are Known to Exacerbate Medical Illnesses

Medication	Key Medical Illness(es)	Effects
Tricyclic antidepressants	Arrhythmia	Tachycardia
	Obesity	Increased appetite
	Orthostatic hypotension	Syncope
	Prostatic hypertrophy	Urinary retention
	Gastrointestinal dysmotility	Constipation
	Epilepsy	May lower seizure threshold
	Liver disease	May cause enzyme elevation
β-Blockers	Cardiac disease	AV nodal blockade
	Diabetes	Poor response to hypoglycemia
	Asthma	Bronchoconstriction
	Orthostatic hypotension	Syncope
	Depression	May worsen depression
Calcium-channel blockers	Arrhythmia	Tachycardia
	Liver disease	May cause enzyme elevation
Divalproex	Liver disease	May cause enzyme elevation
Topiramate	Liver disease	May cause enzyme elevation
Gabapentin	Obesity	Weight gain
Lithium	Cardiac disease	Arrhythmia
	Hypothyroidism	Exacerbates hypothyroid state
NSAIDs	Bleeding disorder	Increases bleeding
	Renal disease	Worsens renal function
	Peptic ulcer disease, gastritis	Worsens or causes ulcers
Triptans	Cardio/cerebrovascular disease	May cause vasoconstriction
	Hypertension	May elevate blood pressure
Ergots	Cardio/cerebrovascular disease	Likely cause vasoconstriction
	Peripheral vascular disease	Peripheral vasoconstriction
Neuroleptic antiemetics	Liver disease	Liver enzyme elevation
	Obesity	Weight gain
CGRP monoclonal antibodies	Gastrointestinal dysmotility	Constipation
Corticosteroids	Obesity	Weight gain
	Diabetes	Hyperglycemia
	Gastritis	Peptic ulcer disease
	Immunosuppression	Infections

are suggestive of causality, but confounding genetic, treatment-related, and social factors make firm epidemiologic conclusions elusive.[15] Pain is demoralizing, and framing it in this manner is probably the most compassionate approach to the patient with mood alterations. Both psychiatric and headache disorders must be treated optimally and concurrently in order to benefit the patient. Some clinicians have attempted to use a parsimonious approach, attempting the treatment of both with one medication. This may be successful by happenstance, but more useful is a coherent attempt by the neurologist and the psychiatrist working together to improve both conditions. Since many psychiatric medications will have interactions with migraine medications, medication dosage adjustment and timing decisions must be made carefully.

Substance abuse can be a confounding factor in headache disorders as well as in many psychiatric conditions. Understanding local substance use patterns and availability and being observant for signs of dependence and addiction are of the utmost importance. Urine toxicology screens can be useful diagnostically as well as to monitor those in remission.

GENERAL CONSIDERATIONS IN ADDRESSING HEADACHES IN THE ELDERLY

The differential diagnosis of headaches in the elderly requires careful attention. These patients can have many concurrent medical problems and these might cause headache either directly or from medications used to treat these disorders. The rate of secondary unsuspected causes of head pain rises throughout adulthood, and therefore thoughtful investigation is important. Some headache types seem to affect the older age demographic almost exclusively, including temporal arteritis and an interesting primary headache variety, "hypnic headache," a benign but annoying nighttime headache which is responsive to small doses of caffeine prior to sleep.

Migraine and other primary headache disorders can affect the elderly, who pose treatment challenges due both to their comorbid illnesses and due to their aging physiologic states. Migraine medications will interact with other medications and doses may need to be reduced due to a higher propensity for adverse effects. Sedation and alterations in cognition are potentially life-threatening adverse effects as is ataxia due to the propensity for falls, and therefore medications with these side effects should be used judiciously. Elderly patients commonly have other painful conditions that predispose them to overuse of analgesics, which may lead to both toxicity and an increased incidence of medication overuse headache.

CONCLUDING COMMENTS

Migraine and other primary headache disorders frequently become problematic in patients with concurrent medical conditions. Systemic medical illnesses themselves may directly cause head pain due to the disease process or its treatment. New headaches are always worth pursuing aggressively, looking for underlying causes, as are headaches that are accompanied by focal neurologic symptoms or signs or those that occur in the setting of systemic illnesses causing head and neck inflammation or central nervous system dysfunction. Treating primary or secondary headaches in medically ill patients poses challenges due to treatment effects on underlying illnesses as well as drug interactions (see Table 59-3). A careful, thoughtful approach to these patients is typically effective, with gratifying results in pain management and quality of life.

RHABDOMYOLYSIS AND MYOGLOBINURIA

The diagnosis of disorders of the neuromuscular system involves localizing the lesion anatomically and then weighing the validity of specific diagnostic hypotheses. Symmetry and rapidity of the disease process are major diagnostic considerations. Pure motor syndromes localize to the anterior horn cells, neuromuscular junctions, or muscles, though, rarely, neuropathies can also produce pure motor deficits. Combinations of motor and sensory deficits suggest radiculopathy, plexopathy, or neuropathy.

A diagnostic strategy complementary to the aforementioned approach employs pattern matching. Neuromuscular diseases present with one of five basic patterns (Table 60-1). Weakness is usually a more prominent feature of demyelinating than axonal neuropathies.

In general, electromyography (EMG) and nerve conduction studies (NCSs) are essential for confirming the anatomic localization, differentiating axonal from demyelinating neuropathies, and making

prognostic statements. Decisions concerning the need for muscle or nerve biopsies should be deferred until electrodiagnostic testing is completed.

DISORDERS OF THE MOTOR NEURON

Amyotrophic lateral sclerosis (ALS) is the most common and prototypic motor neuron disease. It presents with flaccid weakness and atrophy of muscles without associated pain or sensory disturbances. Degeneration of upper motor neurons also occurs, producing spasticity and hyperreflexia in wasted limbs. Most cases are sporadic, but approximately 10 percent are inherited in autosomal-dominant or -recessive patterns. The pathogenesis of ALS is not known, but it is possible that multiple pathogenic mechanisms are at play, including impaired cellular handling of oxidative stress, neuroinflammation, neurotrophic factor deficiency, glutamate-induced excitotoxicity, and defects in protein metabolism and autophagy. There is no cure for ALS, although riluzole and edavarone modestly slow progression of disease.[1] Noninvasive ventilation, careful nutritional monitoring and supplementation, and multidisciplinary care can improve the quality of life. A sporadic clinical variant characterized by solely lower motor neuron involvement (progressive muscular atrophy) is managed similarly.

Hereditary anterior horn cell diseases include spinal muscular atrophy (SMA), Kennedy syndrome, and hexosaminidase A deficiency. Biallelic mutations or deletions in the *SMN1* gene cause SMA. The copy number of a nearly identical gene, *SMN2*, on the same chromosome as *SMN1* determines the disease severity and age of onset. Intravenous *SMN1* gene replacement using a viral vector and an intrathecally administered antisense oligonucleotide therapy have been approved for this condition.[2,3] Kennedy disease (spinal and bulbar muscular atrophy) is an X-linked disease characterized by proximal muscle weakness, muscle atrophy, and fasciculations, especially periorally. Affected individuals often have gynecomastia and testicular atrophy with reduced fertility. Expansion of a CAG repeat in the androgen receptor gene is responsible.

Compression of the spinal cord may result in segmental loss of anterior horn cells. In cervical spondylosis, combined injury to both the anterior horn cells and descending corticospinal tracts may occur, leading to atrophy and weakness in the hands combined with spastic paraparesis; such a presentation mimics that of ALS.

Many viruses have central nervous system (CNS) tropism, but only a few strains cause acute and selective loss of anterior horn cells. Poliovirus is an enterovirus spread via a fecal–hand–oral route. Most patients are either asymptomatic or develop only mild constitutional symptoms. More severe signs and symptoms may occur in nonparalytic poliomyelitis, and the cerebrospinal fluid (CSF) findings are often indicative of aseptic meningitis. Individuals developing acute paralytic poliomyelitis experience constitutional symptoms but also develop rapidly progressive weakness over the course of one to a few days. Weakness is often focal and asymmetric in the limbs or bulbar muscles, but may be symmetric or generalized. It frequently improves over several weeks to months. Rarely, the live-attenuated oral poliovirus vaccine can cause paralytic poliomyelitis. In the United States, an inactivated poliovirus vaccine is used, which does not carry the risk of vaccine-associated poliomyelitis.

Postpolio syndrome consists of slowly progressive new or worsened weakness, together with fatigue or pain in the muscles or joints, typically occurring many years after acute paralytic poliomyelitis in about 20 to 40 percent of individuals. The pathogenesis may involve late denervation of previously reinnervated muscle fibers or musculoskeletal abnormalities.

Viruses other than poliovirus, such as West Nile virus (WNV), echovirus, coxsackievirus, herpes zoster virus, and Epstein–Barr virus may also cause loss of motor neurons. Only about 20 percent of WNV infections are symptomatic, usually manifesting as a febrile illness. A maculopapular rash is common. About 1 percent of infected individuals develop neurologic symptoms that may include meningoencephalitis, flaccid paralysis, or both. As in poliovirus infection, the weakness is often proximal and asymmetric, with no significant sensory abnormalities. The CSF shows a lymphocytic or neutrophilic pleocytosis (30 to 150 cells/mm^3) and high protein content. CSF and serum should be screened for IgM antibodies to WNV. Adding WNV polymerase chain reaction (PCR) testing of both the serum and CSF can increase the diagnostic yield. Treatment is supportive. Rarely, WNV may present with brachial plexopathy, rhabdomyolysis, or a predominantly demyelinating polyneuropathy similar to Guillain–Barré syndrome (GBS).

Paraneoplastic lower motor neuron involvement may occur rarely with lymphoproliferative disorders, thymoma, and various cancers (bronchial, ovarian, renal, and prostate). Patients may have anti-Hu (ANNA-1) and anti-Yo (PCA-1) antibodies, CSF protein level is often elevated, and there is a variable CSF pleocytosis. The weakness may improve after treatment of the cancer.

RADICULOPATHY

Pain or numbness in a dermatomal pattern accompanied by weakness in a segmental pattern suggests a radiculopathy. External compression is the most frequent cause of nerve root injury, by either intervertebral disc herniation or spondylosis. Radiculopathy resulting from degenerative spine disease is discussed further in Chapter 22. Other causes of radiculopathy may include gouty spine disease, Paget disease, Tarlov cysts, and methylacrylate extrusion during spine surgery. Extradural tumors such as schwannomas, neurofibromas, and meningiomas may also produce a radiculopathy. A radiculopathy sometimes results from epidural or spinal anesthesia; the injury may result from direct trauma to the nerve or from chemical injury related to the injected substance.

Diabetic thoracoabdominal radiculopathy (diabetic truncal neuropathy) is a common cause of noncompressive radiculopathy. Patients present with pain and hyperalgesia in a region along the chest or abdomen. The pattern of involvement may be clearly dermatomal, but often the changes span more than one segment. Segmental weakness may manifest as an outpouching of the abdominal wall. The pathophysiology is unclear, but an inflammatory vasculopathy may be responsible.

Compression of multiple lumbosacral nerve roots produces a cauda equina syndrome, which may lead to permanent urinary and fecal incontinence and lower extremity weakness and numbness and thus constitutes a neurosurgical emergency. The usual cause is a large, midline disc herniation. Chronic cauda equina syndrome may be caused by a developmental anomaly, such as a tethered spinal cord.

Spondylosis is the most common cause of polyradiculopathy, although metastatic spinal disease should also be considered. Cancers of the breast, lung, prostate, or kidney, or multiple myeloma metastasize most frequently to the spine. Polyradiculopathy results from direct tumor compression or from leptomeningeal infiltration of the roots by tumor cells (neoplastic meningitis). Treatment of spinal bony metastases often involves external beam irradiation, although decompressive surgery may be necessary in radiation-resistant tumors.

Carcinomatous meningitis often affects the caudal roots first. Cranial neuropathies, meningeal signs and symptoms, and a myelopathy may be associated features. CSF analysis typically shows a pleocystosis, hypoglycorrhachia, elevated protein level, and malignant cells on cytologic analysis. The yield of positive cytology for malignant cells is increased significantly by repeating the lumbar puncture. Treatment is usually palliative and includes radiation therapy and intrathecal chemotherapy. The median survival of patients with leptomeningeal metastases is 4 months.

Infectious causes of polyradiculopathy include cytomegalovirus (CMV), *Borrelia burgdorferi* (Lyme disease), Epstein–Barr virus, herpes simplex virus, *Mycobacterium tuberculosis*, and *Treponema pallidum*. CMV polyradiculopathy usually presents as a late complication of acquired immunodeficiency syndrome (AIDS), but it can be a presenting manifestation of human immunodeficiency virus (HIV) infection. The onset of flaccid paraparesis, lower extremity numbness, and urinary retention may be acute or subacute. A neutrophilic pleocytosis on CSF analysis is a clue to the diagnosis; the diagnosis is confirmed by a culture or CMV DNA PCR assay on CSF. Treatment includes ganciclovir, foscarnet, or both.

Arachnoiditis is a nonspecific term for inflammation of the spinal leptomeninges. Historically, arachnoiditis has been associated with tuberculous and syphilitic meningitis and with obsolete oil-based contrast agents for myelography. Currently, the term often refers to the appearance of thickened meninges and clumping of the nerve roots on magnetic resonance imaging (MRI) of the spine, usually in patients who have undergone lumbar spine surgery. There is controversy about the association of the imaging findings, clinical findings, and symptoms. Arachnoiditis has also been described in association with toxoplasmosis and subarachnoid hemorrhage; sometimes the cause is not known.

DISORDERS OF POSTERIOR ROOT GANGLIA

Diffuse or regional impairment of tactile sensation or gait ataxia without weakness suggests degeneration of posterior root ganglia cells (sensory neuronopathy). Patients may also have facial numbness and autonomic involvement, manifesting as gastroparesis, orthostatic hypotension, sexual impairment, and Adie pupils. EMG and NCSs differentiate sensory neuronopathies from more common distal sensory axonal polyneuropathies. Sensory neuronopathies may be acquired (Table 60-2) or hereditary.

Paraneoplastic sensory neuronopathy (see Chapter 27) is commonly associated with small cell lung cancer but also occurs with breast or ovarian cancer, Hodgkin lymphoma, neuroendocrine tumors, and sarcoma. Symptom onset is generally subacute. Antibodies to the Hu antigen (ANNA-1) are usually present, but their absence does not exclude the possibility of paraneoplastic sensory neuronopathy. Antibodies to the collapsin response-mediator protein 5 (CRMP5) have also been described in some patients with small cell lung cancer. Sensory neuronopathy may occur with other paraneoplastic syndromes. Management is directed to the diagnosis and treatment of the underlying cancer. Treatment of the paraneoplastic condition with intravenous immunoglobulin (IVIg), plasmapheresis, or other immunosuppressive therapies is often disappointing.

Autoimmune or inflammatory conditions associated with sensory neuronopathy (sometimes as the initial manifestation) include Sjögren's syndrome and autoimmune hepatitis. The posterior root ganglia of patients are infiltrated by T lymphocytes. IVIg and plasmapheresis have benefited some patients.

An acute sensory neuronopathy syndrome characterized by the acute onset of widespread sensory symptoms, areflexia, impaired vibratory sensation, and gait ataxia has developed 4 to 12 days after initial antibiotic treatment for a febrile illness. The underlying pathogenesis in such cases may be infectious, postinfectious, or toxic (related to antibiotic use).

Infectious causes of sensory neuronopathy are shown in Table 60-2. HIV infection may cause a sensory neuronopathy. T-cell infiltration of dorsal root ganglia has been found in patients with end-stage AIDS. Many of these patients also have pallor of the cervical portion of the gracile tract at autopsy, suggesting that a "dying-back" axonopathy occurs along with sensory neuron loss.

Latent infection of the dorsal root ganglia occurs following primary varicella zoster virus infection. When cell-mediated immunity is compromised, reactivation of viral replication causes the clinical syndrome of herpes zoster. The elderly, transplant recipients, and HIV-positive patients are particularly vulnerable. The prodromal stage of herpes zoster includes fevers, dysesthesias, and malaise. Several days later, a vesicular eruption appears in a dermatomal distribution. Pathologically, there is intense inflammation of the dorsal root ganglia. Once the lesions become encrusted, they are no longer infectious. Approximately 3 percent of patients develop segmental paresis, perhaps from spread of the virus to the anterior horn cells. Most patients recover muscle strength with time. Treatment during the early stages of infection includes acyclovir, valacyclovir, or famcyclovir. Postherpetic neuralgia may occur, particularly in the elderly. Tricyclic drugs or anticonvulsants are effective treatments, as discussed in Chapter 42. Patients age 50 and older with a history of herpes zoster and immunocompetent patients age 60 or older without a history of herpes zoster should receive the zoster vaccine.

A number of toxins and vitamin deficiencies cause sensory neuronopathy. Because many of these also cause an axonopathy, they are discussed later (pp. 1071–1073).

Hereditary sensory neuronopathy (hereditary sensory and autonomic neuropathy) is both genetically and phenotypically heterogeneous; some forms present with predominantly small-fiber involvement, whereas others have mixed small- and large-fiber involvement. There is variable involvement of the autonomic nervous system. Commercial genetic testing is available for some types.

PLEXOPATHY

Trauma and compression, including at childbirth, cause most plexus injuries; other causes include tumor infiltration, postirradiation injury, and infection. An autoimmune monophasic neuritis, often idiopathic but sometimes associated with diabetes mellitus, may involve portions of either the brachial or lumbosacral plexus.

Sports, motorcycle, and industrial accidents cause traction injury to the brachial plexus. If the arm is located at the side of the patient at the time of impact or is distracted away from the torso, the upper roots and plexus are preferentially injured. If the arm is elevated above the head, the lower trunks and roots are most vulnerable. Compression injury of the brachial or lumbosacral plexus may occur during surgery or coma or from mass lesions such as a hematoma or tumor.

Immune brachial plexopathy (brachial plexus neuritis, neuralgic amyotrophy, Parsonage–Turner syndrome) is an acute monophasic neuropathy that presents with severe shoulder pain accompanied by muscle weakness and atrophy. Both sporadic and hereditary forms exist. Proximal muscle groups are more commonly affected than distal ones; involvement may be either unilateral or bilateral. Sensory loss is mild. Ipsilateral diaphragmatic weakness sometimes occurs from phrenic nerve involvement. Nerve biopsy specimens have revealed perineurial thickening and perivascular inflammatory infiltrates. Corticosteroids or IVIg, or both, have been used in treatment with anecdotally reported success, but controlled studies are needed. Aggressive treatment to control pain is important. The prognosis is excellent, with 60 percent of patients recovering completely within 1 year and 80 percent within a few years.

Nondiabetic lumbosacral radiculoplexus neuropathy refers to a similar disorder that affects the lower extremities. As with immune brachial plexus neuropathy, pain is often the initial symptom. It may occur in the back, buttock, thigh, or leg. Proximal weakness is more common than distal weakness. In time, however, the weakness often becomes more diffuse in the limb, and bilateral involvement is common. Clinically, sensory deficits (despite the pain) tend to be relatively mild. Nerve biopsies have shown evidence of ischemic injury and epineurial perivascular inflammatory collections. Some improvement in strength occurs with time but long-standing motor deficits are common. Case reports suggest a potential benefit of corticosteroids, plasmapheresis, or IVIg therapy, but no positive controlled trials have been published. Diabetic lumbosacral radiculoplexopathy (proximal diabetic neuropathy; diabetic amyotrophy) is discussed in Chapter 19.

Breast and lung cancers are the two most common secondary neoplasms to infiltrate the brachial plexus. Gastrointestinal and genitourinary cancers, melanomas, and lymphomas may also metastasize to the brachial plexus. Colorectal cancer is the most common neoplasm to infiltrate the lumbosacral plexus, but uterine, prostate, and ovarian cancer may also do so; other neoplasms may spread to the lumbosacral plexus metastatically.

Radiation therapy that includes the plexus in the field (as for breast cancer) may produce delayed weakness, dysesthesias, and numbness in the affected limb (Chapter 28). Irradiation causes marked fibrosis of the nerve fibers, loss of myelin, and destruction of the vascular supply. The period between the radiation treatment and onset of symptoms ranges from a few weeks to more than 30 years. Paresthesias in the median-innervated digits are a common initial symptom. Subsequently, weakness of the intrinsic hand muscles develops. Prominent limb pain and a Horner syndrome suggest tumor involvement rather than radiation-induced injury, whereas the presence of fasciculation potentials and myokymia on needle EMG suggests radiation injury. Distinction of these two disorders is aided by MRI.

Patients with radiation-induced lumbosacral plexopathy have generally been treated for lymphoreticular, testicular, uterine, or ovarian cancer. Patients usually present with slowly progressive distal weakness; numbness or paresthesia is less common. Mild pain occurs in 50 percent of patients. The CSF protein concentration may be elevated. As with radiation-induced brachial plexopathy, the condition may stabilize, but patients are often disabled.

Finally, a lower motor neuron syndrome affecting the legs, with relatively intact sensation, may also occur following irradiation of the distal spinal cord and cauda equina. Patients have generally received more than 40 Gy. Pathologic examination of the cauda equina shows a vasculopathy of the proximal nerve roots. Although the condition eventually stabilizes, patients are usually left with significant disabilities. There is no treatment.

Neurogenic thoracic outlet syndrome occurs when an anomalous fibrous band between the first thoracic rib and a cervical rib or elongated transverse process on the seventh vertebral body exerts pressure on the first thoracic nerve root or the lower trunk of the brachial plexus. This leads to wasting and atrophy of the hand muscles, particularly of the thenar eminence, and intermittent pain and paresthesias of the inner arm and medial hand, including the fourth and fifth digits. Electrodiagnostic studies confirm the diagnosis. A chest x-ray may show the cervical rib or an elongated transverse process (Fig. 60-1); the fibrous band shows up as a radiolucency. MRI may be helpful in showing and localizing plexus involvement (Fig. 60-2). Treatment is surgical.

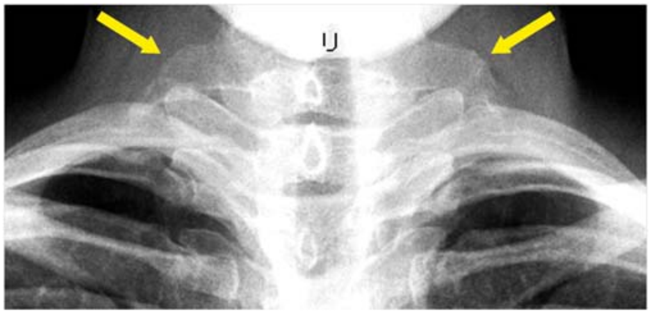

FIGURE 60-1 ▪ Chest radiograph of a 31-year-old right-handed woman with slowly progressive wasting and weakness of the left hand and numbness along the medial left forearm and hand. Bilateral cervical ribs are present (*arrows*). This finding may be associated with the neurogenic thoracic outlet syndrome. A fibrous band originating from the cervical rib compresses the inferior elements of the brachial plexus, leading to a wasted hand.

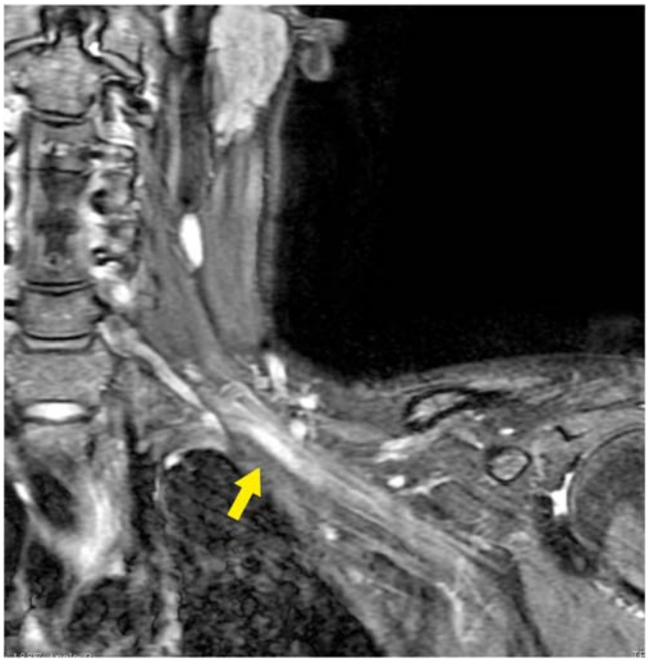

FIGURE 60-2 ▪ Coronal T2-weighted magnetic resonance image (MRI) of the left brachial plexus from the same patient as in Fig. 60-1. There is increased signal in the left lower trunk (*arrow*), illustrating the usefulness of MRI for localizing nerve trunk lesions.

PERIPHERAL NEUROPATHY

The distribution of findings may suggest either a focal, multifocal, or generalized/symmetric pattern of nerve involvement. For the multifocal and generalized neuropathies in particular, identifying the relative involvement of motor and sensory fibers (Tables 60-3 to 60-5) narrows the differential diagnosis. Sensory neuropathies may be further subdivided according to whether predominantly large- or small-diameter fibers are affected (Tables 60-4 and 60-5). Knowing whether the pathogenesis is predominantly axonal or demyelinating (Tables 60-6 and 60-7) also refines the diagnostic search. Generally, patients with axonal neuropathies present with predominantly sensory signs and symptoms, whereas patients with demyelinating neuropathies have more significant weakness. Given the exceptions to this rule, however, NCSs must be performed to distinguish between these two possibilities. Finally, the time course of symptom onset has important implications for

Focal Neuropathy

A focal neuropathy may occur wherever ischemia, trauma, compression, injection, infection, or tumor infiltration affects the nerve. Focal *ischemic neuropathies* are uncommon following brief acute arterial occlusion. An exception to this rule is acute ischemic fibular (peroneal) neuropathy after thrombosis or embolism of the superficial femoral or popliteal arteries. The patient presents with a cool, pulseless distal lower extremity, sudden pain in the calf or foot, and footdrop. The nerve's susceptibility is related to the common occurrence of a single arterial feeder at the lateral aspect of the knee. Once circulation is restored, recovery may take weeks but is often good. Arterial insufficiency may lead to chronic ischemic neuropathies. Brachial artery to cephalic vein shunts placed for hemodialysis have been associated with median, ulnar, and radial neuropathies. A vascular steal syndrome seems to be a major mechanism of nerve injury, but direct compression of nerves and distal limb edema may also play a role.

Benign *tumors* of nerves (schwannomas and meningiomas) usually present as sporadic, solitary tumors with or without neurologic signs or symptoms. In a patient with multiple such lesions, however, neurofibromatosis

should be suspected. An enlarging lesion or the development or progression of neurologic signs should raise suspicion of malignant transformation.

The common *entrapment* neuropathies—median neuropathy at the wrist, ulnar neuropathy at the elbow, and fibular (peroneal) neuropathy at the fibular head—share anatomic factors that increase the susceptibility of the nerve to injury; these factors include superficial nerve location, adjacent bony structures, and enclosure by nonelastic connective tissues. External compression of nerves generally causes focal demyelination before significant axonal loss.

Various medical conditions contribute to carpal tunnel syndrome (CTS; median nerve entrapment at the wrist), the most common compressive neuropathy. Diabetes mellitus is a major risk factor. The pathogenesis of CTS in this context may relate to chronic endoneurial hypoxia and changes in the connective tissues of the nerve sheath or transverse carpal ligament. Hypothyroidism and acromegaly are also associated with CTS. In acromegaly, edema of synovial tissues may cause nerve compression. In pregnancy (Chapter 31), edema and weight gain contribute to increased pressure

in the carpal tunnel. Rheumatoid arthritis is the most important inflammatory condition associated with CTS. Rheumatoid nodules, wrist deformity, and tenosynovitis are all contributory factors. When CTS accompanies a distal symmetric polyneuropathy in a nondiabetic patient, amyloidosis should be considered. If such patients undergo carpal tunnel surgery, fat and ligament tissue should be sent to pathology for analysis for possible amyloid deposition. Other risk factors for CTS include female sex, ganglion cysts, lipomas, nonspecific tenosynovitis, gout, sarcoidosis, multiple myeloma, aromatase inhibitors, and hereditary neuropathy with liability to pressure palsies. Repetitive hand motions in certain occupations may also be contributory. Conservative management of CTS includes the nocturnal use of wrist splints to prevent wrist flexion or extension (which reduces pressure within the carpal tunnel) or oral or injected corticosteroids. For severe neuropathies or for those in whom conservative measures have failed, surgical release of the carpal tunnel is effective.

The evaluation and management of the other common entrapment neuropathies are discussed in standard neurologic texts.

Multifocal Neuropathy

Most multifocal neuropathies are immune mediated or infectious (Table 60-9). The immune-mediated forms may be idiopathic, triggered by an infection or toxin/medication, or associated with diabetes mellitus. The most severe presentation is the acute and catastrophic appearance of multiple mononeuropathies (mononeuritis multiplex) caused by systemic vasculitis.

VASCULITIC NEUROPATHY

Vasculitic neuropathy is an ischemic neuropathy caused by obliteration of the nerve's nutrient blood vessels by inflammatory infiltrates. It usually presents as a subacutely evolving, asymmetric, painful sensory or sensorimotor neuropathy. Often, the deficits are in the distribution of multiple individual nerves (mononeuropathy multiplex). Nerves in the lower extremities are often affected first, but any nerve may be involved. Over time in untreated patients, as additional nerves become injured, motor and sensory deficits may become confluent, thereby mimicking a polyneuropathy. Sometimes, as in the case of cryoglobulinemic vasculitic neuropathy, the initial presentation of a vasculitic neuropathy is symmetric.

Neuropathy may occur with primary vasculitis, in which the underlying cause is not known, or secondary vasculitis, in which the causative factor is identified. The

primary systemic vasculitides are classified according to size of the damaged blood vessels, organs involved, and the suspected immunopathologic mechanisms at play. Polyarteritis nodosa, microscopic polyangiitis, granulomatosis with polyangiitis (Wegener granulomatosis), and eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) are the primary systemic vasculitides most commonly associated with vasculitic neuropathies. The most common vasculitic neuropathy is an idiopathic form similar to polyarteritis nodosa and microscopic polyangiitis but without overt systemic involvement, called nonsystemic vasculitic neuropathy. Because these patients do not have a defined connective tissue or other systemic disease, the diagnosis is established by nerve biopsy. Most of these patients have an elevated erythrocyte sedimentation rate, and a minority are anemic with peripheral leukocytosis and thrombocytosis. Secondary vasculitis may be associated with connective tissue diseases, infections, neoplasms, medications, or toxins.

Given the broad differential diagnosis of vasculitic neuropathy, the laboratory evaluation is extensive and often includes a complete blood count and erythrocyte sedimentation rate; examination for antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, complement levels, and hepatitis B and C serologies; urinalysis with microscopic analysis; and renal and hepatic function tests. The work-up may also include an HIV antibody test, chest x-ray, and Lyme antibody studies. An electrodiagnostic study is essential to document the multifocal nature of the axon loss. A nerve biopsy is often necessary for diagnosis. For the systemic vasculitides, the diagnostic yield is increased if biopsy is performed on both the nerve and muscle.

The systemic vasculitides are often fatal if untreated, so aggressive immunosuppression with combined corticosteroids and cyclophosphamide is usually indicated. When vasculitis is caused by drugs, removal of the offending agent often leads to benefit. For vasculitis associated with chronic viral infections, treatment often includes antiviral therapy or removal of viral antigens by plasmapheresis.

Hepatitis B

Approximately one-third of cases of polyarteritis nodosa are associated with hepatitis B infection. More than 80 percent of patients with hepatitis B–associated polyarteritis nodosa have a neuropathy. Although the clinical features may be indistinguishable from classic polyarteritis nodosa, the disease manifestations of hepatitis B–associated vasculitis may be more severe. Immune complex deposition is thought to be the main immunopathologic mechanism.

Treatment of hepatitis B–related vasculitic neuropathy is specialized. Although immunosuppressive therapies lead to increased viral replication, two retrospective studies suggest that a short course of corticosteroids is beneficial. Following steroid therapy, either tenofovir or entecavir may be used. Plasma exchanges are usually given concurrently over a 10-week period to clear the immune complexes. Relapses are uncommon.

Hepatitis C

A minority of patients with hepatitis C virus (HCV) infection develop a peripheral neuropathy, sometimes associated with cryoglobulinemia. As cryoglobulinemia can cause a vasculitic neuropathy with more severe neurologic deficits, the following discussion focuses on it.

HCV is the most common cause of essential mixed cryoglobulinemia, which occurs in about one-third of patients with HCV; a cryoglobulinemic neuropathy only occurs in 2 to 3 percent of patients. Other manifestations of cryoglobulinemia include edema, palpable purpura, and membranoproliferative glomerulonephritis. The cryoglobulinemia results from an oligoclonal expansion of B-lymphocytes. Most cryoglobulinemic neuropathies are distal, axonal, and symmetric with predominantly sensory deficits. Mononeuropathies, either single or multiple, may also occur. Rarely, patients with cryoglobulinemia may develop demyelinating polyneuropathies associated with IgM binding to myelin.

Patients with HCV-associated cryoglobulinemic neuropathy should be treated with direct-acting antiviral therapy.[4] For refractory cases, immunosuppression with monoclonal anti-CD20 antibodies (rituximab) with or without corticosteroids may be necessary.

Other Infections

Any organism can produce a vasculitis if it elicits either circulating or in situ immune complexes. CMV and herpes zoster are the only two infections known to infect endothelial cells of peripheral nerve blood vessels.

HIV infection (Chapter 43) may rarely cause a systemic vasculitis. It usually occurs in the early symptomatic stage of the disease. Multiple patterns of nerve involvement have been described, including mononeuropathy, mononeuritis multiplex, cranial neuropathies, distal symmetric polyneuropathy, and asymmetric polyneuropathy. The possibility of CMV vasculitis must be excluded in this patient population. In CMV-negative cases, nerve biopsy samples show a necrotizing vasculitis that may involve the endoneurial vessels in addition to the epineurial vessels. Other causes of multifocal neuropathies in HIV patients include neurolymphomatosis and diffuse infiltrative lymphocytosis syndrome.

IDIOPATHIC IMMUNE-MEDIATED MULTIFOCAL NEUROPATHY

Immune-mediated multifocal neuropathies exist in which the target of the immunologic attack is the myelin or axon rather than the blood vessels. These entities include multifocal motor neuropathy, Lewis–Sumner syndrome (or multifocal acquired demyelinating sensory and motor neuropathy), sensory perineuritis, and migratory sensory neuropathy of Wartenberg. In some cases, there is overlap between these neuropathies and GBS and chronic inflammatory demyelinating polyneuropathy (CIDP). Because GBS and CIDP are usually associated with generalized weakness, however, they are discussed separately in a later section.

Multifocal motor neuropathy is important to recognize because it can superficially mimic motor neuron disease, and attention here is focused on this disorder. Patients typically present with painless wasting, weakness, and sometimes fasciculations of the distal upper-extremity muscle groups, although any muscle group may be affected, even the tongue. Careful examination reveals that weakness occurs in a peripheral nerve rather than segmental pattern. Upper motor neuron signs are not present. Patients may complain of mild sensory symptoms such as numbness or paresthesia, but the sensory examination is typically normal. Reflexes tend to be depressed only in regions of weakness. NCSs usually reveal conduction block in motor nerves along with normal sensory nerve conduction responses. Half of patients have elevated titers to GM1 ganglioside.

IVIg is the most effective therapy for multifocal motor neuropathy, with approximately 80 percent of patients responding to it. Its efficacy has been confirmed by multiple randomized, placebo-controlled trials. Other agents that may improve or stabilize the disease include subcutaneous immunoglobulin, cyclophosphamide, azathioprine, rituximab, and interferon-beta. Mycophenolate mofetil did not have an IVIg-sparing effect in a randomized, controlled trial. Although a few patients have been reported to respond to prednisone, it is usually ineffective or may cause an exacerbation of weakness. Plasmapheresis is usually not effective.

SARCOIDOSIS

Neurosarcoidosis is discussed in Chapter 49, to which the reader is referred.

INFECTIOUS NEUROPATHY

Lyme disease and leprosy are important causes of multifocal neuropathy and are discussed separately in Chapters 39 and 41.

Polyneuropathy

The medical disorders discussed in this section cause generalized and symmetric neuropathies. In axonal neuropathies, the sensory and motor deficits are usually length dependent such that the deficits are most severe in the feet. With long-term disease, a classic stocking-glove neuropathy occurs, with or without autonomic involvement. In demyelinating polyneuropathies, however, the weakness may involve proximal and distal muscle groups more equally.

ENDOCRINE NEUROPATHY

Diabetic Polyneuropathy

As discussed in Chapter 19, diabetes mellitus may be associated with both generalized and focal neuropathies. The focal neuropathies include lumbosacral radiculoplexus neuropathy (diabetic amyotrophy; proximal diabetic neuropathy), thoracolumbar neuropathy, entrapment neuropathies, and cranial neuropathies. The generalized neuropathies include distal symmetric sensory or sensorimotor polyneuropathy, acute painful neuropathy, autonomic neuropathy, and acute motor neuropathy.

Approximately 50 percent of diabetics develop a distal symmetric sensorimotor polyneuropathy. Risk factors for polyneuropathy include degree of hyperglycemia, duration of diabetes, age, hypertension, hypertriglyceridemia, and smoking. The association between prediabetes and polyneuropathy is a subject of active debate. A number of investigators have found an increased prevalence of impaired glucose tolerance in patients with idiopathic neuropathy. However, a careful case-control study of patients with idiopathic neuropathy did not show a significant association between prediabetes and neuropathy.

Early symptoms include distal numbness, burning dysesthesias, and allodynia in the feet or toes. Although discomfort is present throughout the day, it often worsens at night or with rest. Cramps are common in the calves and foot muscles. Treatment consists of tight glycemic control, which helps to prevent and slow the progression of the polyneuropathy. Large-scale controlled trials of aldose reductase inhibitors and nerve growth factor in the treatment of diabetic neuropathy have yielded disappointing results. Controlled trials of intravenous and oral preparations of the antioxidant α-lipoic acid have demonstrated its benefit on neuropathy signs and pain.

Other Neuropathies

Hypothyroidism is a common cause of median neuropathy at the wrist (CTS). Myxedematous tissue beneath the flexor retinaculum is thought to cause median nerve compression. Hypothyroidism may also cause a polyneuropathy that presents with distal dysesthesias and stocking-and-glove sensory loss. Reflexes may be diminished with a delayed relaxation phase. Electrodiagnostic and pathologic studies have shown mixed axonal and demyelinating features. Considerable improvement may occur in both CTS and hypothyroid polyneuropathy following replacement therapy.

Acromegaly may cause entrapment neuropathies due to connective tissue hyperplasia and bony overgrowth. A sensorimotor polyneuropathy may also occur associated with hypertrophic, sometimes palpable, nerves.

INFECTIOUS NEUROPATHY

HIV Neuropathy

As discussed in Chapter 43, HIV infection is associated with both acute and chronic, multifocal or generalized polyneuropathies. These include mononeuritis multiplex from vasculitic neuropathy, GBS, CIDP, and distal sensory polyneuropathy. Of all these neuropathies, distal sensory polyneuropathy is by far the most common, occurring in at least 50 percent of patients with advanced HIV infection. In the era before combination antiretroviral therapy, reduced $CD4^+$ lymphocyte cell counts and increased HIV viral loads increased the risk and severity of HIV polyneuropathy. Dideoxynucleoside antiretrovirals also increase the risk of neuropathy, possibly because of toxicity to mitochondria. A polyneuropathy (usually symmetric) may occur as part of the diffuse infiltrative lymphomatosis syndrome.

Patients typically present with burning dysesthesia in feet and ankles, often with prominent allodynia. On examination, small-fiber sensory modalities are affected predominantly. Weakness related to the neuropathy is uncommon, even in advanced cases. There is no specific treatment, although a number of symptomatic treatments for neuropathic pain, including gabapentin, amitriptyline, tramadol, and lamotrigine, are effective.

Other Neuropathies

HCV infection and leprosy may cause generalized and symmetric peripheral nerve involvement, as is discussed earlier in this chapter and elsewhere in this volume.

IMMUNE-MEDIATED NEUROPATHY

Guillain–Barré Syndrome

Once used interchangeably with the label *acute inflammatory demyelinating polyneuropathy*, GBS now encompasses any acute, idiopathic inflammatory polyneuropathy producing progressive muscle weakness and areflexia, regardless of whether the underlying neuropathy is demyelinating or axonal. In many cases, a respiratory or gastrointestinal illness precedes the onset of neurologic symptoms by 1 to 3 weeks. Often paresthesias in the distal limbs herald the onset of the neuropathy. Pain similar to sciatica, myalgia, or a cramp may also occur. Rapidly progressive, symmetric weakness soon follows. Typically the weakness starts in the legs, but it may begin in the arms or face. Symptoms may progress acutely over just a few days or subacutely over as long as 4 weeks. The degree of weakness at the nadir of the progressive phase is highly variable, from mild weakness to quadriplegia with respiratory failure. Maximum deficits occur within 1 month, followed by a plateau lasting for days to weeks and rarely months. Gradual improvement occurs after the plateau phase. Prognosis is good, with a 5 percent mortality rate. Permanent disabilities remain in 5 to 10 percent of patients, mild deficits in 65 to 75 percent, and no deficit in 15 percent. The annual incidence is 1 to 2 cases per 100,000 population.

The initial assessment of GBS patients should include measurements of respiratory capacity and inspiratory force. Patients with a vital capacity of less than 20 mL/kg or a maximum inspiratory pressure less than 30 cmH_2O are likely to require mechanical ventilation. These measurements are much more sensitive than arterial blood gas analysis for predicting incipient neuromuscular respiratory failure. Admission to the intensive care unit (ICU) is warranted for any patient with rapidly progressive disease, significant bulbar or facial weakness, or autonomic dysfunction. Motor findings typically outweigh sensory deficits. One-third of patients may develop facial diplegia. Stretch reflexes are hypoactive or absent.

Blood tests and a lumbar puncture should be undertaken to evaluate for other causes of acute polyneuropathy or polyradiculopathy. In 50 percent of patients, an initial CSF sample will reveal an elevated protein concentration; with subsequent analysis, 90 percent of samples show increased protein, with values ranging from 55 to 250 mg/dL. The CSF is usually acellular with normal pressure. If more than 10 white cells/mm^3 are present, alternative diagnoses should be considered. NCSs commonly show evidence of a polyneuropathy, usually demyelinating, but are sometimes normal when the patient first presents.

In Western societies, GBS is usually a demyelinating polyradiculoneuropathy (acute inflammatory demyelinating polyradiculoneuropathy; AIDP). A number of infections may trigger GBS, including CMV, Epstein–Barr virus, herpesvirus, *Campylobacter jejuni*, *Mycoplasma pneumoniae*, and HIV infection. Rabies and swine flu vaccinations, recent surgery, and pregnancy have also been implicated as triggers for GBS. Both humoral immune responses and T-cell activation are thought to play roles in the pathogenesis. Pathologically, there is the early appearance of lymphocytes surrounding nerve vessels. This is followed by demyelination. Secondary “bystander” axonal degeneration may also occur.

In northern China, the most common GBS subtype is an *acute motor axonal neuropathy* (AMAN) associated with *C. jejuni* infection. These patients often have antibodies to gangliosides, including GM1, GD1a, and GD1b. The strains of *C. jejuni* associated with AMAN have GM1-like epitopes in their lipopolysaccharide membranes that contain a Gal(b1–3)GalNac moiety. Terminal motor axon branches and the internode axonolemma also contain a high concentration of this moiety. Because of molecular mimicry between these bacterial and axon antigens, those portions of the motor axons appear to be the initial targets in the autoimmune attack.

Both AIDP and the less frequent AMAN subtype have been associated with recent Zika virus infection. The viral syndrome precedes the onset of GBS symptoms by a median of 6 days. Treatment is the same as for other presentations of GBS.

There are several other variants of GBS. The most common, the Miller Fisher syndrome, accounts for about 5 percent of all cases of GBS. Patients develop the triad of ophthalmoplegia, ataxia, and areflexia, with varying degrees of limb weakness. Almost all cases of Miller Fisher syndrome are associated with IgG antibodies to GQ1b. Other variants include pharyngeal-cervical-brachial weakness; paraparesis; bilateral facial paresis with distal paresthesias; pure ataxia; acute pandysautonomia; and acute motor–sensory axonal neuropathy. The AMAN variant is usually associated with IgG anti-GM1 antibodies. All variants have in common absent or diminished stretch reflexes, elevated CSF protein concentrations, and electrodiagnostic abnormalities.

For severe cases, treatment includes support in the ICU and immune-modulatory therapy. Plasmapheresis or IVIg is effective in improving short- and long-term neurologic function. The costs of plasmapheresis and IVIg are similar, and the relapse rate for IVIg is no different from that for plasmapheresis. Compared with plasmapheresis, IVIg is associated with fewer complications (e.g., hemodynamic fluctuations), is easier to administer, and is usually available in community hospitals where plasmapheresis may not be accessible. A combination of plasmapheresis followed immediately by IVIg does not lead to significantly better outcomes.

Corticosteroids are not beneficial.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

CIDP is a chronic neuropathy characterized by symmetric weakness, sensory loss, and depressed stretch reflexes. Weakness usually affects both proximal and distal muscle groups. The cranial nerves are rarely involved, but cranial neuropathies may be a presenting feature. A small percentage of patients have papilledema. The weakness must progresses beyond 2 months in order to meet an arbitrary criterion for the diagnosis of CIDP. The clinical course may be relapsing, progressive, or stepwise. There are a number of clinical variants of CIDP manifesting with either pure motor or sensory involvement or with evidence of only distal demyelination. CIDP may occur with certain medical disorders, including monoclonal gammopathies, inflammatory bowel disease, thyroid disease, HIV infection, diabetes mellitus, Charcot–Marie–Tooth neuropathies, and CNS demyelination. Approximately 10 percent of CIDP patients have antibodies directed against proteins expressed at the nodes of Ranvier.[5] Patients with these antibodies do not have segmental demyelination of the nerve fibers. Instead disruption of the nodal architecture blocks conduction of signals along the affected nerve fibers.

The electrodiagnostic and pathologic features are similar to those of GBS. Lumbar puncture typically reveals an acellular CSF with an elevated protein level, but other laboratory tests are unremarkable. NCSs confirm slowed nerve conduction velocities or the presence of conduction block caused by demyelination. Nerve biopsy is occasionally performed, and the findings include endoneurial perivascular inflammation with demyelination, remyelination (onion bulb formations), and secondary axonal degeneration.

Randomized, controlled trials have demonstrated the benefit of corticosteroids, plasmapheresis, subcutaneous Ig, and IVIg. A crossover study demonstrated that plasmapheresis and IVIg are about equally effective. Azathioprine, cyclosporine, mycophenolate, and cyclophosphamide are sometimes reported to be beneficial but have not been tested in controlled clinical trials. Overall, most patients respond to treatment, but relapses are common. Most patients ultimately achieve a remission. Aggressive and early treatment is warranted because unchecked disease may eventually lead to axon loss and muscle atrophy for which there is no specific treatment.

Polyneuropathy Associated With Monoclonal Gammopathy of Undetermined Significance

A monoclonal gammopathy of undetermined significance (MGUS) may present as a symmetric sensorimotor polyneuropathy with variable proportions of axonal or myelin injury. The prevalence of MGUS is 1 to 3 percent in people older than 50 years. Only a minority of those with MGUS ever develop a clinically significant neuropathy, the precise number varying in different series and depending on which heavy chain is involved. Compared with neuropathy patients having IgA and IgG MGUS, patients with IgM MGUS have more sensory ataxia and more evidence of demyelination on electrodiagnostic studies. Specific antibodies can sometimes be found to myelin-specific proteins. The CSF is acellular but the protein concentration is often elevated.

Generally, neuropathies associated with MGUS respond less well to immunosuppressive or immunomodulatory therapy than idiopathic CIDP. IgG and IgA MGUS neuropathies respond better than IgM MGUS neuropathies to plasmapheresis. Improvement has also been documented with rituximab, fludarabine, and alkylating agents. Some patients have responded to IFN-α and IVIg. Long-term studies to determine the relationship between specific immunologic markers and disease recurrence will help to develop targeted therapies.

CRITICAL ILLNESS POLYNEUROPATHY

More than 50 percent of critically ill patients with sepsis and multiorgan disease fail to wean from ventilatory support. Examination in moderately advanced cases reveals flaccid, symmetric weakness, depressed or absent tendon reflexes, and impaired distal sensation. Other causes of weakness in the ICU setting include prolonged neuromuscular blockade from drugs, critical illness myopathy, and cervical myelopathy. CSF protein level is normal or only mildly elevated. Electrodiagnostic studies confirm the presence of a sensorimotor polyneuropathy. Treatment is supportive. The prognosis is variable, depending on the degree of axon loss. A more complete account of this disorder is provided in Chapter 56.

UREMIC NEUROPATHY

Uremic polyneuropathy presents as restless legs, weakness, cramps, and distal paresthesias and dysesthesias in patients with end-stage renal disease (serum creatinine levels of 5 mg/dL or higher). The prevalence among patients undergoing hemodialysis treatment is 50 to 60 percent. Electrodiagnostic studies typically show evidence of distal axon loss with some evidence of demyelination. Usually the neuropathy is slowly progressive, but rapidly progressive uremic neuropathy with prominent demyelinating features has been described. Renal transplantation is the best treatment for uremic polyneuropathy. Further details are provided in Chapter 16.

NEOPLASTIC AND PARANEOPLASTIC NEUROPATHIES

Monoclonal Gammopathy

Multiple myeloma, Waldenström macroglobulinemia, osteosclerotic myeloma (POEMS syndrome of polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes), lymphoma, and leukemia are associated with a monoclonal gammopathy. Generally, symptoms and signs are similar to those of polyneuropathy related to an MGUS. Frequently, these neuropathies are associated with significant distal weakness and some demyelinating features on NCSs.

Amyloidosis

Amyloidosis causes a slowly progressive distal sensorimotor polyneuropathy. Distal lower-extremity pain and paresthesias are common presenting symptoms. On examination, there is usually greater impairment of small- than large-fiber sensory function. Autonomic neuropathy frequently occurs, leading to orthostatic lightheadedness, diarrhea, bladder dysfunction, and impotence. CTS is also common.

In primary amyloidosis, the amyloid fibrils consist of portions of monoclonal immunoglobulin light chains (Bence Jones protein). In almost all these patients, a monoclonal protein may be detected in either the serum or urine. Diagnosis depends on identifying amyloid deposition in tissues. An abdominal fat aspirate is probably the best initial step for establishing the diagnosis; the diagnostic yield is more than 70 percent. If this is negative, a rectal or nerve biopsy may be considered. By suppressing monoclonal light-chain production, alkylating agents extend survival in patients with primary amyloidosis. Autologous peripheral blood stem-cell transplantation is also available, but has a high morbidity and mortality. In familial amyloidosis, the fibrils are usually composed of mutant transthyretin. Molecular genetic testing for transthyretin (TTR) mutations is a sensitive diagnostic test. Sometimes wild-type TTR can form amyloid deposits and also lead to neuropathy. TTR stabilizers (tafamadis and diflunisal) slow the progression of the disease. In addition, TTR antisense oligonucleotide (inotersen) and RNA interference (patisiran) therapies have been approved by the FDA for treatment of TTR amyloid polyneuropathy.[6,7] Orthotopic liver transplantation is an effective treatment for younger patients with amyloid polyneuropathy and the common TTR Val30Met mutation; outcomes for liver transplantation may be poor for other TTR mutations.

Paraneoplastic Neuropathy

Patients with anti-Hu (ANNA-1) antibodies usually present with a sensory neuropathy, but about 25 percent of patients present with a subacute sensorimotor polyneuropathy. Rarely, the associated neuropathy is acute, thereby mimicking GBS. Most of these patients have small cell lung carcinoma.

Peripheral neuropathy occurs as a feature of paraneoplastic syndromes associated with anti-CV2 antibody in about 50 percent of cases. Usually it is a mixed axonal and demyelinating sensorimotor polyneuropathy, but a pure sensory neuropathy may also occur. Rarely, sensorimotor neuropathies have been described with anti-Ri (ANNA-2) and anti-Yo (PCA-1) antibodies.

NUTRITIONAL NEUROPATHY

Vitamin B_1 (Thiamine) Deficiency

Thiamine deficiency is uncommon in industrialized countries. Inadequate consumption may occur in the context of chronic alcohol abuse, total parenteral nutrition, prolonged vomiting, and bariatric surgery. Initial neuropathic symptoms (dry beriberi) include burning dysesthesias in the feet with mild sensory loss. Fatigue, muscle aches, and cramps in the lower extremities are common. Although progression is usually subacute to chronic, the neuropathy sometimes develops over a few days. In severe cases, there may be significant weakness of ankle dorsiflexion and finger and wrist extension in addition to stocking-glove sensory deficits. The recurrent laryngeal nerve may become involved, causing hoarseness. With thiamine supplementation, the neuropathy typically improves, albeit modestly. Further details are provided in Chapter 15.

Vitamin B_6 (Pyridoxine) Deficiency

Deficiency of vitamin B_6 (pyridoxine) causes a distal axonal sensorimotor polyneuropathy. It is a known complication of taking the prescription medications isoniazid and hydralazine. If these medications are prescribed, oral supplementation of vitamin B_6 at daily doses of 50 to 100 mg is advised. Vitamin B_6 deficiency may also occur with chronic peritoneal dialysis or alcoholism.

Overdosing with vitamin B_6 may cause an ataxic sensory neuronopathy associated with degeneration of posterior root ganglia neurons. Stretch reflexes are hypoactive or globally absent. Most patients have numbness, paresthesia, and gait ataxia. Daily ingestion of as little as 200 mg per day has been associated with the development of a peripheral neuropathy in some instances.

Vitamin B_{12} (Cobalamin) Deficiency

The classic neurologic presentation of vitamin B_{12} deficiency is combined degeneration of the dorsal and lateral columns of the spinal cord. Patients present with distal numbness, paresthesias, and, occasionally, dysesthesias. Compared with patients with idiopathic distal polyneuropathy, patients with vitamin B_{12} deficiency are more likely to have concomitant involvement of the upper and lower extremities, initial symptom onset in the hands, and a sudden onset of symptoms. In more advanced cases, paraparesis occurs with extensor plantar responses. Malabsorption is the cause of most cases; it may be due to pernicious anemia, gastric or bowel surgery, or inflammatory bowel disease. Neurologic manifestations of vitamin B_{12} deficiency may occur without anemia or elevated mean corpuscular volume. Testing for elevations of serum homocysteine and methylmalonic acid is helpful when the vitamin B_{12} level is borderline low. With early treatment, the paresthesias may improve, but loss of large-fiber sensory axons is often permanent. Traditionally, vitamin B_{12} is supplemented with weekly to monthly intramuscular injections. Because individuals with pernicious anemia still absorb small amounts of vitamin B_{12}, oral supplementation at a dose of 1,000 to 2,000 μg daily may be equally effective.

Vitamin E Deficiency

Vitamin E deficiency presents as a spinocerebellar ataxia with polyneuropathy. It usually results from lipid malabsorption; errors of vitamin E absorption or transport are less common causes. Pathologically, there is degeneration of sensory axons, posterior root ganglia, posterior columns, and spinocerebellar tracts. The diagnosis is made by measuring serum α-tocopherol levels. Proper supplementation depends on the underlying cause of the deficiency.

Copper Deficiency

Copper deficiency has been associated with a myeloneuropathy characterized clinically by limb paresthesia and spastic paraparesis. Patients have deficits of large-fiber sensation, and many have extensor plantar responses. Often patients have microcytic anemia and neutropenia. Many patients have had prior gastric surgery. Some cases have been linked to excessive zinc levels, which are known to cause copper deficiency. Following copper supplementation, some patients show neurologic improvement.

TOXIC NEUROPATHY

Alcoholic Neuropathy

A distal axonal polyneuropathy is a common complication of chronic alcoholism, occurring in approximately 10 to 50 percent of patients, depending on the study and diagnostic criteria. Superficial sensation is principally impaired and dysesthesias are common. Pathologically, there is loss of sensory and motor axons. The pathophysiology is not fully understood but may involve direct toxicity of alcohol on peripheral nerves; vitamin deficiencies, including thiamine deficiency, are probable contributing factors. Treatment involves abstinence and vitamin supplementation. Prognosis is good for mild to moderate neuropathy after 3 to 5 years of abstinence. Further details are provided in Chapter 33.

Neuropathies Associated With Heavy Metal Exposure

Severe lead poisoning produces a subacute, asymmetric, predominantly motor neuropathy that preferentially affects the wrist and finger extensors. Footdrop is another common manifestation. Prognosis for recovery is good if the lead exposure is eliminated. Abdominal pain, anemia, encephalopathy, and mild sensory deficits may also occur.

Arsenic ingestion typically causes acute abdominal pain followed in 5 to 10 days by dysesthesias in the hands and feet. This is followed by an axonal polyneuropathy presenting as symmetric ascending weakness. The weakness may progress over several weeks. Recovery depends on the degree of axonal loss.

Additional details about the neurologic complications of heavy metal exposure are given in Chapter 35.

Medications and Other Chemicals

Medications and chemicals generally cause a subacutely progressive symmetric, distal, and length-dependent neuropathy, with sensory and motor axonal degeneration. A careful review of occupational exposures to toxins as well as exposures related to hobbies usually leads to candidate toxins. If the exposure is terminated, the neuropathy may continue to worsen for days to weeks (“coasting”) before its course is arrested. A number of toxins have been incriminated (Table 60-6 and Chapter 35).

HEREDITARY NEUROPATHY

Hereditary neuropathy typically presents with slowly progressive distal weakness and numbness. Examination of the feet may reveal pes cavus and hammertoes, features reflecting long-standing atrophy and weakness of the intrinsic foot muscles. Only those hereditary neuropathies with prominent systemic manifestations are discussed here.

Adrenomyeloneuropathy

Adrenomyeloneuropathy is a milder phenotype of adrenoleukodystrophy, the X-linked disease associated with degeneration of white matter and the adrenal cortex caused by mutations of the *ABCD1* gene. Adrenomyeloneuropathy may present from childhood to middle age, usually in men, but occasionally in women. Patients present with a spastic paraparesis, sphincter abnormalities, and sexual dysfunction with or without symptomatic adrenal insufficiency or cognitive problems. The neuropathy is responsible for weakness and depressed ankle reflexes. NCSs typically have shown a mixed axonal and demyelinating polyneuropathy. Testing for very-long-chain fatty acids is the initial diagnostic test for both males and females. Bone marrow transplantation is an effective treatment for those with MRI evidence of brain involvement and minimal neuropsychologic findings. Reduction of hexacosanoic acid by Lorenzo’s oil remains an investigational therapeutic approach for adrenoleukodystrophy.

Fabry Disease

Fabry disease is an X-linked recessive disorder of the gene encoding α-galactosidase A. Deficiency of this lysosomal enzyme causes widespread accumulation of globotriaosylceramide (GL-3) in cells throughout the body. Males present in adolescence with crises of severe pain in the extremities, vascular cutaneous lesions (angiokeratomas), hypohidrosis, corneal and lenticular opacities, and proteinuria. Renal function gradually deteriorates over time, leading to end-stage renal disease. In middle age, cardiovascular and cerebrovascular disease is another cause of significant morbidity and mortality. Patients have a distal small-fiber polyneuropathy with normal nerve conduction velocities. Pain may respond to phenytoin, carbamazepine, or gabapentin. The diagnosis is usually made by demonstration of deficient α-galactosidase A activity in plasma, leukocytes, or cultured cells. Hemodialysis or renal transplantation is often necessary. An expert panel has recommended that enzyme replacement therapy be initiated as early as possible for all males and for females with significant disease.

Porphyria

Inherited defects in the hepatic enzymes responsible for heme synthesis—the hepatic porphyrias—may be associated with acute episodes of CNS and peripheral nervous system dysfunction. These disorders include acute intermittent porphyria, hereditary coproporphyria, and variegate porphyria. The erythropoietic porphyrias are associated with photosensitivity but not neurologic disease. Between attacks, patients with hepatic porphyrias are normal. An attack is typically triggered by a drug that activates the hepatic cytochrome P-450 system, although hypoglycemia and hormonal factors may also contribute.

Clinically, patients present with acute, severe colicky abdominal pain accompanied by psychiatric disturbances. Often, medications used to treat pain and anxiety only exacerbate the attack by inducing certain hepatic enzymes. A painful, often asymmetric axonal neuropathy typically appears 2 to 3 days after the onset of abdominal pain. The weakness frequently begins in the upper extremities. Proximal or distal muscle groups may be involved. Reflexes are usually lost in proportion to weakness, unlike the early areflexia typically seen in GBS. Despite the pain, sensory deficits are usually mild and patchy. The combination of abdominal pain and neuropathy makes the clinical presentation similar to heavy metal intoxication.

Screening for the hepatic porphyrias involves an analysis of the heme precursors in urine. The results of the urinalysis may be normal in asymptomatic carriers. Treatment includes stopping all medications that could potentially exacerbate the attack and infusing heme. Although recovery from the psychiatric disturbances is typically rapid, recovery of the peripheral nerves depends on the severity and extent of the axon loss; ultimate recovery of the peripheral nervous system is generally good.

Refsum Disease

Refsum disease is an autosomal-recessive disorder characterized by anosmia, retinitis pigmentosa, deafness, ataxia, ichthyosis, and neuropathy. Symptoms may begin at any age. Over 90 percent of cases are associated with mutations of the phytanoyl-CoA hydroxylase gene; less than 10 percent are associated with mutations of the *PEX7* gene. The consequence of these mutations is a build-up of phytanic acid in various tissues. The presence of high levels of serum phytanic acid (>200 μmol/L) establishes the diagnosis. Phytanic acid deposition in Schwann cells and the endoneurial space leads to a distal, symmetric sensorimotor neuropathy. Reduction of phytanic acid concentrations by dietary restriction, plasmapheresis, or lipid apheresis improves ichthyosis, sensory neuropathy, and ataxia but may not benefit the retinitis pigmentosa, anosmia, and deafness.

Tangier Disease

Tangier disease is a rare autosomal-recessive disorder caused by mutations in both alleles of the adenosine triphosphate-binding cassette A1 gene (*ABCA1*). The protein deficiency causes decreased lipid removal from cells, widespread tissue accumulation of cholesteryl esters, and the absence of plasma high-density lipoproteins (HDLs). Absent HDLs with normal triglyceride level and the presence of enlarged orange tonsils differentiates Tangier disease from other lipoprotein disorders. Patients may develop corneal opacities or hypersplenism. Despite the HDL deficiency, atherosclerosis does not develop earlier than normal. Polyneuropathy may take one of three forms: asymmetric, relapsing-remitting sensorimotor mononeuropathies, usually associated with normal conduction velocities; symmetric, slowly progressive distal polyneuropathy; and a slowly progressive neuropathy affecting the face and upper limbs with distal hand weakness and facial diplegia and accompanied by dissociative sensory loss that may mimic the presentation of a syrinx. There is currently no specific treatment for Tangier disease.

NEUROMUSCULAR JUNCTION DISORDERS

In disorders of the neuromuscular junction (Table 60-10), patients present with weakness but not numbness. The congenital myasthenic syndromes are discussed elsewhere.

Botulism

Botulism is an acute paralytic illness caused by a toxin produced by *Clostridium* bacteria. Botulism results from (1) ingestion of the preformed toxin with absorption through the intestines, accounting for the vast majority of cases of adult food-borne botulism; (2) ingestion of clostridial spores that colonize the intestines and produce the toxin, accounting for virtually all forms of infant botulism and occurring rarely in adults with altered intestinal flora; or (3) infection of a wound, with local production and absorption of the toxin ("wound botulism"). Improperly preserved food is the most common cause of food-borne botulism. In California, wound botulism has become a recognized complication of intravenous "black tar" heroin use. Botulism may occur in rare instances among patients treated with botulinum toxin for dystonia or other movement disorders.

Adult food-borne botulism is characterized by rapidly progressive cranial nerve palsies, descending weakness, and autonomic dysfunction. The most common symptoms and signs include dysphagia, hypoactive gag reflex, dry mouth, diplopia, ptosis, extraocular movement abnormalities, fixed or dilated pupils, bulbar or limb weakness (especially proximally), constipation, nausea,

TABLE 60-10 ■ Disorders of the Neuromuscular Junction

- Botulism
- Congenital myasthenic syndromes
- Lambert–Eaton myasthenic syndrome
- Myasthenia gravis
- Medications
  - Anesthetics (e.g., ether, isoflurane, lidocaine, methoxyflurane, procaine, succinylcholine)
  - Antibiotics (e.g., aminoglycosides, ampicillin, fluoroquinolone, lincosamides, macrolides, polymyxins, tetracyclines)
  - Anticonvulsants (e.g., phenytoin, trimethadione)
  - Cardiac drugs (e.g., β-adrenergic blockers, bretylium, calcium-channel blockers, lidocaine, procainamide, quinidine, trimethaphan)
  - Hormones (e.g., adrenocorticotropic hormone, corticosteroids, thyroid hormone)
  - Psychiatric drugs (e.g., lithium, phenelzine, phenothiazines)
  - Rheumatoid arthritis drugs (e.g., chloroquine, D-penicillamine)
  - Other medications (e.g., anticholesterol drugs, anticholinesterase toxicity, any respiratory depressant, aprotinin, botulinum toxin, carnitine, checkpoint inhibitors, curare and its derivatives, ergonovine, aminoglycoside eyedrops, β-adrenergic blockers, corticosteroids, gadolinium, interferon-alpha and -beta, intravenous radiographic contrast media, methimazole, oxytocin, quinine, tetanus antitoxin)
- Electrolyte disturbances
  - Calcium
  - Magnesium
- Toxins (e.g., cocaine, carbamate insecticides, organophosphate insecticides, black widow spider venom, scorpion venom, snake venom, tick neurotoxin)

and vomiting. Stretch reflexes are usually hypoactive or absent but may be normal. Mental status, sensation, and CSF are usually normal. There is usually no response to edrophonium chloride (Tensilon). Atypical symptoms, signs, and ancillary test results are not uncommon and do not exclude the diagnosis. The symptoms and signs in infant botulism are similar to those in adults, with the additional features of hypotonia, poor suck, and failure to thrive. Symptoms usually begin 18 to 36 hours after ingestion of the spores and progress rapidly over 2 to 4 days; recovery begins within a few weeks.

Eight toxin types have been described (A, B, C1, C2, D, E, F, and G), but human botulism is associated only with types A, B, and E and, rarely, with F and G. In all forms of botulism, the toxin initially becomes disseminated via the systemic circulation before uptake by the terminals of peripheral cholinergic axons. Once the toxin is inside the nerve terminals, essential proteins for acetylcholine (ACh) release are cleaved. Subsequently, both muscarinic and nicotinic nerve terminals degenerate. Recovery from botulism, therefore, requires regrowth of axon terminals and restoration of the neuromuscular junction.

The diagnosis of botulism is usually confirmed by the detection of the toxin in the serum, stool, or wound. In addition, the wound and stool specimens are cultured to identify the offending organism. Electrodiagnostic studies are also helpful in showing impaired neuromuscular transmission.

Treatment consists of early antitoxin administration and supportive care. For adults, an equine trivalent antitoxin is effective against the type A, B, and E toxins. An effective human antitoxin (BabyBIG) is available specifically for infants and has a much lower risk of anaphylaxis than the equine product.

Wound debridement and antibiotics are indicated for wound botulism but should probably be delayed until the antitoxin is given. Prognosis is usually excellent with proper supportive and respiratory care. Recovery may take several weeks to months, depending on the degree of nerve end-terminal destruction.

Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is an autoimmune disorder in which antibodies directed against presynaptic voltage-gated calcium channels cause proximal limb and trunk weakness. Significant ptosis and bulbar weakness are uncommon. A striking clinical feature of LEMS is that strength often improves following brief exertion. Autonomic symptoms such as a dry mouth, constipation, and urinary retention are frequent. Tendon reflexes are usually hypoactive or absent but may improve after brief exercise.

Approximately 50 to 60 percent of patients with LEMS have an associated small cell lung cancer. Approximately 3 percent of patients with small cell lung cancer develop LEMS. Nonparaneoplastic LEMS also occurs, particularly in younger individuals.

Marked post-tetanic facilitation of the compound muscle action potential establishes the diagnosis. Detecting the presence of calcium-channel antibodies also confirms the diagnosis.

Survival in paraneoplastic LEMS depends on the treatment of the underlying neoplasm. Anticholinesterase drugs alone may modestly benefit strength. The drug 3,4-diaminopyridine is more effective; it works by blocking potassium channels, thereby prolonging the activation of voltage-gated calcium channels. The increased concentrations of calcium in the axon terminals facilitate ACh release presynaptically. Other treatments that may be effective include plasmapheresis, IVIg, prednisone, and azathioprine.

Myasthenia Gravis

There are two clinical forms of myasthenia gravis: ocular and generalized. In the ocular form, weakness is restricted to the eyelids and extraocular muscles. Individuals with generalized myasthenia frequently also have weakness of those muscles plus variable weakness of bulbar, respiratory, or limb muscles.

About 50 percent of patients present with ptosis or diplopia. Of these, about half will progress to generalized myasthenia gravis. A number of autoimmune diseases may be associated, including autoimmune thyroid disease and, more rarely, rheumatoid arthritis and systemic lupus erythematosus (SLE).

Approximately 75 percent of myasthenics have thymic abnormalities. Thymic hyperplasia is the most common abnormality; about 15 percent of patients have a thymoma, usually a noninvasive cortical thymoma. Approximately one-third of patients with a thymoma develop myasthenia gravis. Because of the risks of thymoma, MRI or CT of the mediastinum is necessary for all newly diagnosed myasthenic patients. Thymectomy is generally recommended for all patients with thymomatous myasthenia gravis. In rare instances, myasthenia gravis has been associated with small cell lung cancer and Hodgkin disease. Rarely, a medication such as D-penicillamine can induce the onset of autoimmune myasthenia gravis, possibly through antigenic mimicry.

The diagnosis is made by the history, examination, presence of ACh receptor antibodies (present in up to 90% of cases of generalized disease), edrophonium chloride test, and electrophysiologic studies. Approximately 35 to 50 percent of patients testing negative for ACh receptor antibodies have antibodies to LRP4 or muscle-specific receptor tyrosine kinase (MuSK). It is rare for patients to be positive to more than one of these antibodies. Patients with LRP4 antibodies do not have a distinct MG phenotype.[8] Most patients with MuSK antibodies are women, and many have prominent bulbar, neck, and respiratory weakness. Repetitive nerve stimulation testing for myasthenia gravis may be normal or only mildly abnormal in patients with MuSK-seropositive myasthenia. Treatment of myasthenia gravis consists of anticholinesterases, immunomodulation, thymectomy, or some combination of these approaches. A major prospective, multicenter trial has shown the benefit of thymectomy for seropositive, nonthymomatous generalized myasthenia gravis.

Medications and Toxins

A number of medications (Chapter 32) and toxins impair neuromuscular transmission. These are summarized in Table 60-10.

MYOPATHY

Myopathies usually present with symmetric, proximal weakness. Involvement of the neck flexors and extensors and the facial muscles is not uncommon, but weakness of the extraocular muscles is rare. Muscle atrophy and depressed stretch reflexes occur in advanced cases. The common causes of myopathy are listed in Table 60-11. The congenital and genetic myopathies are beyond the scope of this discussion and are covered in general neurology textbooks. Although myalgia may occur with certain myopathies, most myopathies (including the inflammatory myopathies) are painless. Exercise intolerance and exercise-induced muscle cramps are clues to one of the metabolic myopathies.

The evaluation for a suspected myopathy begins with measurement of serum creatine kinase (CK) activity. Increased serum CK levels usually imply sarcolemmal injury. Normal serum CK levels may occur with disuse atrophy, corticosteroid myopathy, mitochondrial myopathies, and critical illness myopathy associated with thick-filament loss. Many of the metabolic myopathies are associated with normal serum CK levels between attacks. Mild to moderate serum elevations of CK are generally seen with the inflammatory myopathies, toxic myopathies, and adult-onset muscular dystrophies. High serum CK levels are associated with severe toxic/necrotizing myopathies (related to medications or severe electrolyte disturbances) and muscular dystrophy presenting in childhood. Needle EMG supports the clinical diagnosis and excludes the possibility of a neuropathy. The electromyographer may also advise the best target for a muscle biopsy, which is often required for a definitive diagnosis.

TABLE 60-11 ■ Acquired Myopathies

Endocrine
- Acromegaly
- Corticosteroids
- Hyperparathyroidism
- Hyperthyroidism
- Hypothyroidism

Infectious
- Cysticercosis

Medication-Related
- Chloroquine
- Colchicine
- Corticosteroids (see endocrine causes)
- Fibric acid derivatives (clofibrate, gemfibrozil, and others)
- 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (lovastatin, simvastatin, and others)
- Malignant hyperthermia (usually from general anesthetics)
- Vincristine
- Zidovudine

Metabolic and Toxic
- Alcohol
- Critical illness
- Hyperkalemia
- Hypokalemia
- Uremia

Endocrine-Related Myopathy

ACROMEGALY

Slowly progressive proximal weakness not associated with muscle atrophy occurs in about half of acromegalic patients. Many patients have decreased exercise tolerance. Serum CK levels may be mildly elevated. When growth hormone levels normalize, the myopathy usually resolves.

CORTICOSTEROID MYOPATHY

Corticosteroid myopathy may occur with either excessive exogenous or endogenous corticosteroids and is characterized by the insidious onset of proximal limb weakness. Patients who develop weakness usually have other stigmata of long-term corticosteroid use, including a moon facies, suprascapular fat pad, and fragile skin. Old age and cancer are risk factors for corticosteroid myopathy. Myalgias may occur. Serum CK levels are typically normal.

The dose and duration of corticosteroid treatment associated with the development of a myopathy vary widely, but most patients have received therapy for at least 4 weeks. With high-dose corticosteroids, however, the weakness may occur within 2 weeks of starting therapy. The fluorinated corticosteroids, including triamcinolone, betamethasone, and dexamethasone, are particularly likely to cause myopathy. Pathologically, there is selective atrophy of the type 2, glycolytic muscle fibers without muscle degeneration or inflammation. The pathogenesis probably relates to impairment of muscle protein and carbohydrate metabolism. The goal of treatment is to lower the corticosteroid dose to as low a level as possible. Recovery may take weeks to months but is usually excellent.

A severe, acute necrotizing myopathy can result from large doses of intravenous corticosteroids combined with a neuromuscular blocking agent, usually in the setting of treatment for status asthmaticus. There is probably overlap between this condition and critical illness myopathy (Chapter 56).

HYPERPARATHYROIDISM AND OSTEOMALACIA

Proximal muscle weakness may be associated with primary and secondary hyperparathyroidism, vitamin D deficiency, and other disorders of vitamin D metabolism.

Patients with primary hyperparathyroidism often complain of weakness and fatigue, but objective loss of muscle power is uncommon. Proximal weakness may be associated with discomfort on movement. Muscle stretch reflexes tend to be brisk. Serum CK levels are normal. Pathologically, atrophy of type II muscle fibers is a consistent feature. Secondary parathyroidism usually occurs in the setting of renal failure. The myopathy associated with uremia is discussed later.

Osteomalacia presents with proximal weakness and bone pain. Nutritional deficiency of vitamin D is the leading cause of osteomalacia worldwide, but gastrectomy and celiac sprue are responsible for most of the cases in the United States. Renal tubular acidosis and anticonvulsant therapy may also cause osteomalacia by interfering with vitamin D metabolic pathways. Vitamin D deficiency may lead to secondary hyperparathyroidism; it may then be difficult to determine which factor is more important in the pathogenesis of the weakness. When vitamin D—deficient patients are supplemented with vitamin D, the response is variable and any improvement occurs over many weeks.

HYPERTHYROIDISM AND HYPOTHYROIDISM

Approximately 50 percent of thyrotoxic patients develop weakness. The pattern of weakness is typically proximal; patients frequently complain of fatigue and breathlessness. Myalgia is common. Usually the onset is insidious, although the onset may be more rapid in severe hyperthyroidism. In fact, rhabdomyolysis with myoglobinuric renal failure may occur in the setting of a thyroid storm. In general, however, severe generalized weakness in thyrotoxic patients should raise the suspicion of concomitant myasthenia gravis. Serum CK levels are usually normal. The EMG reveals small, short, polyphasic motor units without abnormal spontaneous activity. In addition to nonspecific myopathic findings, muscle biopsies may reveal a lower proportion of type I fibers. Following treatment, the proportion of type I fibers increases. Prognosis for recovery is excellent once a euthyroid state is achieved.

Thyrotoxic periodic paralysis is characterized by recurrent attacks of generalized weakness lasting for minutes to days. The weakness may be provoked by a carbohydrate meal, cold, or rest after exercise. It is usually seen in young Asian or Native American adults. The paralytic attacks are not related to the duration or severity of the thyrotoxicosis. Treatment of acute paralytic attacks includes potassium supplements. The paralytic attacks disappear once the patient is maintained in a euthyroid state.

Hypothyroidism causes a myopathy characterized by proximal weakness, fatigue, slowed movements and reflexes, cramps, stiffness, myoedema, and muscle enlargement. The serum CK level is elevated even in asymptomatic hypothyroid patients and is frequently elevated more than 10 times the upper limit of normal in symptomatic patients. The EMG findings may be normal. Nonspecific myopathic findings are seen on muscle biopsy. After thyroid supplementation, recovery is excellent.

Infectious Myopathies

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

As discussed in Chapter 43, several different types of myopathy have been associated with HIV infection. First, an inflammatory myopathy resembling polymyositis (PM) both clinically and pathologically may occur. Although it may present at any stage of HIV infection, it is usually a complication of AIDS. Patients present with slowly progressive proximal arm and leg weakness. Serum CK levels are elevated, often more than 10 times the upper limit of normal. Pathologically, the findings are similar to idiopathic PM. Viral particles have not been identified in muscle cells. Most cases respond to corticosteroid therapy.

Second, a nemaline rod myopathy may occur with or without associated inflammation in HIV patients. Third, inclusion-body myositis (IBM) has been described in HIV patients. It is clinically and pathologically indistinguishable from sporadic IBM, except that the age at onset is earlier. Fourth, muscle atrophy and weakness occur in the HIV wasting syndrome. Pathologically, there is atrophy of the type II muscle fibers. Tumor necrosis factor α (TNF-α) is implicated in the pathogenesis of this syndrome. Fifth, myoglobinuria (sometimes recurrent) may occur at any stage of HIV infection. Multiple factors, including concomitant medication use, probably contribute to its pathogenesis. Sixth, a pyomyositis manifesting as localized pain and swelling in a limb may occur. It is usually associated with *Staphylococcus aureus* infection. Seventh, a proximal myopathy associated with myalgias in the thighs and calves may occur with high-dose zidovudine (AZT) treatment. Serum CK levels may be normal or mildly elevated. Pathologically, many fibers reveal "ragged red" features consistent with mitochondrial toxicity. Discontinuation of the medication usually results in improvement but sometimes not full recovery.

VIRAL MYOSITIS

Viruses implicated in causing a myopathy include adenovirus, coxsackievirus A and B, echovirus, influenza A and B, Epstein–Barr virus, adenovirus, echovirus, parvovirus, parainfluenza virus, paramyxovirus, CMV, hepatitis B, herpes simplex virus, herpes zoster, human T-lymphotropic virus 1 (HTLV-1), and HIV. Myalgia is the most common neuromuscular symptom associated with viral illness. After the viral illness, swollen muscles and sometimes rhabdomyolysis with myoglobinuria occur. For many of the virus strains mentioned here, there is no clear evidence that the virus actually infects or replicates within human muscle tissue. In such cases, the pathogenesis of the muscle injury is uncertain.

OTHER INFECTIONS

The three most common parasitic infections of muscle are toxoplasmosis, cysticercosis, and trichinosis.

Toxoplasmosis is the most common protozoan infection to cause a myositis, the others being sarcocystis, trypanosomiasis, microsporidiosis, and malaria. *Toxoplasma gondii* is transmitted to humans by ingestion of undercooked meats and by contact with cat feces. Patients present with a fever accompanied by any one of multiple possible systemic features, including lymphadenopathy, pericarditis, hepatosplenomegaly, meningoencephalitis, and myositis. The myositis associated with toxoplasmosis resembles idiopathic PM and dermatomyositis (DM). Pathologically, cysts containing bradyzoites may be seen in muscle fibers or near inflammatory infiltrates. Prognosis for a full recovery is excellent following treatment.

Cestode (tapeworm) infections resulting in myopathy include cysticercosis, echinococcosis, coenurosis, and sparganosis. Cysticercosis caused by *Taenia solium* infection may result from eating uncooked infected meat (particularly pork) and by the fecal–oral route. Patients may present with enlarged yet weak muscles (pseudohypertrophy). Myalgia and muscle tenderness are common.

Nematode (roundworm) infections associated with a myopathy include trichinosis, toxocariasis, cutaneous larva migrans, and dracontiasis. Trichinosis occurs after ingestion of inadequately cooked meat. Following a prodrome of abdominal cramps and diarrhea, patients develop generalized weakness that may be accompanied by the classic cutaneous stigmata of DM. Serum CK levels are elevated and eosinophilia is present.

Inflammatory Myopathies

DM, PM, and IBM present with subacute to chronic, symmetric proximal limb weakness with sparing of the ocular muscles. All share evidence of lymphocytic infiltration of the muscle, but important differences exist among these diseases, particularly in mechanisms of pathogenesis and response to treatment. Autoimmune necrotizing myopathies present in a similar fashion but lack lymphocytic infiltrates.

DERMATOMYOSITIS AND POLYMYOSITIS

The annual incidence of DM and PM in the general population is 0.1 to 1 per 100,000. Women are affected more often than men. Most patients present with a several-month history of subacute proximal weakness, usually without significant muscle atrophy. Typically, the onset of the weakness cannot be precisely recalled. Other symptoms may include dysphagia, nasal regurgitation, or aspiration from weakness of oropharyngeal muscles or the upper esophagus. Myalgias and muscle tenderness occur in 25 to 50 percent of cases but tend to be mild. Muscle pain is more prominent in viral or bacterial myositis, the inherited metabolic myopathies, polymyalgia rheumatica, and fibromyalgia.

In DM, various cutaneous manifestations may precede or accompany the onset of weakness. These include Gottron sign (scaly, erythematous rash over the extensor surfaces of the metacarpophalangeal and interphalangeal joints; a similar rash may occur over the extensor surfaces of the elbows and knees), diffuse flat erythema in the anterior neck and chest and other sun-exposed areas, swelling and reddish violaceous discoloration of the upper eyelids (heliotrope rash), periungual erythema, dilated nail-bed capillary loops, and rough, cracked skin at the fingertips (so-called mechanic's hands). Of note, patients with DM and SLE often share the same 308A polymorphism of the TNF-α promoter region, which suggests that ultraviolet light-induced production of TNF-α may contribute to light sensitivity in both diseases.

Interstitial lung disease is an important complication of PM and DM. Particularly for PM, the presence of interstitial lung disease is associated with antibodies to the histidyl-transfer RNA (histidyl-tRNA) synthetase (anti-Jo-1). The lung disease may precede the myopathy or accompany it in 5 to 40 percent of patients with DM and PM and may present acutely with a nonproductive cough, dyspnea, hypoxemia, and lung infiltrates or chronically with dyspnea. Sometimes it is discovered in asymptomatic patients on screening chest radiographs. The presence of interstitial lung disease is a poor prognostic factor for long-term survival. Patients with DM and PM may have cardiac involvement, which may manifest as supraventricular arrhythmias, atrioventricular conduction blocks, and bundle branch block. Congestive heart failure has also been described.

Malignancies are seen in 6 to 45 percent of DM patients and in 0 to 28 percent of PM patients. A wide variety of cancers are associated with DM including ovarian, lung, pancreatic, stomach, and colorectal cancer, and non-Hodgkin lymphoma. Non-Hodgkin lymphoma and lung and bladder cancers have been associated with PM. Age-appropriate cancer screening tests should be performed in all patients; in those over age 65 years, CT scans of the chest, abdomen, and pelvis are recommended. Pelvic ultrasonography and transvaginal ultrasound are advocated by some experts. Full laboratory screening studies are also important.

PM and DM may overlap with scleroderma, SLE, and, rarely, rheumatoid arthritis and Sjögren syndrome. In scleroderma, a bland myopathy with mild to absent elevations of serum CK levels is common. In a few patients, severe proximal muscle weakness occurs with significant serum CK elevations. Overall, the incidence of myositis in scleroderma ranges from 5 to 17 percent. In North American patients, the anti-PM-Scl antibody is a marker for scleroderma-myositis. PM and DM also occur in association with SLE. The presence of autoantibodies against nuclear components helps distinguish a PM-SLE overlap syndrome from idiopathic PM. Serum CK levels are usually elevated in PM and DM and generally reflect the disease activity; levels are generally higher in PM than DM and may even be normal in active DM.

Serum antibody tests to nuclear and cytoplasmic components help support the clinical diagnosis of PM or DM, assist the diagnosis of overlap syndromes, and categorize subgroups of inflammatory myopathies. Muscle-specific antibodies have specific associations with HLA haplotypes and certain disease manifestations. These include antibodies to aminoacyl transfer RNA synthetases, components of the signal recognition particle (SRP), and nuclear helicase/adenosine triphosphatase Mi-2. About 50 to 75 percent of those with antibodies to cytoplasmic transfer RNA synthetases (including anti-Jo-1) have interstitial lung disease. Patients with anti-SRP antibodies often have acute-onset severe myositis without an associated rash or lung disease. Patients with anti-Mi-2 antibodies usually have a florid rash and an abrupt onset of weakness. Patients with anti-MDA5 antibodies may have amyopathic DM and interstitial lung disease.

MRI shows evidence of inflammation in muscles and subcutaneous fat, fibrosis, and calcification. Because MRI is noninvasive, it can be performed serially to assess disease progression and monitor response to treatment; it may also be used to identify a site for biopsy.

EMG typically reveals increased insertional activity and fibrillation potentials with myopathic (low-amplitude, short-duration, polyphasic) motor unit potentials. Ideally, a muscle biopsy should be performed on a superficial muscle with abnormal findings on EMG of the homologous contralateral muscle.

Pathologically, the inflammation in PM is perivascular, perimysial, and endomysial. There is no evidence of damage to the capillaries. There is invasion of non-necrotic muscle fibers ubiquitously expressing major histocompatibility complex (MHC)-1 by cytotoxic CD8$^+$ T cells. These findings support the hypothesis that the cytotoxic T cells recognize an antigen bound to MHC-1. The identity and origin of this putative antigen are not known. MHC-1 is normally not expressed on the surface of muscle fibers.

In DM, the inflammation is predominantly in the perivascular or interfascicular space and less so in the endomysium. The inflammatory infiltrate is primarily composed of B cells and CD4$^+$ T cells. Unlike PM, the immune attack appears to be primarily directed against the vascular endothelium. The sequence of events is thought to include antibody deposition on the endothelial cells, followed by complement activation, and, finally, membrane attack complex (MAC)–mediated microvascular injury. Chronic ischemia is thought to produce perifascicular atrophy, a hallmark pathologic feature of DM.

Corticosteroids are widely recognized as first-line treatment for PM. The typical daily dose is 1 to 1.5 mg/kg. This dose is continued until strength improves and then a careful, slow taper is started. A number of agents, including azathioprine, methotrexate, cyclosporine, tacrolimus, or mycophenolate mofetil, may be used concurrently or subsequently for a corticosteroid-sparing effect. Patients taking prednisone plus azathioprine have a better functional outcome and need a lower prednisone maintenance dose than those taking prednisone alone. For refractory cases of DM and PM, IVIg appears to be effective. Results from a large randomized controlled trial of rituximab in myositis failed to meet the primary endpoint. Antitumor necrosis factor agents have shown mixed results in small randomized clinical trials. Plasmapheresis did not show a benefit in a double-blind, placebo-controlled trial.

INCLUSION-BODY MYOSITIS

IBM is a slowly progressive, debilitating myopathy of unknown cause. It is the most common myopathy in patients older than 50 years. Early involvement of the finger flexors, wrist flexors, knee extensors, and ankle dorsiflexors is common. Dysphagia may occur, which may be treated with a cricopharyngeal myotomy. A wide variety of autoimmune diseases have been described in association with IBM. Hyporeflexia is common; some patients have clinical and electrodiagnostic evidence of a peripheral neuropathy.

The serum CK level can be normal or up to 10-fold above the upper limit of normal. The EMG findings are similar to those of DM and PM, except that long-duration motor unit potentials are commonly observed and do not exclude the diagnosis of IBM. Many patients with IBM have anti-NT5C1A antibodies, but obtaining a muscle biopsy is generally indicated to confirm the diagnosis.[9]

Pathologically, there is endomysial inflammation with a $CD8^+$ T-lymphocyte predominance, basophil-rimmed vacuoles with eosinophilic inclusions, and intracellular amyloid deposits detected by fluorescence microscopy of Congo red-stained sections or electron microscopy demonstrating 15- to 18-nm tubulofilaments. The vacuoles contain various products of muscle degradation including myeloid bodies, membrane fragments, and debris. In addition, numerous proteins also expressed in Alzheimer disease are found in muscle fibers. This has led to the notion that IBM is a degenerative disease associated with aging. There is generally no effective immunomodulating treatment, although individual patients have responded to corticosteroids, IVIg, and mycophenolate mofetil.

NECROTIZING AUTOIMMUNE MYOSITIS

Necrotizing myopathies are usually toxin-induced and resolve with removal of the toxin; rarely, they are immune mediated and chronic. Patients present with progressive, symmetric proximal muscle weakness of acute or subacute onset. Some patients have distal weakness, and many have dysphagia. Serum CK levels can be elevated markedly (over 20 times the upper limit of normal). The autoimmune disorder may be idiopathic or, rarely, relates to malignancies or use of statin drugs. Paraneoplastic necrotizing myopathy may occur with gastrointestinal tumors, small cell lung cancer, and breast cancer. Other patients with necrotizing autoimmune myositis, usually without malignancies, have antibodies to the signal recognition particle (anti-SRP antibodies). An endomysial microangiopathy leading to capillary loss occurs in anti-SRP myopathy. Rarely, statin drugs may cause a necrotizing autoimmune myositis that persists despite discontinuation of the drug. These patients usually have anti-HMGCR antibodies; some patients with autoimmune necrotizing myopathies associated with anti-HMGCR antibodies have never been exposed to a statin drug.

SARCOIDOSIS

Granulomatous inflammation of muscle is usually associated with sarcoidosis but can also be seen in infectious disease, inflammatory bowel disease, foreign body reactions, thymoma, lymphoma, and myasthenia gravis. It may also occur without any evidence of systemic disease.

Asymptomatic involvement of the muscle occurs in 50 to 80 percent of cases of sarcoidosis. Symptomatic involvement occurs in less than 3 percent of cases. Most patients with sarcoid myopathy present with slowly progressive, proximal weakness. Rarely, patients present with acute myositis or a palpable nodular type of myopathy. The response to corticosteroid therapy is unpredictable. Compared with sarcoid myopathy, patients with isolated granulomatous myopathy have milder, predominantly distal weakness, and the response to corticosteroids tends to be better.

POLYMYALGIA RHEUMATICA

Polymyalgia rheumatica presents with achiness and morning stiffness in the shoulder and hip girdles in patients older than 50 years. Malaise, fever, and anorexia with weight loss are common. There is an association with temporal arteritis and rheumatoid arthritis. The erythrocyte sedimentation rate is almost always increased. Despite functional limitations, confrontational motor testing is generally normal, as also is muscle biopsy. MRI or ultrasonography of the shoulders consistently reveals evidence of bursitis. The symptoms usually respond to low-dose corticosteroids.

Critical Illness Myopathy

Patients with critical illness may develop an acute, acquired myopathy associated with exposure to high-dose corticosteroids and neuromuscular blocking agents (Chapter 56). Critical illness myopathy may be suspected first when patients fail to wean from mechanical ventilation. Patients have flaccid, diffuse weakness that affects the limbs, neck flexors, and diaphragm. Tendon reflexes are usually depressed. Approximately one-third of ICU patients treated for status asthmaticus develop critical illness myopathy. Other risk factors include severe medical illness, renal failure, and hyperglycemia. Patients with critical illness myopathy may also have clinical and electrodiagnostic features of critical illness polyneuropathy. Critical illness myopathy should be distinguished from rhabdomyolysis with myoglobinuria, which can also occur in the ICU setting. Electrodiagnostic testing helps to clarify the diagnosis. Needle EMG reveals fibrillation potentials in limb muscles of some but not all patients. Short, small, polyphasic motor unit potentials are seen. Electrical inexcitability of the muscle to direct needle stimulation occurs in this entity but not in polyneuropathy. Most patients have elevations of serum CK levels, but a normal level does not exclude the diagnosis. Pathologically, there is muscle-fiber atrophy with evidence of a disrupted intramyofibrillar network. Loss of thick filaments (myosin) is a characteristic feature. The pathogenesis is uncertain but may involve glucocorticoid-induced proteolysis of contractile proteins in the setting of muscle-fiber denervation. There is no specific treatment for critical illness myopathy, but corticosteroids and neuromuscular blocking agents should be limited, if possible. Neurologic recovery is usually excellent, assuming that the patient recovers from the underlying medical illness.

Metabolic and Toxic Myopathies

ALCOHOL

Alcoholics may develop an acute necrotizing or chronic myopathy. The acute form presents as an attack of pain and swelling in a limb, usually the calf or thigh. In severe cases, myoglobinuria occurs. The attack usually occurs in the course of a heavy drinking binge. If probed, patients may recall prior bouts of pain and swelling in the limbs associated with earlier drinking binges. Serum CK levels are often markedly elevated. Recovery usually occurs over 1 to 2 weeks, but patients are prone to have subsequent episodes of acute myopathy if drinking is resumed.

The chronic form presents as chronic limb-girdle weakness with preserved reflexes. Serum CK levels are usually normal but may be elevated. Muscle biopsy specimen abnormalities are usually mild and include type II fiber atrophy.

HYPERKALEMIA OR HYPOKALEMIA

Hyperkalemia causes acute generalized weakness and cardiac arrhythmias. The weakness typically begins in the legs and then generalizes over hours to days. Respiratory failure occurs in about 50 percent of cases. Painful dysesthesias may precede the onset of weakness. Reflexes are usually absent. In most cases, the serum potassium level exceeds 7.5 mEq/L. Paralysis only occurs in patients with some degree of chronic hyperkalemia. Electrodiagnostic testing has shown slowing of nerve conduction velocities and low compound muscle action potential amplitudes. The immediate treatment goal is to prevent a cardiac arrhythmia, which can be achieved with an infusion of calcium gluconate.

Hypokalemia may be associated with acute paralysis or subacute myopathy. Acute hypokalemic paralysis occurs in patients with chronic potassium depletion. The onset of weakness occurs over hours to days. Once it starts, the weakness tends to accelerate. In mild cases, weakness may be limited to the legs, but in severe cases quadriplegia with neuromuscular respiratory failure may occur. Extraocular muscles are spared. The potassium level is always below 3.0 mEq/L. The subacute myopathy associated with hypokalemia is characterized by the onset of proximal limb weakness over weeks to months. Serum CK levels are elevated, sometimes markedly. Pathologically, there is muscle-fiber necrosis with multiple vacuoles in some muscle fibers. Occasionally, the course may be more rapid, associated with myalgia, tenderness, and myoglobinuria. Once the hypokalemia is corrected, recovery is rapid and complete.

UREMIA

Uremic myopathy, characterized by proximal weakness, limited endurance, and rapid fatigability, occurs in patients with end-stage renal disease. It usually only occurs with glomerular filtration rates below 25 mL/min. Approximately 50 percent of dialysis patients have this condition. Often, the weakness is mild, and EMG and serum CK levels are normal. Pathologically, there is atrophy of type II muscle fibers. A number of metabolic derangements may contribute to this condition, including secondary hyperparathyroidism, impaired vitamin D metabolism, carnitine deficiency, and reduced clearance of toxic "middle molecules." Insulin resistance, alterations of mitochondrial metabolism, and anemia may also have roles in pathogenesis. Although there is currently no specific treatment for uremic myopathy, an emphasis should be placed on preventing secondary hyperparathyroidism and improving the patient's nutritional status. Carnitine supplementation may be considered. Renal transplantation offers the best chance of improvement.

Medication-Induced Myopathy

Many different medications cause a myopathy (Chapter 32). Most of these cause a necrotizing myopathy that presents clinically with the acute to subacute onset of generalized weakness. In severe cases, myoglobinuria occurs. Myalgias may occur. Serum CK values are usually elevated. Pathologically, necrosis and regeneration of muscle fibers occur, with myophagocytosis. Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors), fibric acid derivatives (clofibrate, gemfibrozil, and others), organophosphates, α-aminocaproic acid, and hypervitaminosis E are all associated with a necrotizing myopathy. Any medication that lowers potassium levels, including diuretics, licorice, and laxatives, may produce a myopathy. Chronic hydroxychloroquine or colchicine use can cause vacuolar myopathy; impaired renal function significantly increases the risk of colchicine-induced myopathy. A few medications (e.g., zidovudine) cause a mitochondrial myopathy. Once the offending medication is discontinued, most patients make a rapid and full recovery.

Statin-Induced Myopathy

Statins rarely cause a necrotizing myopathy with hyper-CKemia. In most patients, the myopathy reverses in weeks to months after withdrawal of the statin, and the serum CK levels normalize. In a subset of patients, however, the myopathy persists despite drug discontinuation. Evidence for an autoimmune basis for this myopathy includes: (1) expression of MHC-1 antigen on non-necrotic muscle fibers, (2) the presence of autoantibodies against muscle 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR), and (3) improvement with immunosuppressive therapies such as prednisone. High levels of HMGCR in regenerating muscle fibers may be responsible for triggering or perpetuating the immune response.

RHABDOMYOLYSIS AND MYOGLOBINURIA

Any cause of muscle injury leads to an increase in serum concentration of myoglobin. Urine dipstick tests are positive when urine concentrations of myoglobin reach 0.5 to 1 mg/dL. If the concentration of myoglobin in the urine surpasses 250 μg (normal is less than 5 ng/mL), the urine will have a cola-color tinge. This reflects destruction of more than 100 g of muscle.

Recognition of myoglobinuria is important because of the potentially life-threatening complication of acute

tubular necrosis. Management includes hydration with alkaline fluids and induced diuresis with hyperosmolar agents such as mannitol. Electrolyte imbalances, such as hyperkalemia or hypocalcemia, may cause cardiac arrhythmias and require prompt reversal. The prognosis for neurologic recovery is usually excellent given the tremendous regenerative capacity of skeletal muscle.

Rhabdomyolysis leading to myoglobinuria may occur when there is direct injury to the sarcolemma or when energy failure occurs. In addition to pigmenturia, presenting symptoms include myalgia, weakness, and muscle swelling. The many causes of myoglobinuria are outlined in Table 60-12.

It should be noted that vigorous exercise (e.g., military physical fitness training) elevates serum CK values in most people (commonly exceeding five times the upper limit of normal), but visible myoglobinuria or muscle weakness is rare. Polymorphisms in the myosin light-chain kinase, α-actin 3, and creatine kinase MM genes have all been associated with higher serum CK elevations after exercise and may be risk factors for exertional myoglobinuria.

Recurrent myoglobinuria, regardless of whether it is associated with exercise, should prompt an investigation into a metabolic myopathy. Glycogen storage diseases, fatty acid oxidation disorders, and mitochondrial cytopathies have all been associated with recurrent myoglobinuria. Diagnosis of these disorders usually requires the analysis of specific enzyme activities in muscle biopsies.

PROGNOSIS

BRAIN DEATH

VEGETATIVE AND MINIMALLY CONSCIOUS STATES

Consciousness is a complex and elusive concept that has been the subject of extensive thought and speculation by philosophers, theologians, and scientists since antiquity. The fact that consciousness may mean different things depending on the context (philosophy, religion, science) demonstrates the importance that understanding normal and disordered consciousness holds across a wide variety of fields of study. In medicine, disorders of consciousness are pervasive among the effects of systemic diseases on the nervous system. Because alterations in consciousness may have important diagnostic, therapeutic, and prognostic implications, a pragmatic approach using the neurologic principle of localization and the medical approach of differential diagnosis is useful. The spectrum of consciousness, from wakefulness to coma to brain death, has an anatomic and biologic substrate.

CONSCIOUSNESS

Historical Perspective

Ever since the Greek physician Galen (130 to 200 A.D.) recognized that a wound of the brain could affect the mind, the roles of consciousness and thought as manifestations of brain injury and impairment have held a special role. During the Renaissance, the philosopher Descartes (1596 to 1650) focused on the "mind–brain problem." He thought that the pineal gland was the seat of the soul, and this structure therefore played a special role in his concept of consciousness, although contemporaries granted this honor to the corpus callosum. Late nineteenth and early twentieth century efforts such as William James's "stream of consciousness" focused on psychologic, not anatomic, mechanisms. Although the effect of systemic diseases on consciousness has been recognized since Hippocrates in the fifth century B.C. described "madness on account of bile," the ability to ascribe testable anatomic and biologic correlates to consciousness is distinctly modern. The two main advances that have made this possible are (1) development of an operational definition of consciousness that has practical applicability and (2) understanding of the anatomic substrate of consciousness.

Definition of Consciousness

In medicine, consciousness can be defined as awareness of self and the environment. Thus, decreased consciousness involves impairment of this state of awareness, with coma being its absence. Consciousness

and conscious behavior have two basic components: arousal and content. Arousal is behaviorally related to the level of alertness or wakefulness. Content describes the complex range of cognitive functions, including thought, memory, and language. As described later, a simplified anatomic model of consciousness gives arousal and content distinct anatomic localizations. Arousal and content may be independent but are frequently interdependent. For content to be present or at least to be assessed clinically, some degree of arousal must be present. Conversely, if decreased arousal (e.g., from sedative drug intoxication) is overcome by a noxious stimulus, content may be seen to be largely normal until arousal fades again. A description of the state of consciousness of an individual must take into account both level of arousal and quality of content. Different diseases and neuroanatomic sites may be implicated, depending on the specifics of the state of consciousness. The term *level of consciousness* usually refers to level of arousal (Table 61-1).

Anatomy of Consciousness

Although somewhat of an oversimplification, the two different components of consciousness are mediated by two distinct neuroanatomic systems (Fig. 61-1). Arousal is mediated by the ascending reticular activating system (RAS). The RAS is located in the brainstem and is a loosely arranged column of neurons extending from the upper third of the pons to the diencephalic structures of the thalamus and hypothalamus.[1] Projections via subcortical relay nuclei, primarily in the thalamus, integrate RAS-mediated arousal with more diffuse cerebral cortical functions. Experimental studies have demonstrated that stimulation of the RAS in a sleeping animal results in immediate behavioral arousal, but when the RAS is destroyed, no amount of sensory stimulation reverses coma, even with subcortical and cortical structures intact.

The content of consciousness is localized more broadly throughout the cerebral cortex. Certain cognitive functions are diffusely localized throughout both cerebral hemispheres, whereas other functions may have more narrow localization. Receptive language and expressive language are principally localized to the superior temporal lobe or posterior frontal lobe, respectively, of the dominant hemisphere. Although various aspects of memory may be stored diffusely, the mesial temporal lobes and mammillary bodies are important for storage of new short-term memory. Conversely, processes such as thought, orientation, attention, and planning are localized diffusely, especially among both frontal lobes. Because a severe impairment of receptive language is likely to alter the state of awareness of self or environment (as far as can be deduced by examination), some may consider it an altered state of consciousness. Others place more emphasis on impairment of bihemispheric dysfunction, evidenced by decreased attention, concentration, and coherent thought, as defining altered content of consciousness. The important lesson is that different aspects of the content of consciousness may have different anatomic localizations and that global impairment of cognitive function implies bilateral cerebral hemispheric dysfunction or disease.

Implications for Systemic Diseases

Coma, or unconsciousness, is a state of unresponsiveness in which the subject has closed eyes and cannot be aroused appropriately with stimuli. For coma to be present, one of two general anatomic conditions must be satisfied: there must be significant impairment of either the RAS or both cerebral hemispheres (Table 61-2). Structural lesions usually cause coma through direct brainstem involvement or through brainstem displacement or compression with subsequent RAS involvement. The underlying pathologic processes are often primary neurologic disorders such as intracerebral hemorrhage, traumatic brain injury, subdural hematoma, brain tumors or

FIGURE 61-1 ■ Neuroanatomy of consciousness. The reticular formation [also known as the reticular activating system (RAS)] is a loosely arranged column of neurons located in the brainstem. Arousal is largely mediated by the RAS through projections to the cerebral cortex through the thalamus. The content of consciousness is localized more diffusely throughout the cerebral cortex. The reticular formation is distinguished from other brain structures associated with induction of sleep. (From Felten DL, Jozefowicz R: Chapter 11. Brain stem and cerebellum. p. 172. In Neuroscience - Felten 1E, Netter Image ID: 8534.)

abscesses, or large cerebral infarctions with mass effect. Transtentorial herniation because of a supratentorial mass, direct brainstem impingement from an infratentorial lesion, or direct parenchymal brainstem involvement from hemorrhagic or ischemic stroke are common examples. Less commonly, subfalcine herniation or bihemispheric mass lesions may lead to coma with an intact brainstem due to diencephalic injury. Metabolic disturbances, by contrast, usually cause coma from diffuse bihemispheric involvement, which presumably results in disconnection between the RAS (and subcortical thalamic relay nuclei) and the hemispheres. The neurologic examination of the comatose patient is an important key in distinguishing the cause and anatomic basis of coma, specifically the presence or absence of brainstem and cranial nerve abnormalities such as pupillary or extraocular movement dysfunction. The cause of lesser degrees

of impaired level of consciousness can also be assessed by determining whether bihemispheric or brainstem dysfunction is responsible.

Sleep should be considered as a separate and distinct entity. Externally, patients in coma initially appear asleep, but sleeping individuals can be roused and then respond to the environment. Normal sleep has several stages that have distinct electroencephalographic (EEG) patterns as discussed in Chapter 51. The EEG findings in coma may vary, depending on the cause, but, in general, do not resemble those of sleep. Altered consciousness in systemic disease is a pathologic state in contrast to sleep, which is a necessary and normal function.

MECHANISMS OF IMPAIRED CONSCIOUSNESS IN SPECIFIC DISEASES

A practical approach to determining the cause of impaired consciousness in systemic disease requires an understanding of the mechanisms by which primary neurologic disorders as well as systemic diseases may affect the central nervous system (CNS). The neuroanatomic localization of consciousness implies that both focal and global, or diffuse, processes may alter the level or content of consciousness. Structural causes are intuitively easier to understand than many metabolic or diffuse causes. Compression, distortion, or infarction of the brainstem and RAS are processes for which urgent interventions, such as neurosurgical evacuation of a mass lesion or thrombectomy of an occluded artery, may be indicated. In contrast, metabolic encephalopathies cause impaired consciousness (either content or arousal) by interfering diffusely with the functions of the brain on a biochemical level; however, some metabolic encephalopathies can be considered "structural" on a microscopic level when they result in direct cellular brain injury. Although the mechanisms by which systemic diseases cause alteration in consciousness are diverse, they can be divided into three broad categories: metabolic encephalopathies, focal neurologic manifestations of systemic disorders, and primary neurologic disorders caused by systemic disease.

Metabolic Encephalopathies

Metabolic encephalopathy is the most frequent cause of disordered consciousness in systemic diseases and is defined as an alteration in consciousness caused by diffuse or global brain dysfunction from impaired cerebral metabolism. The list of metabolic encephalopathies is extensive and includes such disparate conditions as hypoxic-ischemic encephalopathy, hepatic encephalopathy, drug overdose, bacterial meningitis, and the postseizure state. The principal reason for grouping together this wide variety of disorders is that the neurologic examination may appear quite similar regardless of the underlying etiology. Nevertheless, the cause of the metabolic encephalopathy is the fundamental determinant of treatment and prognosis. Thus, considering the biochemistry of metabolic encephalopathies is of prime importance in their differentiation.

Two common themes emerge with regard to presumptive etiologies of metabolic encephalopathies in systemic disease: impaired substrate delivery (glucose or oxygen) to the brain or release by a systemic disease of a circulating substance that crosses the blood–brain barrier (or enters through a broken blood–brain barrier) and causes neuronal and cellular dysfunction (Table 61-3). The former, implicated in hypoxic-ischemic encephalopathy and hypoglycemia, may result in irreversible brain injury. The latter, implicated in most metabolic encephalopathies associated with organ system dysfunction (e.g., hepatic, renal) or with systemic infection, may be largely reversible if the underlying disorder is treated.[2] Although there are exceptions, this mechanistic differentiation can be of great importance in determining treatment and prognosis.

When substrate delivery to the brain is globally reduced, encephalopathy and eventually coma may result. Hypoxia, and especially hypoxia-ischemia, may result in permanent cerebral damage diffusely or in selectively vulnerable areas such as the hippocampus, cerebellum, and thalamus. The degree and duration of hypoxia or decreased cerebral blood flow determine the severity and irreversibility of damage. Hypoxic-ischemic encephalopathy most commonly results from severe hypotension or cardiac arrest and is mediated by the neuronal ischemic injury cascade, which includes release of excitatory amino acids, intracellular calcium influx, lipid peroxidation, and cell breakdown. Multiple clinical trials have demonstrated a beneficial effect of immediate treatment of severely neurologically impaired survivors of cardiac arrest with mild hypothermia (maintaining 33° to 36°C for 12 to 24 hours), and this treatment is part of standard resuscitation guidelines as discussed in Chapter 9.[3] Hypoglycemic encephalopathy is potentially reversible, but permanent damage may occur if it is not treated early. Hypertensive encephalopathy may be due to disordered cerebral autoregulation, elevated cerebral vascular resistance, and subsequent globally decreased cerebral blood flow. These substrate-delivery encephalopathies have altered cerebral oxygen and glucose delivery as a common pathway, regardless of cause, and may result in severe permanent neurologic damage if not treated urgently.

In contrast, systemic organ failure is a common cause of metabolic encephalopathy and carries a different prognosis than the substrate-delivery encephalopathies. Kidney (uremia) and liver failure are common causes. Carbon dioxide narcosis from pulmonary failure and, rarely, pancreatic failure can also cause encephalopathy. The biochemical mechanism of uremic encephalopathy is not known precisely, but decreased ability to utilize adenosine triphosphate by the uremic brain and elevated calcium content in the cerebral cortex and hypothalamus have been suggested. In hepatic encephalopathy, endogenous benzodiazepine-like substances may play a role, as suggested by animal studies and from experience in humans with improvement after administration of flumazenil. In hepatic failure,

elevated levels of α-ketoglutaramate in the cerebrospinal fluid (CSF) correlate with systemic elevations in ammonia as well as depth of coma. Patients with fulminant hepatic failure may also have severe diffuse cerebral edema, and the acutely increased intracranial pressure provides a structural basis for the coma in this situation. Abnormal function of endocrine organs may cause encephalopathy through primary mechanisms (e.g., myxedema coma, thyrotoxicosis, hypocortisolemia) or through changes in electrolytes or the cerebral acid–base environment (e.g., hypercalcemia in hyperparathyroidism).

Encephalopathy frequently accompanies sepsis, especially when associated with multisystem organ failure. Critically ill patients may have multiple reasons for encephalopathy including primary organ failure (especially of kidneys and liver), electrolyte abnormalities, and concurrent use of sedative agents to facilitate interventions such as mechanical ventilation. However, sepsis itself is associated with a metabolic encephalopathy. Although proposed mechanisms of septic-associated encephalopathy range from multiple microabscesses throughout the brain to alterations in cerebral blood flow mediated by nitric oxide, circulating cytokines that cross the blood–brain barrier and are released during sepsis or the systemic inflammatory response syndrome are likely to be implicated. In contrast to substrate-delivery metabolic encephalopathies, these alterations in consciousness are generally thought to be largely reversible if the underlying organ pathologic process or sepsis is reversed.

Electrolyte and acid–base disturbances are common causes of encephalopathy. Among these, hyponatremia, hypernatremia, and hypercalcemia are most commonly associated with a decreased level of consciousness. In most circumstances, these encephalopathies are reversible, although rapid correction of hyponatremia should be avoided to decrease the potential of osmotic demyelination syndrome.

A global decrease in the cerebral metabolic rate of oxygen consumption may occur during profound hypothermia and following sedative drug overdose. This is reversible if substrate delivery is maintained. Thus, general anesthesia itself can be viewed as a cause of reversible metabolic encephalopathy or coma. Metabolic encephalopathy, often without a markedly decreased level of consciousness, may be caused by numerous prescription medications and may be mistaken for dementia in the elderly. Encephalopathy may also be a manifestation of collagen vascular disease (e.g., systemic lupus erythematosus, SLE), or systemic cancer. Although the latter may be mediated by electrolyte disturbances in the setting of the syndrome of inappropriate secretion of antidiuretic hormone or through paraneoplastic antibodies or circulating cytokines, these disorders may also cause alterations in consciousness from focal processes related specifically to the underlying cancer or collagen vascular disease.

The term *delirium* refers to a state of globally disturbed consciousness in which a subject has decreased attention and an altered sensorium, usually developing over hours to days and often with fluctuating symptoms. Agitation and hallucinations may be present but are not required for the diagnosis. Delirium has historically been a general descriptive term akin to metabolic encephalopathy and distinguished from dementia by its fairly abrupt onset, altered sensorium, and association with other medical conditions. However, more recently, delirium has been used specifically to describe a state of fluctuating confusion in hospitalized patients, often in those who are critically ill. The presence of delirium has been associated with worsened clinical outcome in these patients, and some studies have suggested that delirium is itself an independent condition with a pathophysiology and treatment distinct from the many other systemic diseases known to cause metabolic encephalopathy. The neurotransmitter acetylcholine is particularly implicated in delirium.[4] Predisposing factors include older age, dementia, sensory impairment, sleep deprivation, and the use of sedative medications. Inflammatory serum markers and genetic polymorphisms of the apolipoprotein E gene have also been suggested as predictors of presence or duration of delirium. In the intensive care unit, the use of the sedative medication dexmedetomidine has been associated with less delirium than benzodiazepine infusions. Long-term cognitive impairment has been associated with delirium in acutely hospitalized patients, especially those with pre-existing cognitive impairment.[5] It is distinctly uncommon, however, for delirium to lead to a chronic vegetative or minimally conscious state. It remains controversial whether delirium is a target for specific treatment or is principally an indicator of the need for aggressive treatment of underlying medical problems and minimization of sedative usage in the hospital.

Systemic Disorders With Focal Neurologic Manifestations

A variety of systemic disorders may cause alteration of consciousness through either infiltration of the CNS or the presence of discrete lesions. Occasionally, patients may appear clinically to have a diffuse encephalopathy, but close examination reveals focal neurologic signs. In this setting, the distinction between metabolic encephalopathy and diffuse multifocal cerebral disease may be clinically difficult and appear to be only a matter of semantics. Pathologically, however, the processes are quite different, with the latter representing more than just an alteration in substrate delivery or a global process related to circulating systemic factors. The three categories of systemic disease that most often manifest in this manner are collagen vascular diseases, systemic malignancies, and diffuse infections.

Neuropsychiatric complications are frequent clinical manifestations of SLE.[6] Neuropathologic findings in these patients vary from normal to the presence of diffuse microinfarcts. Lupus cerebritis commonly manifests as a focal process with pathologic findings of a bland, and occasionally necrotizing, vasculopathy with perivascular inflammatory infiltrates. There is debate whether this represents a “true” vasculitis or a more infiltrative process surrounding, rather than invading, the vessels. Particular neurologic manifestations depend on lesion location, and aphasia due to focal lesions in the language regions or abulia due to bifrontal lesions are common. Neurosarcoidosis most often manifests as meningeal inflammation or focal cranial neuropathies but can occur as a large cerebral or brainstem mass lesion that affects consciousness.

Systemic cancer affects consciousness in a variety of ways. Cancer may cause metabolic problems related to electrolyte disturbances and primary organ dysfunction. Focal neurologic manifestations in patients with cancer more likely suggest metastatic disease to the CNS, as discussed in Chapter 26. Metastatic brain tumors are much more common than primary brain tumors. Most commonly occurring supratentorially, mass effect from metastases may cause cerebral herniation with brainstem compression or bihemispheric dysfunction. Meningeal carcinomatosis often spares consciousness, except when so extensive that intracranial vessels at the base of the brain are affected, leading to stroke. Cancer treatments themselves may have effects on consciousness. Metabolic encephalopathy may be caused by certain chemotherapeutic agents, and cranial irradiation may result in focal necrosis that may be initially difficult to differentiate from recurrent tumor.

Infection may also cause focal or global neurologic disturbances of consciousness. Brain abscess, meningitis, or encephalitis may occur in otherwise normal individuals or in those with compromised immune systems due to a variety of systemic diseases. Several systemic infections are particularly associated with focal processes or infiltration of the nervous system including human immunodeficiency virus (HIV) infection, syphilis, and Lyme disease. Direct infection of neurons by HIV may result in HIV encephalopathy. Although described as a diffuse encephalopathy, it is probably a “microscopic structural” process related to global infection and infiltration. Progressive multifocal leukoencephalopathy (PML) occurs from infection with the JC papovavirus and manifests principally as cerebral white matter lesions that may involve altered consciousness. Patients immunocompromised from HIV infection are also at risk of a myriad of CNS problems, including primary CNS lymphoma, toxoplasmosis, and other opportunistic infections, discussed further in Chapter 44. Syphilis may have a variety of CNS manifestations; consciousness may be affected by strokes in meningovascular syphilis, and dementia occurs in tertiary syphilis. Lyme neuroborreliosis may cause generalized confusion that has been mistaken for psychiatric disease. Like a number of other systemic disorders including SLE, sarcoidosis, PML, and syphilis, Lyme disease may have the neuroimaging appearance of diffuse cerebral white matter (or demyelinating) lesions, and therefore, may mimic multiple sclerosis.

Systemic Diseases Presenting as Primary Neurologic Disorders

Seizures, stroke, and acute mass lesions are primary neurologic disorders that may occur secondary to systemic diseases. Generalized seizures, by definition, result in alteration or loss of consciousness. Stroke and acute mass lesions may cause alterations in consciousness depending on their location. Although systemic diseases such as hypertension and diabetes are implicated in the genesis of stroke, cancer is implicated in metastatic CNS disease, and many systemic disorders cause seizures, certain conditions have primary neurologic diagnoses as their principal manifestation. An example of a systemic disorder that may present initially with seizures or severe encephalopathy is hemophagocytic lymphohistiocytosis (HLH). A form of severe excessive immune activation, HLH often has systemic manifestations such as hepatic or renal impairment and may be associated with hematologic or solid malignancies or rheumatologic disorders. Magnetic resonance imaging (MRI) of the brain often shows scattered lesions on T2-weighted imaging, and CSF is abnormal in about half of cases.

Large-vessel ischemic strokes may occur from either embolic or thrombotic causes. Infective endocarditis or marantic endocarditis (as in SLE or cancer) may result in embolic infarction that may alter consciousness depending on stroke location and size, as discussed in Chapter 6. Hypercoagulable states may occur in cancer or autoimmune disorders and cause thrombotic large-vessel occlusion of the cerebral arterial circulation. Hypercoagulability may also lead to thrombosis of the cerebral venous sinuses; alterations in factors V and VIII as well as proteins C and S during a protein-losing enteropathy such as during an ulcerative colitis flare are a potential cause. Leukemia with white blood cell counts in excess of 100,000/μL, polycythemia vera with hematocrit greater than 55 percent, and essential thrombocythemia with a platelet count above 1,000,000/μL may each increase blood viscosity leading to thrombotic occlusion. Small-vessel or lacunar infarcts rarely result in alterations in consciousness. Cerebral vasculitis, however, is often associated with confusion and alteration in behavior and the content of consciousness due either to large-vessel stroke or, more commonly, to widespread mid-size and small-vessel infarction. Although cerebral vasculitis may occur in isolation (e.g., granulomatous angiitis of the nervous system), numerous connective tissue disorders, including polyarteritis nodosa and Churg–Strauss syndrome, may be implicated (see Chapter 50).

Cerebral mass lesions that lead to a decrease in the level of consciousness usually develop rapidly. Primary and secondary brain tumors may manifest in this manner, but acute intracranial hemorrhage is the most common responsible lesion. Hypertension is the most common cause of intracerebral hemorrhage. Coagulopathy in the setting of liver failure, disseminated intravascular coagulation, or thrombotic thrombocytopenic purpura may precipitate a spontaneous intracerebral, subdural, or epidural hematoma. Mild head trauma, which would otherwise be well tolerated, may lead to severe intracranial bleeding with subdural or intraparenchymal hematoma formation if a concomitant coagulopathy is present.

APPROACH TO PATIENTS WITH DISORDERED CONSCIOUSNESS

The fundamental goal of evaluation of patients with disorders of consciousness is to distinguish processes that may cause ongoing brain injury from those that are reversible if concurrent systemic diseases are treated adequately. The manifestations of systemic diseases in the CNS are protean, and "benign" and "malignant" causes of altered consciousness may appear clinically similar. Thus, an orderly approach to the evaluation of patients is essential for timely and accurate diagnosis, which can direct focused treatment. The approach should combine clinical neurologic assessment with judicious use of other diagnostic studies including neuroimaging, electrophysiologic evaluation, CSF analysis, and other laboratory tests.

Neurologic History and Examination

The neurologic findings in patients with altered consciousness and the time course of onset are the principal components of patient assessment. All supporting studies, regardless of their nature, must be interpreted within the context of the neurologic examination. The neuroanatomy of consciousness forms the underpinning for neurologic assessment, and it is this localization that allows the formation of a differential diagnosis. The first step is to define whether the primary disturbance is of content or arousal.

When content of consciousness is impaired in patients who are alert and without marked decrease in the level of consciousness, neurologic assessment focuses on higher cortical function. Abnormalities of language, visuospatial orientation, and visual fields suggest a focal cerebral cortical lesion. Disordered attention, concentration, and short-term memory usually indicate a more global process involving both cerebral hemispheres. In the former case, stroke, tumor, a demyelinating process, or focal abscess should be considered, and neuroimaging may be diagnostic. In disorders of global cerebral content, a diffuse process is implicated; depending on the history and associated medical and neurologic findings, a primary neurologic process such as Alzheimer disease or a global metabolic encephalopathy from organ dysfunction, medications, or postictal state may be responsible.

The more urgent circumstance occurs in patients with decreased level of arousal, especially coma. Processes, either structural or metabolic, that develop acutely tend to involve a disproportionately decreased level of consciousness compared with those that develop over much longer periods of time. The initial focus of the neurologic examination of the stuporous or comatose patient should be in defining the anatomic localization of the process, distinguishing between brainstem (RAS) and bihemispheric disease. This is also often the distinction between structural (usually RAS) and metabolic (usually bihemispheric) causes of coma. A notable exception is the locked-in state, in which a structural lesion, usually a stroke, involves the brainstem but spares the RAS.[7] Patients who are "locked in" are not comatose and may have intact consciousness; motor function in the form of eye opening and blinking is usually retained, whereas horizontal ocular movements and appendicular motor function are typically absent. Thus, the first step in clinical evaluation of the apparently comatose patient is to exclude the possibility of the locked-in syndrome, which is suggested by the observation that the patient can open their eyes and blink to command.

Once coma is established, assessment of brainstem and motor function can proceed. Abnormalities of pupillary function, ocular motility, corneal and gag reflexes, and respiratory function help distinguish an intact from an impaired brainstem. Preserved pupillary function is a hallmark for distinguishing between metabolic and structural causes of coma. Reflexive ocular movements (oculocephalic reflexes tested with "doll's eyes" or "cold caloric" maneuvers) are typically preserved in metabolic coma. Occasionally, however, odd conjugate downgaze, skew deviation, and loss of ocular reflexes are found in deep coma caused by metabolic disorders, especially liver failure or sedative drug overdose. Unilateral absence of the corneal or gag reflex suggests structural brainstem impairment. Motor function is symmetric in coma of metabolic origin. Depth of coma, regardless of cause, may determine whether purposeful response to pain is present. Gross asymmetry of purposeful or reflex motor response to pain suggests a structural process. Patients in deep coma of metabolic cause, especially from sedative drug overdose, may exhibit symmetric flexor or extensor posturing, with retained brisk pupillary reflexes and intact brainstem reflexes.

Neuroimaging

Findings on clinical examination direct the need for, and type of, neuroimaging. Most patients without a history of head trauma who are somnolent with a global alteration in cognitive function and intact brainstem reflexes have a metabolic encephalopathy. When a known systemic cause of metabolic encephalopathy, such as uremia, liver failure, or sedative or other drug use, is present, neuroimaging may not be necessary. Conversely, all patients with coma of unknown etiology require urgent head imaging.

The principal value of early neuroimaging is to evaluate for structural processes. Computerized tomography (CT) is particularly effective at demonstrating acute intracranial hemorrhage and in most centers is more easily obtained in neurologically impaired patients than MRI; therefore noncontrast CT is the best first option for neuroimaging in patients with acute alteration or loss of consciousness. CT in acute stroke (within the first 12 hours) may be normal or show only subtle abnormalities such as loss of gray–white differentiation or mild edema. CT is greater than 93 percent sensitive for subarachnoid hemorrhage within the first day following aneurysm rupture, and nearly always shows acute intraparenchymal or extra-axial processes such as hemorrhage and mass lesions that are causing cerebral herniation. By contrast, head CT in metabolic encephalopathy is usually negative or nondiagnostic.

MRI is much better than CT at delineating specific anatomic structures, especially in the posterior fossa. It is usually not necessary in the emergency setting when CT has been performed. An important exception is when cerebral venous sinus thrombosis is suspected; CT with contrast demonstrates a sign known as the "empty delta" in approximately 30 percent of cases; this represents clot in the torcula, where the superior sagittal sinus meets the paired transverse sinuses.[8] However, MRI with contrast, especially when done with magnetic resonance venography, is highly sensitive and specific for thrombosis of the sagittal sinus or other intracranial venous sinus that might be the cause of coma. Contrast CT venography is also an option. For patients in whom altered consciousness or coma is not acute, MRI may be preferable to CT because it is more likely to reveal cerebral metastases, subtle signs of infection or cerebral swelling, or changes that are sometimes seen in certain metabolic conditions, such as basal ganglia abnormalities in liver disease or posterior white matter changes in hypertensive encephalopathy or eclampsia.

Electrophysiologic Studies

EEG and evoked potentials are the major electrophysiologic modalities of diagnostic use in patients with altered consciousness. They are used mainly to exclude seizures (especially nonconvulsive status epilepticus), to confirm the diagnosis of certain metabolic encephalopathies that may have characteristic EEG patterns, and to provide a guide to prognosis in irreversible cerebral injuries, especially hypoxic-ischemic encephalopathy. EEG is indicated in patients with coma of unknown etiology, especially those who have nondiagnostic head imaging studies.

Nonconvulsive status epilepticus is a disorder in which generalized seizures continue without gross motor manifestations of convulsions. This may occur in patients who present with clinically apparent seizures and then continue to seize even after clinical evidence of convulsions ceases. It includes patients with frequent complex partial seizures or absence status (spike-wave stupor). Subclinical electrographic seizures may be identified in up to 20 percent of patients with significant primary neurologic injuries (such as stroke or traumatic brain injury) who undergo continuous EEG monitoring in the neurologic intensive care unit. Studies of inpatients with primarily medical illness outside the intensive care unit have found electrographic seizures in 7 to 10 percent of those monitored with EEG.[9] Although this form of status epilepticus as the sole reason for decreased level of consciousness is uncommon, the diagnosis cannot be made without an EEG. Overt status epilepticus, especially myoclonus or nonconvulsive status, after a hypoxic-ischemic cerebral insult usually carries a poor prognosis.

Metabolic encephalopathies have a relatively uniform pattern on EEG, with diffuse bilateral slowing of the background rhythm. As metabolic coma deepens, amplitude may decrease. Triphasic waves may be found in hepatic encephalopathy but are nonspecific and present in other metabolic encephalopathies, including uremic and septic encephalopathies. In patients with hepatic encephalopathy who are receiving flumazenil as a diagnostic or therapeutic maneuver, EEG monitoring can demonstrate return of more normal background rhythms concurrent with improvement in level of consciousness. As with nonconvulsive seizures, other features such as lateralized or generalized periodic discharges may occasionally be seen on EEG in patients with severe metabolic encephalopathies.

Evoked potential monitoring is usually reserved for the evaluation of comatose patients. Short-latency somatosensory evoked potentials (SEPs) are typically preserved in reversible metabolic encephalopathies. However, in conditions that cause neuronal death, they may be abnormal and of prognostic value. In hypoxic-ischemic encephalopathy, bilateral absence of the N20 component of the somatosensory evoked potential (SSEP) to median nerve stimulation is strongly predictive of a very poor neurologic outcome (see Chapter 9). However, timely availability and variable expertise in interpretation remain shortcomings to widespread implementation.

Cerebrospinal Fluid and Other Laboratory Studies

Prior to the development of CT and MRI, lumbar puncture was a standard part of the investigation of patients with alterations in consciousness. Lumbar puncture is currently performed selectively when meningitis and encephalitis are diagnostic possibilities or when the etiology of coma remains elusive despite clinical evaluation, laboratory testing, and neuroimaging. In comatose patients, neuroimaging should be performed before lumbar puncture because of the rare but potential risk of precipitating transtentorial herniation.

Lumbar puncture may be of particular diagnostic utility in patients with an altered level of consciousness related to unsuspected cerebral venous sinus thrombosis from a hypercoagulable state, in which an elevated opening pressure may be the first diagnostic clue of increased intracranial pressure due to venous outflow obstruction. Analysis of the CSF may also be helpful for evaluation for suspected neurosyphilis, Lyme disease, and neurosarcoidosis. In other conditions such as HIV encephalopathy, CSF cell counts may be mildly elevated. A CSF pleocytosis may rarely be present after seizures, even when no apparent CNS infection is present, but this is uncommon and remains a diagnosis of exclusion.

Laboratory testing of serum glucose, electrolytes and of renal and liver function is a fundamental part of the evaluation of all patients with alterations in consciousness. It is important that metabolic derangements found on laboratory testing match the neuroanatomic localization of the patient's syndrome; otherwise, further laboratory, neuroimaging, electrophysiologic, and CSF testing may be required. For example, a patient with liver failure, unilateral impairment of ocular reflexes, and a hemiparesis requires urgent neuroimaging to rule out an intracranial mass lesion such as an acute hematoma, especially because patients with liver failure often have concurrent coagulopathy. Also, when the degree of electrolyte abnormality does not correlate with the depth of alteration in consciousness (e.g., deep coma with a mildly depressed serum sodium concentration), more extensive neurodiagnostic testing should occur.

Diagnosis and Treatment: Coordinated Clinical Approach

The major concern in the management of patients with altered consciousness is preservation or restoration of brain function. The resuscitation principles of maintaining the airway, breathing, and circulation should always be attended to first. By ensuring oxygenation, ventilation, and adequate brain and tissue perfusion, impaired substrate delivery to the brain may be restored and secondary brain injury limited.

A fingerstick or serum glucose level should be performed urgently in all patients with new-onset coma or stupor in order to rule out hypoglycemia as a cause or contributing factor. Neurologic examination should then proceed. Urgent hematologic and biochemical screening tests, including renal and possibly hepatic function studies, should be performed concurrently with neuroimaging, usually CT scanning. Based on these results, EEG and lumbar puncture can be considered. If alteration in consciousness is mild or of relatively long standing, investigation can proceed less urgently.

PROGNOSIS

Prognostication of outcome gives physicians, patients, and families reasonable expectations that can aid in decisions to proceed with, or limit, medical care. It is essential that the prognosticator keep in mind the continuum of prognosis and outcome, recognizing that what would be considered a poor prognosis to some may be acceptable to others.

Coma is one of the most compelling neurologic conditions in which prognostication is often sought. The most important overall determinant of prognosis in coma is the cause of the coma, especially whether the coma is caused by injury to the brain (e.g., from trauma, hypoxia-ischemia, prolonged hypoglycemia) or is secondary to systemic factors (e.g., sedative drug overdose, liver failure, sepsis). In the latter case, prognosis is linked more to the severity of the underlying disease than to the coma itself, although coma in organ failure or sepsis is usually a marker of grave illness that often carries with it a poor prognosis.

There are, however, some general principles to prognostication in coma that may apply across illnesses. There is more information regarding prognosis for hypoxic-ischemic encephalopathy after cardiac arrest than for any other cause of altered consciousness in systemic diseases (see Chapter 9). Historically, specific aspects of the clinical examination performed at different times after resuscitation from cardiac arrest have been used as either the singular or most relied-upon predictors of long-term functional outcome. However, most of these studies were performed prior to the routine use of therapeutic hypothermia and targeted temperature management for severely brain-injured cardiac arrest survivors. While neurologic examination findings of brainstem impairment or motor response no better than extensor posturing to painful stimulus seen 3 to 7 days after resuscitation are still concerning for a poor prognosis, reliance exclusively on the neurologic examination for prognostication after cardiac arrest has been replaced with multimodality prognostication using a range of tests. In addition to the neurologic examination, these may include EEG testing for assessment of background rhythm and reactivity, serum neuron-specific enolase, somatosensory evoked potentials, CT or MRI imaging days after resuscitation, and quantitative pupillometry. No single test is sufficiently reliable for prognostication of a poor outcome to serve as a basis to make decisions to limit care within the first days after resuscitation, and concordance across multiple or all tests is of most utility.[10]

Predictors, either clinical or laboratory-based, for outcome from other causes of metabolic coma are much less available. In a series from several decades ago in which recovery from various forms of coma was assessed, 35 percent of patients with hepatic coma and 34 percent of patients with coma caused by renal failure regained independent function, whereas only 12 percent of patients comatose from hypoxia did so. In another study, it was found that only 8 percent of patients with coma of diverse causes recovered fully or with minimal disability when oculovestibular reflexes were absent. The mortality rate in patients with coma from sepsis-associated encephalopathy and multisystem organ failure approaches 40 percent; this is, however, similar to the mortality rate of multisystem organ failure itself, suggesting that the underlying critical illness, not the presence of coma, defines prognosis in this circumstance. The presence of intact brainstem reflexes (pupils and ocular movements) suggests a more favorable outcome than otherwise in metabolic coma; presumably, these metabolic causes of coma do not usually cause permanent cerebral damage sufficient to cause neuronal death. Most patients who recover from their underlying systemic illness recover completely from coma of metabolic origin. This is not always the case, however, and suggests that some patients with severe critical illness from acute respiratory distress syndrome, sepsis, or electrolyte disturbances may acquire secondary brain injury from either impaired substrate delivery or mechanisms yet to be elucidated.[11]

BRAIN DEATH

The diagnosis of brain death has medical, legal, and ethical implications. In the United States and most other countries, brain death is a prerequisite to most organ donation, although donation following cardiac death is now being used in certain circumstances. Brain death is equivalent to circulatory death (defined by absence of cardiac and respiratory functions) as a medical and legal definition of death, and the time of determination of brain death is considered the time of death. The Uniform Determination of Death Act states that "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards." Despite ample medical and legal precedent for the concept and importance of brain death, several surveys have indicated lack of knowledge and consistent application of clinical definitions and diagnostic criteria. The Quality Standards Subcommittee of the American Academy of Neurology has developed standardized criteria for the determination of brain death in adults, and these form a reasonable, currently accepted medical standard.[12]

The determination of brain death is based primarily on clinical criteria (Tables 61-4 and 61-5), with use of supportive diagnostic tests when necessary. Several prerequisites must be met. It is essential that there be a diagnosis of a CNS catastrophe that is compatible with brain death. These include neurologic disorders (e.g., subarachnoid hemorrhage) and systemic diseases (e.g., hypoxic-ischemic encephalopathy, massive brain edema from fulminant hepatic failure). Complicating conditions that may confound the neurologic examination must be excluded, such as hypothermia (≤36°C), hypotension (systolic blood pressure ≤100 mmHg), drug effects such as from neuromuscular blocking agents or sedatives, and facial or cervical trauma that makes it impossible to perform the neurologic examination.

The three clinical features of brain death, all of which must be demonstrated, are cerebral unresponsiveness, absence of brainstem reflexes, and apnea. Cerebral unresponsiveness is demonstrated by absence of cerebral motor response to painful stimulus (supraorbital and nail-bed pressure in all extremities). Brainstem reflexes that must be demonstrated as absent include pupillary light reflex (usually ≥ 4 mm in size), ocular movement (absent oculocephalic response or "doll's eyes" and absent response to cold caloric testing), facial sensation and motor response (absent corneal reflex), and pharyngeal response (absent gag and cough reflexes). Apnea is confirmed when the $Paco_2$ is documented to rise, following ventilator discontinuation, above 60 mmHg (or 20 mmHg above baseline in patients with chronic carbon dioxide retention) without clinical evidence of respiratory effort, indicating absence of function of central respiratory chemoreceptors and neurons located in the medulla. Independent confirmation by a second physician is required for the clinical diagnosis of brain death.

Several confirmatory laboratory tests may be used in the determination of brain death but do not supersede the clinical examination. The use of confirmatory tests is not required and is usually reserved for patients in whom clinical examination cannot be reliably performed because all conditions that may confound the clinical neurologic assessment cannot be excluded. In patients who have received significant doses of sedative agents (e.g., high-dose barbiturates for treatment of elevated intracranial pressure), clinical examination is unreliable for the diagnosis of brain death. In this circumstance, a cerebral blood-flow study demonstrating absence of blood flow to the brain is sufficient for the diagnosis of brain death.

TABLE 61-4 ■ Conditions to Be Excluded in Using Clinical Criteria for Brain Death

Hypothermia–i.e., temperature ≤36°C

Hypotension/shock–i.e., systolic blood pressure ≤100 mmHg

Hypoxia–i.e., Pao_2 ≤60 mmHg

Sedative drug effects–e.g., high-dose barbiturates

Neuromuscular blocking agents–check peripheral nerve stimulator (for "train-of-four" twitches)

Severe facial trauma–inability to check pupillary or ocular movement function

Severe cervical trauma–high cervical injury interferes with assessment of apnea

TABLE 61-5 ■ Clinical Criteria for Diagnosis of Brain Death

- Diagnosis compatible with brain death (e.g., head trauma, stroke, hypoxic-ischemic encephalopathy)
- All confounding conditions excluded (see Table 61-4)
- Cerebral unresponsiveness: no response to central painful stimulus (supraorbital pressure, temporomandibular joint) in all extremities
- Absence of brainstem reflexes
  - No pupillary reflexes (usually in brain death ≥4 mm in size)
  - No ocular movement (absent doll's eyes or absent response to cold caloric testing)
  - No facial sensation and motor response (absent corneal reflex)
  - No pharyngeal response (absent gag and cough reflexes)
- Apnea: no clinical evidence of respiratory effort when the $Paco_2$ is documented to rise above 60 mmHg (or 20 mmHg above baseline in patients with chronic CO_2 retention)
- Independent confirmation by a second physician

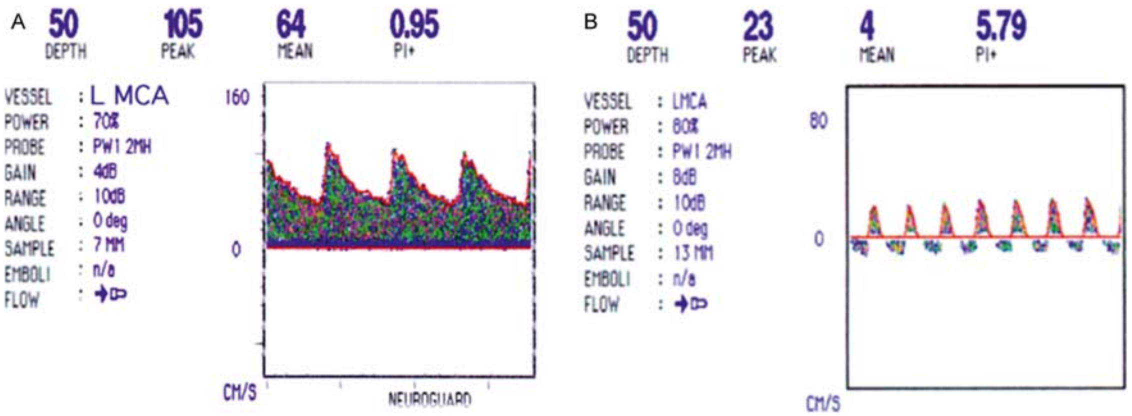

FIGURE 61-2 ■ Diagnosis of brain death by transcranial Doppler ultrasonography (TCD). *A*, Normal blood flow velocity and direction in the left middle cerebral artery (LMCA). *B*, Findings in brain death. Direction of flow is reversed during diastole, indicating cerebral circulatory arrest. For the use of TCD as a confirmatory test in brain death, these findings must be present in both anterior circulations as well as in the posterior circulation.

Formerly, conventional angiography was performed, but currently a nuclear medicine technetium-99m brain scan is often used. Transcranial Doppler ultrasonography (Fig. 61-2) can also be used provided that adequate insonation windows can be obtained. In the absence of sedative medications and hypothermia, EEG performed according to certain specific technical standards can be used when a confirmatory test is necessary.

Some ethical issues remain with regard to brain death. Legally, “irreversible cessation of all functions of the entire brain, including the brainstem” indicates brain death, but it has been left to the medical community to decide how to demonstrate this. When the accuracy of these stated clinical criteria has been reviewed, the diagnosis of brain death has been considered secure. Some have suggested that prolonged unconsciousness or a persistent vegetative state (PVS) is similar to brain death because purposeful consciousness cannot be regained; although these latter circumstances have been supported in terms of withdrawal of medical support and care due to medical futility, they do not meet the medical or legal definitions of brain death and should not be considered equivalent. Some individuals and cultures do not accept the notion of brain death as equivalent to circulatory death, which can present challenges regarding ongoing medical care and the medical—legal interface.

VEGETATIVE AND MINIMALLY CONSCIOUS STATES

Brain death could be considered the ultimate loss of consciousness. The neuroanatomy of brain death requires the loss of function of both cerebral hemispheres and the RAS, although it may not be possible clinically to determine cortical function when the RAS and entire brainstem have been completely destroyed. There are, however, circumstances of permanent loss of consciousness other than brain death. It is uncommon for a sleep-like coma state (eyes closed) to persist for more than 2 to 4 weeks. After this time, patients with permanently disordered consciousness usually evolve to a chronically unresponsive state with eyes open. When subjects exhibit this eyes-open unconsciousness with no awareness of self or the environment for more than 1 to 3 months, the definition of a PVS is met. PVS is also known as the unresponsive wakefulness syndrome (UWS). This state may result from a variety of insults, including acute conditions such as traumatic brain injury, hypoxic-ischemic encephalopathy, and encephalitis, as well as being an end result of chronic neurodegenerative disorders such as Alzheimer disease. Clinically, the UWS appears to involve an intact brainstem and absent cerebral cortical function. Autopsy results have largely confirmed this neuroanatomy, showing extensive cortical and hippocampal damage after hypoxic-ischemic encephalopathy and subcortical diffuse axonal injury after trauma. Occasional reports have demonstrated severe brainstem damage, but not in isolation. However, postmortem examination of a prominent UWS case from the 1980s regarding the right of surrogates to limit ongoing care demonstrated severe bilateral damage to the thalamus, out of proportion to any damage found in the cortex or brainstem, suggesting that the thalamus is important for cognition and that severing the connections between the RAS and cerebral cortex may be sufficient to impair consciousness, perhaps permanently. Thus, different neuroanatomic lesions may lead to the clinical picture of a PVS/UWS and perhaps even the clinical diagnosis of brain death.

It is now clearly recognized that some patients evolve to a clinical state in which they remain severely impaired and unable to perform functionally useful activity and self-care, despite demonstrating evidence of behavioral consciousness and interaction with their environment. This state is known as the *minimally conscious state* and, in contrast to the vegetative state, patients in this state may follow occasional commands, reach for objects, localize noxious stimuli, or demonstrate contingent vocalization, smiling, or crying. Because these activities may be only partially present and able to be performed only intermittently, distinguishing the vegetative and minimally conscious states may be clinically challenging. However, this clinical distinction is important. While patients who meet the definition of chronic vegetative state after a year or more are unlikely to improve, some patients in a prolonged minimally conscious state do show delayed improvement, especially if traumatic brain injury is the initial cause. Unfortunately most of these patients still remain in a state of severe disability.

The concept of distinguishing vegetative from minimally conscious states may additionally be of ethical importance as minimally conscious patients are awake, may perceive pain, and may raise concerns among families and caregivers regarding patient-level communication and long-term care goals. The best way to distinguish these states is through prolonged and multiple neurologic examinations by different examiners who can objectively document their findings. Interestingly, several recent studies have examined functional neuroimaging using functional MRI or positron emission tomography in these two patient groups.[13] In one study including 54 patients, 5 patients (4 diagnosed clinically as vegetative and 1 as minimally conscious, all as a result of trauma) were able to willfully modulate brain activity seen on functional MRI in response to verbal questions, with activity primarily seen in the supplementary motor area or the parahippocampal gyrus, depending on whether the directions were related to motor or sensory imagery.[14] No patient in a vegetative state or minimally conscious state from hypoxic-ischemic brain injury in this study demonstrated willful modulation of brain activity. Another recent study found EEG activation in 15 percent of acutely brain-injured patients who were clinically unresponsive to spoken commands.[15] A single-patient study, in which a patient in a minimally conscious state 6 years after traumatic brain injury underwent thalamic stimulation with an implantable deep brain stimulator, found improvement in arousal and motor control. The use of brain–computer interfaces to help patients in minimally conscious states interact with their environment is an area of evolving research.

SYSTEMIC COMPLICATIONS OF DEMENTIA
- Dysphagia and Aspiration
- Agitation and Delirium
- Depression and Other Mood Disorders
- Falls
- Orthostatic Hypotension
- Sleep Disorders
- Gastrointestinal and Genitourinary Complications

Dementia is a common problem among the elderly and is associated with a number of important systemic complications. Epidemiologic studies estimate the prevalence of Alzheimer disease, the most common form of dementia, in the United States to be approximately 3 percent between ages 65 and 74, 17 percent between ages 75 and 84, and 32 percent over age 84, which ensures that nearly every physician will encounter patients with dementia.[1] Alzheimer disease is the sixth leading cause of death in the United States and continues to increase in prevalence with an aging population.[1] The purpose of this chapter is to review the causes of dementia and the systemic problems that result in order to arm practitioners with the tools necessary to care effectively for this vulnerable patient population.

CAUSES OF DEMENTIA

Most dementias are the result of progressive neurodegenerative diseases (Table 62-1). These conditions usually lead to death within 5 to 10 years of clinical onset.[1] Patients may also acquire dementia after a temporally isolated event such as a severe traumatic brain injury or encephalitis. In such cases, the dementia is not progressive, and some recovery or adaptation can be expected over time. Dementia may also be reversible when caused by certain treatable systemic conditions; these cases are especially important to recognize, diagnose, and treat.

Alzheimer Disease

Alzheimer disease is the most common cause of dementia in the elderly. The disorder almost invariably begins with insidiously progressive short-term memory loss followed by diminished cognitive function in a range of domains that most often include language, visuospatial ability, and praxis. Memory loss is often initially misattributed to normal aging, often leading to a delay in diagnosis. Symptoms are more closely linked to the relative density of tau neurofibrillary tangles than β-amyloid plaques in different brain regions; the highest density of tangles is usually found in the medial temporal lobes, regions critical for the formation of new memories. Other frequently involved areas include the parietal lobes, which are involved in visuospatial processing. The course is relentlessly progressive and universally fatal,

TABLE 62-1 ■ Common Causes of Dementia

Pathology	Disease
Neurodegenerative Diseases	
β-Amyloid, tau	Alzheimer disease
Tauopathy	Frontotemporal lobar degeneration Progressive supranuclear palsy Corticobasal degeneration Chronic traumatic encephalopathy
Synucleinopathy	Dementia with Lewy bodies Parkinson disease Multiple system atrophy
Chronic ischemia	Vascular dementia
Transactive response DNA-binding protein 43 (TDP-43)	Frontotemporal lobar degeneration
Fused in sarcoma protein	Frontotemporal lobar degeneration
Treatable Causes of Dementia	
Infectious	Chronic meningitis (e.g., mycobacterial, fungal) HIV infection Neurosyphilis (general paresis)
Metabolic	Hypothyroidism Vitamin B_{12} deficiency Obstructive sleep apnea
Psychiatric	Depression
Structural	Hydrocephalus Chronic subdural hematoma Brain tumor

leading to death within 4 to 8 years from the time of diagnosis.[1] Death is often from aspiration pneumonia or other complications of the bed-bound end-stage of the illness. While social graces are usually preserved early in the course of the illness, behavioral problems such as aggression, agitation, and episodic delirium often emerge in later stages and are particularly problematic for caretakers. Falls are also common when patients develop postural instability later in the disease course.

Risk factors for Alzheimer disease include age, the presence of the APOE ε4 allele, having a first-degree relative with the disease, low educational attainment, traumatic brain injury, tobacco use, hearing loss, diabetes, hypertension, obesity, hypercholesterolemia, sleep-disordered breathing, social isolation, and depression.[2] Factors associated with reduced rates of the disease include regular exercise, social engagement, and higher educational attainment.[2] Whether addressing these risk factors prevents Alzheimer disease remains unclear. Less than 1 percent of cases are inherited in an autosomal dominant pattern and these are mainly caused by mutations in the genes encoding amyloid precursor protein, presenilin 1, and presenilin 2.[1] There is no treatment that halts the progression of the disease. Centrally-acting acetylcholinesterase inhibitors such as donepezil, rivastigmine, and galantamine, and the *N*-methyl-D-aspartate receptor antagonist memantine will boost cognition at various stages of the illness and may as a result temporarily improve quality of life or delay nursing home placement, although clinical effects are marginal.[2]

Vascular Dementia

Cerebrovascular disease carves several paths to dementia. The accumulation of multiple large-territory infarctions in the setting of atrial fibrillation, intracranial atherosclerosis, or other causes of recurrent large-vessel ischemic stroke results in dementia with cognitive deficits referable to the infarcted brain territories. Because dementia progresses with each successive stroke, patients may demonstrate a stepwise decline in function. These patients rarely present to medical care with unexplained cognitive complaints because they are already known to have suffered multiple infarctions.

More common among patients presenting with memory or cognitive dysfunction is dementia resulting from the accumulation of innumerable ischemic lesions in the subcortical and periventricular white matter due to chronic small-vessel disease. The clinical syndrome is one of slowly progressive frontal lobe dysfunction, with problems in working memory and executive function. Involvement of the basal ganglia may result in a shuffling gait and postural instability that resembles parkinsonism. Pathologic examination reveals chronic ischemia with arteriolosclerosis and often amyloid angiopathy of small arterioles. Vascular dementia in many series is the second most common cause of dementia in North America and Europe, accounting for nearly 15 percent of cases.[3]

The incidence of vascular dementia increases with age, and patients are more likely to have hypertension, diabetes, hyperlipidemia, atrial fibrillation, obesity, or a history of tobacco use.[3] Vascular dementia is associated with chronic kidney disease, coronary artery disease, and peripheral vascular disease, although these associations may be mediated by common risk factors. No treatment is known to slow its progression, but physical activity may be protective against its development.[3] It is not known whether aspirin, smoking cessation, or treatment of vascular risk factors prevents or slows the progression of dementia, but these are all standard aspects of secondary stroke prevention and are therefore often a part of the treatment plan for patients with vascular dementia. Donepezil, rivastigmine, galantamine, and memantine have a modest benefit in vascular dementia similar to their effect on cognitive function in Alzheimer disease, but no benefit on global functioning.[3]

Synucleinopathies

The synucleinopathies include dementia with Lewy bodies, Parkinson disease, and multiple system atrophy. The pathologic hallmark of all synucleinopathies is the Lewy body, composed primarily of insoluble α-synuclein aggregates. These aggregates are not common in normal aging; α-synuclein itself is a normally soluble neuronal protein with uncertain function. The role of Lewy bodies and α-synuclein in the pathogenesis of disease is also not well understood.

Parkinsonism is a prominent early feature of most synucleinopathies and describes a clinical syndrome consisting of rigidity, bradykinesia, postural instability, and resting tremor. Rapid eye movement (REM) sleep behavior disorder, in which brainstem projections to the spinal cord that induce atonia during REM sleep are disrupted, causing patients to act out their dreams in dramatic fashion, is another symptom common to the synucleinopathies. REM sleep behavior disorder can precede the onset of parkinsonism in the synucleinopathies by many years.[4] Dysautonomia (e.g., postural hypotension, constipation, urinary incontinence), olfactory dysfunction, and mood disorders are also common early features of this group of disorders.

DEMENTIA WITH LEWY BODIES

Dementia with parkinsonism is the hallmark of this disorder. This diagnosis is likely when cognitive dysfunction manifests prior to or within 12 months following the onset of parkinsonism. Other core features include well-formed visual hallucinations (often of animals), fluctuations in alertness and cognition, and REM sleep behavior disorder.[4] Periodic unresponsiveness is often mistaken for syncope or seizure. Cognitive dysfunction consists of impaired visuospatial ability, attention, and executive function, with relatively preserved memory early in the disease course. Patients are exquisitely sensitive to dopamine antagonists and can develop prolonged encephalopathy and rigidity after exposure to relatively small doses of neuroleptics. Donepezil and rivastigmine are effective at ameliorating the cognitive symptoms and are often titrated to higher doses than those used for Alzheimer disease. The rate of progression is similar to Alzheimer disease although survival after diagnosis may be slightly shorter in Lewy body dementia.

PARKINSON DISEASE

Parkinson disease is a slowly progressive motor disorder in which dementia is usually a late feature. There is degeneration of dopaminergic neurons in the substantia nigra pars compacta in the midbrain. The prevalence of dementia in patients with this disease is approximately 30 percent, and it usually manifests a decade or more into the illness. Clinical features may echo those of Lewy body dementia, although memory dysfunction is sometimes more prominent. Cholinesterase inhibitors modestly improve cognitive symptoms in Parkinson disease dementia.[4]

MULTIPLE SYSTEM ATROPHY

Multiple system atrophy is categorized into two subtypes based on the predominant motor features: parkinsonian (MSA-P, previously known as striatonigral degeneration) and cerebellar (MSA-C, previously olivopontocerebellar atrophy). Both are characterized by a progressive decline in multiple neurologic systems and include autonomic dysfunction manifested by urinary incontinence, erectile dysfunction, orthostatic hypotension, and central sleep apnea; bulbar dysfunction manifested by dysphagia; and either prominent cerebellar ataxia or parkinsonism. Dementia occurs in up to 20 percent of patients with multiple system atrophy and tends to feature executive and visuospatial dysfunction.[5] The course is typically more rapid than that of Parkinson disease and similar to Lewy body dementia and Alzheimer disease.

Tauopathies

The tauopathies are a group of neurodegenerative diseases associated with an abnormal aggregation of tau protein in the brain. The most common is Alzheimer disease, considered separately above.

FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia is a clinically, pathologically, and genetically diverse disorder. On neuropathologic

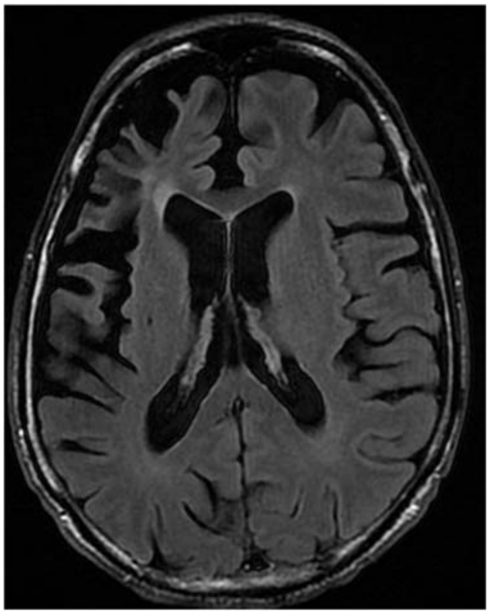

FIGURE 62-1 ■ Frontotemporal dementia. T1-weighted magnetic resonance image of the brain demonstrates atrophy of the nondominant (*right*) frontal lobe out of proportion to other areas.

examination, many cases are associated with inclusions containing tau, a microtubule stabilizing protein.[6] The neuropathology in other cases with similar clinical phenotypes demonstrates inclusions containing TAR DNA-binding protein of 43 kDa (TDP-43) and no tau staining; others are tau negative and TDP-43 negative but positive for the protein fused in sarcoma; and still others are tau negative, TDP-43 negative, fused in sarcoma negative, and ubiquitin positive.[6] Because of overlap between clinical and pathologic subtypes, it is difficult to predict an individual patient's pathology with certainty using current diagnostic techniques, but in general the clinical syndromes associated with tau inclusions are behavioral variant frontotemporal dementia, progressive nonfluent aphasia, progressive supranuclear palsy (PSP), and corticobasal syndrome. Semantic dementia, a variant of frontotemporal dementia with progressive impairment in naming and single-word comprehension, is usually associated with TDP-43 pathology. Many TDP-43-positive cases have comorbid motor neuron disease. There are no specific treatments.

The average age of onset is between 50 and 60 years; the incidence does not increase with age. Frontotemporal dementia accounts for a significant proportion of dementia cases in people aged 45 to 65. The time between onset of symptoms and death is slightly shorter than that in Alzheimer disease. The behavioral variant presents with personality changes, apathy or impulsivity, emotional blunting, loss of empathy and social awareness, lack of insight, mental rigidity, change in eating habits, and poor personal hygiene, all reflecting degeneration predominantly of the nondominant frontal and temporal lobes (Fig. 62-1). When the pathologic process affects the dominant hemisphere, progressive nonfluent aphasia is the typical phenotype and is associated with fewer behavioral changes and more prominent language difficulties.

PROGRESSIVE SUPRANUCLEAR PALSY

Falls are often the earliest symptom in patients with this disorder because of axial rigidity and vertical gaze palsy, the combination of which results in significant postural instability. Other motor symptoms include gait freezing, bradykinesia, rest tremor, apraxia of eyelid opening, dysphagia, and apraxia of speech.[5] Cognitive dysfunction is characterized by a frontal lobe syndrome with executive dysfunction and deficits in working memory, judgment, multitasking, and cognitive processing speed.[5] Neuropsychiatric symptoms also include apathy, disinhibition, dysphoria, and anxiety. Patients are often first misdiagnosed with Parkinson disease, but the diagnosis becomes clear due to the lack of rest tremor, development of a vertical gaze palsy, relatively rapid progression (the median time from onset to death is approximately 8 years), and poor response to dopamine.

CORTICOBASAL DEGENERATION

The term corticobasal degeneration is reserved for patients with a specific pathologic diagnosis, the hallmark of which is tau inclusions. In life, corticobasal degeneration is clinically heterogeneous; patients may present with behavioral variant frontotemporal dementia, progressive nonfluent aphasia, or a more classic corticobasal syndrome that includes asymmetric dystonia and rigidity, isolated limb myoclonus, apraxia, neglect, alien limb phenomenon, and dementia with features similar to PSP.[5] Conversely, some patients diagnosed in life with corticobasal syndrome are found to have Alzheimer disease, PSP, or TDP-43 pathology at autopsy.

CHRONIC TRAUMATIC ENCEPHALOPATHY

A specific pattern of perivascular intracellular phosphorylated tau aggregates can be found at autopsy in the cerebral cortex of patients exposed to repeated head trauma. This pathologic finding is termed chronic traumatic encephalopathy (CTE), and a dose-dependent relationship appears to exist between amount of exposure to head trauma and severity of the neuropathologic findings.[7] The clinical significance of CTE is an area of ongoing research, and validated clinical diagnostic criteria do not yet exist. Patients with CTE at autopsy often demonstrated mood disorders and problems with memory and executive function during life. The age of onset tends to be earlier than that of Alzheimer disease and the course can be progressive or static.

Systemic Diseases Causing Dementia

A number of systemic disorders may cause cognitive decline and mimic Alzheimer disease or other neurodegenerative diseases. These disorders are of importance because they are often treatable. Cognitive decline in most of these conditions is chronic, although occasionally patients present subacutely. Subacute severe cognitive decline, also referred to as rapidly progressive dementia, has a much wider differential diagnosis that is beyond the scope of this chapter.

Cognitive dysfunction is an increasingly recognized neurologic complication of *human immunodeficiency virus (HIV) infection*, discussed in Chapter 43. Previously known by such terms as AIDS dementia complex and HIV encephalopathy, the currently accepted terminology is HIV-associated neurocognitive disorder, with three stages of disease defined based on neuropsychologic testing: asymptomatic neurocognitive impairment, mild neurocognitive disorder, and HIV-associated dementia. Cognitive impairment is described as subcortical, with impaired information-processing speed, multitasking, decision-making, working memory, and verbal fluency. While the incidence of HIV-associated dementia has declined in the era of antiretroviral therapy, the milder subtypes continue to be common, with 33 percent of patients having asymptomatic neurocognitive impairment and 12 percent mild neurocognitive disorder in a large cohort, raising concern that HIV-associated neurocognitive disorder may represent the effect of a reservoir of viral replication sequestered behind the blood–brain barrier. Patients with progressive neurocognitive decline despite suppression of plasma HIV viral load may have detectable HIV RNA in the CSF; in such patients modifying the antiretroviral regimen based on the genotype resistance profile of HIV in the CSF and the regimen's CNS penetration effectiveness may lead to stabilization of the neurocognitive syndrome. According to guidelines from the United States Preventive Services Task Force, HIV screening should be a routine part of healthcare maintenance and, by extension, testing is reasonable in any patient presenting with cognitive symptoms.

Public health efforts directed at screening and treatment have led to a decline in the prevalence of the neurologic complications of *syphilis* (Chapter 39). Tertiary syphilis is therefore a less important cause of dementia than in the past. General paresis, or the dementia caused by syphilis, is a result of direct infection of neural tissue by *Treponema pallidum* and occurs decades after the primary infection. Patients develop progressive memory loss and personality change. Because nontreponemal tests such as the rapid plasma reagin and Venereal Disease Research Laboratory can be negative in late syphilis, a treponemal test such as the fluorescent treponemal antigen absorption and a lumbar puncture should be performed when the disease is suspected. Lymphocyte count and protein concentration are usually elevated in the spinal fluid.

Rarely, *chronic meningitis* such as that caused by *Mycobacterium tuberculosis* (Chapter 40) or *Cryptococcus neoformans* (Chapter 45) may lead to chronic cognitive decline. Usually the dementia in these cases is accompanied by systemic symptoms of chronic infection such as weight loss, night sweats, and occasional fever. Cognitive symptoms typically have features of delirium including waxing and waning levels of alertness and attention. These conditions are readily distinguished from neurodegenerative diseases with a lumbar puncture demonstrating inflammatory spinal fluid.

In addition to fatigue, cold intolerance, hair loss, myxedema, and weakness, *hypothyroidism* is associated with cognitive dysfunction. The symptoms are usually slowed cognitive processing, impaired learning, and depression. The disorder is readily diagnosed by checking serum levels of thyroid-stimulating hormone.

Deficiency of vitamin B_{12} is associated with an increased risk of developing Alzheimer disease, vascular dementia, and Parkinson disease, but there is no compelling evidence that treatment of the deficiency prevents the development of dementia or improves outcomes in patients who have already developed it. However, there are rare cases of patients presenting with dementia and vitamin B_{12} deficiency who have demonstrated sustained recovery following vitamin supplementation, and therefore a trial of this benign treatment is a reasonable approach to these patients.

Structural lesions such as a chronic subdural hematoma, tumors, and hydrocephalus may also lead to dementia. It is for this reason that brain imaging is part of the standard work-up for dementia. Although subdural hematoma may present with seizures or focal neurologic deficits, in some cases the hematoma expands slowly and causes only cognitive symptoms, with subtle or no motor signs. Similarly, brain tumors can mimic neurodegenerative disease, with slow-growing low-grade tumors more likely to do so than glioblastoma or metastases. Symptoms depend on the location of the tumor. Frontal tumors may cause behavioral symptoms such as apathy, loss of insight and judgment, and difficulty with working memory and executive function. Temporal lesions may result in progressive aphasia and memory loss.

Communicating hydrocephalus is associated classically with the triad of dementia, incontinence, and gait disorder, but patients often present with only one of these symptoms. The dementia is typically characterized by frontal lobe dysfunction with symptoms similar to those seen in vascular dementia, although descriptions of large series with robust cognitive testing are lacking. The gait disorder is typically that of gait initiation failure, often described as a magnetic gait, where the feet appear stuck to the floor. Treatment is placement of a ventriculoperitoneal shunt. When the diagnosis is suspected after careful correlation between the history, neurologic findings, and brain imaging demonstrating ventriculomegaly out of proportion to sulcal atrophy (Fig. 62-2), a lumbar puncture should be performed. Because hydrocephalus with elevated intracranial pressure can lead to an identical clinical presentation, measurement of the opening pressure is critical. A good response to ventriculoperitoneal shunt is predicted if the patient's symptoms improve after a large volume (30 to 50 ml) of cerebrospinal fluid is removed. Importantly, many cases of so-called normal-pressure hydrocephalus will turn out to be early presentations of a neurodegenerative condition; this possibility should be excluded rigorously.

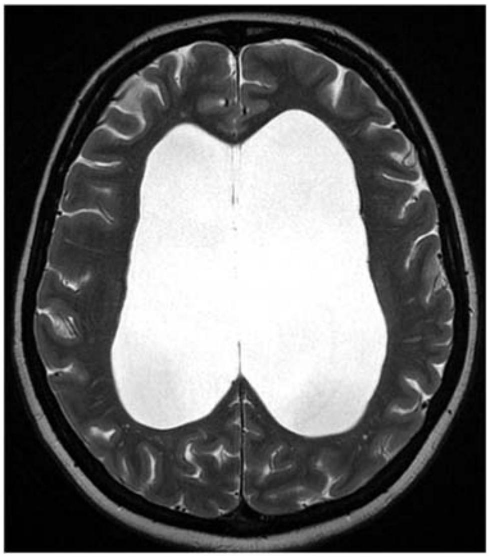

FIGURE 62-2 ▪ Communicating hydrocephalus. T2-weighted MRI of the brain showing ventriculomegaly out of proportion to sulcal atrophy.

Screening for *depression* should be performed during the evaluation of all patients with cognitive symptoms or complaints both because patients with depression may present with memory complaints and because patients with neurodegenerative disease frequently have comorbid depression that contributes to poor cognition. In contrast to patients with neurodegenerative disease who often lack insight into their forgetfulness and frequently confabulate, patients with depression are frequently concerned about memory loss. In depression, bedside neuropsychologic testing classically reveals deficits in memory retrieval with associated mild deficits in attention in addition to the affective disorder.

Obstructive sleep apnea is another important cause of cognitive disturbances. The excessive daytime sleepiness that occurs reduces the ability to focus sustained attention and results in executive and memory dysfunction. In addition, sleep apnea is a risk factor for cerebrovascular disease and stroke, which can augment cognitive decline over time. Effective screening for the sleep disorder includes asking bed partners about snoring and querying the patient about daytime sleepiness; positive screening should trigger a referral for overnight polysomnography.

SYSTEMIC COMPLICATIONS OF DEMENTIA

Patients with dementia are vulnerable to a number of systemic complications (Table 62-2). These complications, especially aspiration leading to pneumonia and falls resulting in hip fracture, are often the cause of death in patients with advanced dementia. Familiarity with these complications of dementia will help providers caring for this population of patients anticipate and, in some cases, prevent these problems.

Dysphagia and Aspiration

Dysphagia occurs in up to half of patients with dementia.[8] In the setting of dementia, the neuroanatomic basis of dysphagia is complex and poorly understood. It tends to occur at earlier stages in the synucleinopathies and Alzheimer disease than in frontotemporal dementia. Dysphagia results in decreased oral intake, malnutrition, dehydration, and is a significant risk factor for aspiration

TABLE 62-2 ■ Systemic Complications of Dementia and Neurodegenerative Disease

Neurodegenerative Disease	Common Systemic Complications
Alzheimer disease	Agitation/delirium Dysphagia/aspiration Falls
Vascular dementia	Falls Depression
Parkinson disease	Dysphagia/aspiration Falls Orthostatic hypotension Excessive daytime sleepiness REM sleep behavior disorder Fatigue Constipation Depression
Dementia with Lewy bodies	As with Parkinson disease, plus: Agitation/delirium Hallucinations and sensitivity to antipsychotics
Multiple system atrophy	As with Parkinson disease, plus: Urinary incontinence Sleep-disordered breathing (sleep apnea, stridor, central hypoventilation)
Frontotemporal dementia	Motor neuron disease
Progressive supranuclear palsy	Falls
Corticobasal syndrome	Falls

REM, rapid eye movement.

of oral contents and resultant pneumonia, which is a common cause of death among the demented elderly. This raises two important questions: can aspiration and aspiration pneumonia be prevented, and how should families of demented patients be counseled regarding the risk and outcome of recurrent aspiration?

Aspiration occurs when food or saliva penetrates the trachea beyond the level of the true vocal folds due to incomplete or delayed closing of the epiglottis during the act of swallowing. During swallowing, the hyoid muscles contract and elevate the larynx, causing the epiglottis to seal the opening to the trachea and allowing oral contents to pass safely into the esophagus. Neurologic disease can cause aspiration due to lesions in the cortex, brainstem, cranial nerves, neuromuscular junction, or muscles that results in incoordination, slowness, or weakness of the swallowing mechanism. In dementia, one theory is that dysphagia is due to disruption of the cortical control of swallowing, causing apraxia and tactile-oral agnosia. Synucleinopathies may disrupt brainstem swallowing networks and cause dysphagia; α-synuclein is also found in sensory neurons in the region of the esophagus critical for initiating the deglutition reflex, suggesting a more local effect. Dysphagia and aspiration occur more typically with liquids than with solids in neurologic disease because liquids enter the posterior oropharynx more quickly and require more complete closure of the trachea and a more rapid swallow mechanism.

Patients with dementia should be routinely screened for symptoms of dysphagia, not only to predict and prevent aspiration, but also to assess nutritional status and quality of life with respect to eating. Clinical signs of dysphagia that are most predictive of aspiration include dysphonia and a wet voice or cough after a trial of swallowing 10 ml of thin liquid. An episode of pneumonia in a nursing-home patient is a likely indication of dysphagia and aspiration. When aspiration is suspected, patients should be referred to a speech and swallow therapist to assess the risk of aspiration through a formal dysphagia evaluation that could include a videofluoroscopic swallowing examination or a flexible endoscopic evaluation of swallowing. In addition, the therapist can recommend dietary modifications or swallowing techniques that may lessen the risk of aspiration.[8]

Dietary modifications to reduce the frequency of aspiration consist of thickening liquids to a nectar- or honey-thick consistency to allow the poorly coordinated swallowing mechanism time to function effectively by slowing the passage of oral contents from the posterior oropharynx into the esophagus.[8] The honey-thick consistency is more effective than nectar-thick consistency in reducing aspiration risk compared with thin liquids, but neither reduces the incidence of pneumonia in patients with dementia and Parkinson disease.[8] The chin-tuck, in which patients swallow with their chin touching their chest, also reduces the risk of aspiration but not pneumonia, and, while less effective than thickened liquids, it is preferred by patients. Practical challenges to these interventions include the supervision required to remind patients with dementia about proper swallowing technique and an increased risk of dehydration with thickened liquids.

Observational studies have not shown percutaneous enteral feeding tubes to reduce rates of pneumonia or prolong survival in patients with dementia, although no randomized trials have been conducted.[9] There are even more limited data on the effect of nasogastric feeding tubes on quality of life.[9] Patients with dementia in whom tube feeding is considered are often at the end-stages of their disease; among nursing home residents with advanced dementia, the 1-year mortality after feeding tube insertion was 64 percent in a study of United States Medicare and Medicaid beneficiaries. In another study, median survival after feeding tube insertion was 177 days.[9] In the absence of disease-modifying treatment or a clear benefit of tube feeding, the utility of this intervention in patients with dementia has been questioned. Despite this, approximately one-third of nursing home residents with dementia in the United States have feeding tubes.[9]

Tube feeding may not alter the risk of aspiration pneumonia and mortality in part because dysphagia is not the only risk factor for pneumonia among frail elderly patients. Restricting patients' oral intake does not prevent aspiration of saliva or regurgitated stomach contents. In addition to dementia, other risk factors for pneumonia include pre-existing lung disease, congestive heart failure, diabetes, malnutrition, bad oral health, and poor functional status. Proton pump inhibitors and histamine receptor antagonists are also risk factors for development of pneumonia.

Placement of an enteral feeding tube therefore requires careful discussion with patients and their caregivers, with all parties having a full understanding of the intervention's uncertain benefit in patients with dementia. Because patients with dementia in whom a decision about enteral feeding is being made often lack decision-making capacity, the responsibility for the decision may fall on surrogate decision-makers who struggle with a perceived dichotomy of providing or withholding nutrition. If patients have not made their wishes clear in advance, this can be a difficult position for surrogates. Reframing the decision to include the option of comfort feeding, which consists of hand feeding with the goal of comfort only, can provide caregivers with an acceptable option in which feedings are still being provided despite the risks of aspiration, but the potential harms of a feeding tube are avoided.[9]

Agitation and Delirium

Demented patients sometimes display aggressive or irrational behavior. Because of the practical challenges in managing such behavior and the emotional burden of seeing a loved one act in a manner incongruent with their usual personality, this can be one of the biggest challenges faced by caregivers of demented patients. Agitation may occur in the setting of delirium or it may be a feature of the dementia itself. Delirium is an acute alteration in mental status with a fluctuating course, impaired attention, and disorganized thinking or an altered level of consciousness in which patients are sometimes somnolent and relatively docile but can also be hypervigilant, impulsive, difficult to redirect, and combative.

Delirium is a common complication of dementia in hospitals, nursing homes, and the community. At least 50 percent of patients with dementia become delirious when hospitalized, and delirium is a common reason dementia patients present to the emergency department.[10] After an episode of delirium resolves, patients with dementia often do not return to their albeit impaired premorbid level of cognitive and physical function, and may experience an accelerated trajectory of cognitive decline.[10] Patients hospitalized with delirium superimposed on dementia have a fivefold increased mortality rate compared with demented patients hospitalized without delirium, and also experience longer lengths of hospital stay and increased rates of institutionalization, highlighting the need for delirium prevention, early detection, and treatment.[10]

Although delirium superimposed on dementia may occur without a specific trigger, there are a number of iatrogenic, metabolic, and systemic derangements that can precipitate an episode of delirium. In such cases, the delirium will not resolve until the underlying problem is diagnosed and treated. Medications are perhaps the most frequent iatrogenic precipitants of delirium. Polypharmacy as well as specific medication classes such as opiates, benzodiazepines, and anticholinergics have been implicated. For this reason, the first step in the treatment of delirium is a thorough review of the patient's medication list, including prescription, nonprescription, and alternative medicines. Attention should be given to reducing doses, minimizing polypharmacy, and replacing neurologically active medications with alternatives. Systemic infections such as cystitis or pneumonia are also common causes of delirium in patients with dementia, as are uremia, hepatic disease, electrolyte and glucose disturbances, urinary retention, constipation, hip fracture, and major surgery.[10] Indeed, delirium may be the first sign of a metabolic problem or infection and should trigger a laboratory and infectious work-up. Hospitalization itself may precipitate delirium in dementia patients, due to the sudden relocation to an unfamiliar environment, sleep deprivation, and confinement to a hospital bed. For this reason, hospitalization of demented patients should not be undertaken lightly. In some cases delirium will only resolve when the patient is returned to their home environment.

Among patients with dementia, agitation and delirium often peak in the afternoon and evening, a phenomenon known as "sundowning." The pathophysiologic basis of sundowning is not clear. It is theorized that degeneration of neurons involved in circadian rhythms in both the suprachiasmatic nucleus and the basal forebrain underlie the development of this time-dependent behavior.

Strategies to prevent delirium differ slightly between the hospital and the nursing home or community setting. In the hospital, multicomponent nonpharmacologic interventions have been demonstrated in randomized trials to lower the incidence of delirium; no medications are known to reduce delirium among hospitalized demented patients. Patients with cognitive impairment are frequently reoriented, and visits with volunteers and family members involve structured reminiscence. Maintenance of a normal sleep–wake cycle is achieved by minimizing night-time interruptions for vital signs and diagnostic tests, avoiding daytime naps, providing cognitive stimulation and mobilization throughout the day, and keeping the hospital ward quiet at night. Sensory deprivation is minimized by providing hearing aids, portable amplifying devices, corrective lenses, and adaptive equipment such as telephones with large keypads for those with impaired vision. Tethers such as restraints and bladder catheters are carefully avoided. Attention is paid to maintaining hydration orally, and patients are monitored and treated for hypoxemia, constipation, and urinary retention. Meta-analyses demonstrate that the odds of delirium can be reduced by at least 40 percent with these interventions, and this multicomponent approach is recommended in several guidelines.[10]

When delirium does occur in the hospital, the initial focus should be on diagnosing and treating the underlying cause, if found. The same nonpharmacologic measures effective in preventing delirium should be employed to treat it. Pharmacotherapy should be reserved for situations in which patients pose a danger to themselves or to the hospital staff. If medications must be administered, the initial choice should be an antipsychotic at the lowest dose possible, and prescribers should recognize the medication is being used as a sedative and not as a treatment for delirium. However, these agents must be used with caution because they are associated with an increased risk of death in the elderly and are not approved by the United States Food and Drug Administration for this indication. Antipsychotics are also especially dangerous in dementia with Lewy bodies and should be avoided due to the possibility of precipitating a rapid and sometimes permanent encephalopathy and rigid state, even in low doses. Benzodiazepines should be avoided except in cases of alcohol withdrawal delirium.

Outside the hospital setting, agitated and aggressive behavior is less often the result of an acute metabolic or infectious problem—although these triggers should never be overlooked—and more often the result of the neurodegenerative process itself or sundowning. In this setting, interventions are aimed at reducing the incidence and severity of agitated outbursts and deescalating aggressive behavior. Both pharmacologic and nonpharmacologic measures have been studied.

Pimavanserin, a serotonin (2A) agonist, is approved by the U.S. Food and Drug Administration for the treatment of hallucinations and delusions in patients with Parkinson disease, but not for the treatment of agitation. There are no approved treatments for aggressive behavior in patients with dementia of any cause. Citalopram, a selective serotonin reuptake inhibitor, demonstrated a modest reduction in agitation among patients with Alzheimer disease in a single randomized trial; notably, cognition worsened with treatment.[2] Atypical antipsychotics are the most widely studied medications for the prevention of agitation in patients with dementia. Meta-analyses of randomized controlled trials found risperidone, aripiprazole, and olanzapine effective in reducing psychotic symptoms and aggression in Alzheimer disease.[11] Risperidone and olanzapine also reduced caregiver burden. Of concern, however, is the finding that atypical antipsychotics increase the risk of death in patients with dementia, likely mediated by an increased incidence of cardiovascular and cerebrovascular events and pneumonia. Antipsychotics also increase the risk of extrapyramidal side effects and accelerate cognitive decline and can dramatically worsen cognition in patients with Lewy body dementia. The use of atypical antipsychotics for behavioral modification in dementia should therefore be reserved for cases where agitation poses a risk to the safety of the patient or caregiver. In such cases, careful documentation of the consent process is important. Antipsychotics, pimavanserin and citalopram can all prolong the QTc interval, which must be monitored periodically. Cholinesterase inhibitors are not effective for prevention of agitation in Alzheimer disease, but are helpful in dementia with Lewy bodies.[11]

Nonpharmacologic prevention of agitation at home and in the nursing home setting focuses on behavioral techniques aimed at anticipating and avoiding triggers, meeting unmet needs, diffusing aggressive behavior, and minimizing caregiver upset. Several randomized trials have examined caregiver training and support strategies and demonstrate greater improvements in problem behaviors and caregiver well-being than atypical antipsychotics.[11] While these types of interventions show promise and lack the risks of pharmacotherapy for agitation in dementia, nonpharmacologic methods require significant investment in human resources without a clear financial incentive and have received less attention and research funding to date.

Depression and Other Mood Disorders

Comorbid mood disorders are highly prevalent among patients with dementia. It is estimated that at least 20 percent of patients with Alzheimer disease have comorbid depression, and rates are even higher in Parkinson disease.[2] Anxiety is also common in neurodegenerative diseases.

Depression has also been identified as a risk factor for dementia in multiple cohort studies, but it is not clear whether depression represents a prodromal phase of dementia, the consequence of dementia, or a modifiable risk factor.[2] Several studies finding a two- to fourfold increased risk of developing dementia later in life among patients with depression in their youth or middle age support the hypothesis that early or midlife depression is a potentially modifiable risk factor.[2]

Among patients with dementia, data regarding treatment of depression are limited. Psychologic therapy employing techniques used in patients with depression without dementia may have a small effect and can be attempted.[2] Randomized trials have not demonstrated efficacy of antidepressants in patients with dementia, although selective serotonin reuptake inhibitors are nevertheless frequently prescribed in this setting.[2] Given their lack of proven efficacy, however, they should be prescribed with caution and patients should be carefully monitored for adverse effects.

Falls

Falls are an early feature of some dementias and a late feature of others. The parkinsonian syndromes are all characterized by early falls due to axial rigidity and loss of postural reflexes resulting in postural instability. In PSP, the inability to look down because of the supranuclear gaze palsy from which the disease's name is derived is an additional exacerbating factor. In other dementias, while postural instability due to the neurodegenerative disease may contribute to falls, the cause is often multifactorial, with additional risk factors including dizziness, lower extremity weakness, visual impairment, polypharmacy, orthostatic hypotension, and a home environment that is not optimized for elder living.

Falls are a dangerous and much-feared event for patients with dementia and their caregivers. A fall leading to a broken hip often leads to the end of independent living and carries a high mortality rate. It is estimated that the probability of falling within 1 year among patients older than 65 years is 19 to 36 percent; this figure is higher in patients with dementia.[12] For this reason, fall prevention is an important part of the care of elderly demented patients.

The most important factor that predicts future falls in older adults is a prior fall within the past year, with positive likelihood ratios of 2.3 to 2.8.[12] Among patients who have not fallen, subjective and objective assessment of gait and balance is likely the most efficient means of screening for those at highest risk. A self-perceived mobility problem has a positive likelihood ratio of 1.7 to 2.0; objective assessments revealing an inability to stand for 10 seconds while keeping the heel of one foot touching the toe of the other, an inability to tandem walk, and taking more than 13 seconds to walk 10 meters, each have positive likelihood ratios of 2.0 to 2.4.[12] For inpatients, the risk of falls can be assessed using one of several tools, including the St. Thomas Risk Assessment Tool in Falling Elderly Inpatients, the Morse Fall Scale, and the Hendrich Fall Risk Model. Factors predictive of inpatient falls using these tools include a history of recent falls, agitation, visual impairment, the need for frequent toileting, requirement of an aid for ambulation, and gait impairment.

Among community-dwelling elderly adults, the risk of falling can be reduced by roughly 25 percent with multifactorial prevention interventions, especially if the interventions include an exercise program that targets balance, gait, and strength.[13] These interventions typically include a risk assessment that reviews medications; assessment of basic and instrumental activities of daily living; measurement of orthostatic blood pressure and visual acuity; evaluation of gait, balance, and cognition; and a detailed assessment of home safety. This risk assessment is followed by targeted interventions that may include elimination of high-risk medications (such as antipsychotics and other potentially sedating medications), a physical therapy or exercise program, education of patients and caregivers, and home safety improvements. In the inpatient setting, falls can be prevented with the same multicomponent intervention designed to prevent delirium.[10]

Orthostatic Hypotension

Postural hypotension is a common complication of certain dementias, especially synucleinopathies. Patients with these disorders should be assessed for this condition when presenting with low blood pressure, dizziness, or falls. Assessment and treatment of postural hypotension are discussed in Chapter 8.

Sleep Disorders

Disturbances of sleep are common among patients with dementia. Some disorders, such as sundowning and insomnia, are common to all forms of dementia, whereas others appear unique to the synucleinopathies. This predilection may be due to the predisposition of α-synuclein aggregates to affect brainstem neurons and interrupt projections involved in arousal and modulation of tone during sleep.

REM sleep behavior disorder is a condition common to the synucleinopathies in which patients act out their dreams during REM sleep. During REM sleep, pathways descending from the lower brainstem to the spinal cord normally cause atonia. It is hypothesized that degeneration of these descending fibers allows uninhibited flow of cortical signals generated during dreams to cause muscle activation. The movements associated with REM sleep behavior disorder are dramatic; often patients have to stop sleeping with their bed partner in consequence. The sleep disorder may precede the development of other manifestations of a synucleinopathy by many years, and approximately 80 percent of patients with REM sleep behavior disorder will develop a synucleinopathy if followed for 10 or more years.[14] Clonazepam taken 30 minutes before bedtime is often effective in treating REM sleep behavior disorder but may cause excessive daytime sleepiness, sleep apnea, behavioral disorders, and unsteadiness, especially in demented patients; melatonin at doses of 3 to 9 mg in the evening has also been helpful in nonrandomized studies.[14] Medications that cause REM sleep behavior disorder, such as selective serotonin reuptake inhibitors, should be discontinued.

Large cohort studies suggest 40 to 50 percent of patients with Parkinson disease suffer from excessive daytime sleepiness, with smaller studies finding similar rates among patients with dementia with Lewy bodies.[4,15] Daytime sleepiness can be exacerbated by the use of the dopamine agonists ropinirole and pramipexole, but it occurs in Parkinson disease independently of medications as well.[15] Fatigue is also a common symptom in Parkinson disease and is more highly correlated with depression than sleepiness, but often occurs independently of both. The degree of daytime sleepiness can be assessed using the Epworth Sleepiness Scale. Treatment for excessive daytime sleepiness should start with education on sleep hygiene in order to reduce insomnia. Patients should be screened for sleep apnea and referred for a sleep study if appropriate. Unfortunately, studies of stimulants such as modafenil, methyphenidate, and caffeine have not demonstrated efficacy in reducing either excessive daytime sleepiness or fatigue in Parkinson disease.[15]

Excessive daytime sleepiness occurs at a similar frequency in multiple system atrophy as in Parkinson disease, but it is correlated with a higher incidence of sleep-disordered breathing.[5] Sleep-disordered breathing in multiple system atrophy manifests as obstructive sleep apnea, nocturnal stridor, and central hypoventilation and is an important condition for clinicians caring for these patients to recognize.[5] These disorders may also occur in other synucleinopathies but do so less frequently. Stridor is due to dystonia of the vocal cords and can result in airway obstruction; it is a risk factor for shortened survival in multiple system atrophy. Treatment with continuous positive airway pressure (CPAP) or botulinum toxin injections to the vocal folds, guided by electromyography, may be successful. Tracheostomy may be necessary in cases where stridor occurs during wakefulness or CPAP is not tolerated, although sudden death may still occur due to central hypoventilation.

Gastrointestinal and Genitourinary Complications

Constipation is a prominent feature of the synucleinopathies.[5,15] Its cause may be disruption of parasympathetic efferents by α-synuclein pathology in the brainstem, dysfunction of the enteric nervous system due to α-synuclein accumulation in myenteric plexus, or a combination of both.[15] Treatment consists of osmotic laxatives such as macrogol, the prosecretory locally acting chloride channel activator lubiprostone, and probiotics combined with prebiotic fiber.[15]

Incontinence is common in end-stage dementia. In most dementias, the mechanism of incontinence is one of impaired central inhibition, due to involvement of either pontine or forebrain micturition centers, resulting in urge incontinence. This is in contrast to multiple system atrophy, in which a neurogenic bladder with large postvoid residuals and overflow incontinence is the rule as part of a more systemic autonomic neuropathy. There are few studies of nonpharmacologic management of urinary incontinence in dementia; among these, timed and prompted voiding may be of benefit. Anticholinergic medications should be used with caution given the risk of precipitating delirium in elderly patients with dementia. Bladder catheters should be avoided because they increase the chance of infection and provide a tether to the patient's bed, thereby decreasing mobility and increasing the risk of delirium.

CONCLUDING COMMENTS

Neurologic disorders are often progressive, may be incurable, and commonly lead to significant disability. Palliative care is an important aspect of their management and may be required at any stage of the disease process. This chapter focuses on one specific aspect of palliative medicine, namely end-of-life care, which is often inadequate even in advanced societies.

With the advent of increasingly sophisticated technology and more powerful pharmacologic agents, it has become possible to prolong the last stages of life in patients with severe and irreversible medical disorders, in whom a long-term favorable outcome cannot be achieved. In some instances, the futile use of sophisticated technology to maintain certain bodily functions in individuals with no prospect of useful recovery has involved major financial outlay, an added burden on patients in advanced stages of incurable disease, and unnecessary and prolonged emotional distress to relatives and friends. Indeed, impersonal advances in modern medicine have led to increasing indignity and fear in many individuals as the end of life draws near, and some will die with unrelieved and uncontrolled symptoms.

Neurologists are often required to look after patients at the end of life either because a primary neurologic disorder reaches a terminal phase or because patients with primary medical disorders develop a catastrophic neurologic complication leading to consultation. The ability to recognize the last hours or days of life, that is, to diagnose “dying,” is an important clinical skill that is a prerequisite to the provision of appropriate care.[1] Such patients are usually obtunded, able to take only sips of fluids, unable to take oral medications, and unresponsive to modifications in their therapeutic regimen; there may be no obvious reversible precipitant of their deterioration. Patient management is optimized when there is agreement between members of the healthcare team that the patient is indeed dying.[1] In this circumstance, it is important to avoid giving conflicting messages to patients and their families about the likely course of events.

PHYSICIAN–PATIENT INTERACTIONS

It is the responsibility of all physicians to provide adequate care for patients who have a terminal disease or are dying. The focus of care changes from attempts to reverse or cure an underlying disease to providing compassionate and sensitive care for patients facing imminent death. Such care may be required for no more than a few hours or for as long as several months, depending on the nature of the underlying disorder. Patients or their surrogates will need to be informed of the severity of their disease, and—depending on the circumstances—this is generally best accomplished gradually and with

sensitivity, bearing in mind what they do (and do not) want to know. Patients want hope and reassurance—not necessarily that they will live but that there are options to help their isolation, fear, physical discomfort, and mental distress. Physicians must assume responsibility for helping patients to deal with the bleak uncertainty of the future and to cope with the sense of isolation and dependency that is often experienced with the approach of death. Fears concerning pain or discomfort can often be alleviated by proper explanation, and supportive care by family, friends, and medical attendants may help to diminish otherwise overwhelming feelings of isolation and uncertainty. Some physicians still feel a certain guilt or responsibility for the death of patients, and this colors their approach to patients who are dying. Such attitudes will change only with the wider appreciation that death is but a natural milestone.

With the increasing emphasis on the scientific aspects of modern medicine, the art of the discipline—its human side—is often overlooked. Physicians must be prepared to spend time with their patients to provide support, education, and adequate symptomatic relief and to work with them and their family to enable them to come to terms with events. Unfortunately, however, such discussion and resultant decision-making substantially in advance of death are uncommon. The demands on physicians by patients may be considerable as death approaches. It is especially important for physicians to understand the needs of patients who are unable or unwilling to communicate with them. Patients need to know that they will continue to receive support and care from their physician throughout the process of dying. A cursory glance at patients during the course of a busy ward-round is quite inadequate in this regard. Patients may worry especially if they are to be moved from their home to a hospital, or from one medical facility to another. It should therefore be stressed that they are not being abandoned, that their care will be coordinated and continuity of care assured.

The family, also, may require considerable attention from physicians. This requires a sensitivity to their needs and the ability to communicate fully with them at all times, providing adequate responses to their queries; meeting with them after death has occurred often helps to settle unresolved fears and concerns. The care of terminally ill patients and their families usually requires the cooperation of the entire healthcare team, including nursing staff, social workers, physical and occupational therapists, respiratory therapists, dieticians, and psychotherapists, as well as physicians. The spiritual needs of the family must not be overlooked, and the clergy have an important role in this context.

In many countries, the general public has expressed increasing dissatisfaction with the care received by people who are dying. Fueled by concerns about the quality of end-of-life care, support has grown for the concept that patients with terminal illnesses should have the right to request assistance in dying. The extent to which physicians can assist in this regard is governed by national statutes, and the extent to which physicians choose to become involved in this context is personal and individual. Regardless, many individual physicians support the legalization of medically assisted suicide and voluntary euthanasia, although numerous professional organizations oppose such an approach. Medically assisted suicide involves providing the means for patients intentionally to kill themselves, whereas voluntary euthanasia consists of the deliberate killing of patients at their request. The provision of appropriate palliative care for dying patients would make such radical alternatives unnecessary in many instances. Pain relief, for example, must be adequate even if, as an unintended side effect, the medications used to control pain lead to some shortening of life in consequence.

Ethicists and educators have emphasized patient autonomy in the decision-making process. However, in a study of 8,308 hospitalized patients, 67 percent ultimately preferred to leave medical decisions to their doctor, even though 97 percent wanted their physician to offer them therapeutic choices and consider their opinions.[2] Thus, both patient autonomy and physician beneficence remain important in guiding clinical care. Some patients with advanced medical disease may seek a particular therapeutic intervention that seems unjustified to their physician. Clinicians should behave in a manner that does not conflict with their own beliefs; if differences with patients and their families cannot be resolved by discussion and explanation, it is sometimes worthwhile to transfer patients—with their consent—to the care of another physician. Physicians have the responsibility of withholding treatment when the distress or other adverse effects of therapy cannot be justified by unrealistic hopes of curing or arresting the underlying medical disorder and of withdrawing life-prolonging maneuvers when these have become too burdensome for patients.

Competent adults have the right to refuse medical treatment or to request its discontinuation. Despite this, many patients dying in hospital continue to receive unwanted interventions such as intensive life support that postpone death. Patients' refusals of supportive measures often signify no more than a wish to do without the burden of life-sustaining medical treatment rather than a wish to die. The goals of such treatment must constantly be reappraised by patients, relatives, and medical staff. Even routine procedures such as radiographs, blood tests, and respiratory care may become unwelcome and tiresome interruptions during the last days of life, and the need for them must be re-evaluated as the patient's condition deteriorates. When patients do refuse treatment, however, physicians are responsible for ensuring that this is not an impulsive decision but is based on an understanding of the implications of such a choice.

For competent patients to make informed decisions, it is important that they are properly educated by their physician about their prognosis and options. They should also be encouraged to use advance directives such as a living will to ensure that their own wishes regarding medical intervention are followed if they later become unable to express their preferences because of physical or mental limitations. Such directives should be reviewed and updated regularly. A durable power of attorney for health care in the United States gives another person the power to make medical decisions for the patient as necessary. It is important that physicians educate patients about such opportunities and the ability to make advance directives. Physicians also must be able to assess a patient's competence to make decisions and properly inform proxy decision-makers about the patient's disorder, therapeutic options, and prognosis. Proxies are generally expected to make decisions based on what the patient would have wished, and this assumes some knowledge of the patient's preferences (the substituted judgment standard). Without such knowledge, the proxy can only balance the benefits of any treatment or course of action against the possible burdens (the best interests standard). When the perceived benefits are greater, consent is provided; if the likely burdens exceed any potential benefit, consent is refused.

However, there is a discrepancy between theoretical ethical concepts and clinical reality. A study of dialysis patients revealed that many would allow their designated surrogate to override their advance directives if this was in their interests. Another study found that many elderly or seriously ill hospitalized patients (more than 70%) would not want their stated resuscitation preferences to be followed if they were to lose decision-making capacity but preferred that their family and physician make such decisions for them.[3] It seems that proxy decision-makers have the discretion to assess novel and perhaps unforeseen circumstances, make moral judgments, and sometimes make decisions that differ from the patient's original intent; for example, because the patient's wishes cannot be applied in certain clinical contexts.[4]

When patients do not have the capacity to make clinical decisions and have no designated surrogate, many states allow a next-of-kin surrogate to be appointed. Decisions by both patient-designated and next-of-kin surrogates are prone to error. A systematic literature review and analysis of 16 eligible studies involving 151 hypothetical scenarios and 2,595 surrogate–patient pairs, which collectively analyzed 19,526 patient–surrogate paired responses, showed that surrogates predicted patients' end-of-life treatment preferences with only 68 percent accuracy.[5] Surrogates were least accurate in scenarios involving stroke or dementia. Surprisingly, accuracy was not improved when the patient had designated the surrogate or by prior discussion between patients and surrogates about treatment preferences. Nevertheless, surrogates were more accurate than physicians in predicting patients' treatment preferences.

To better understand the moral obligations of the patient–proxy relationship, Fins and colleagues surveyed 50 patient–proxy pairs and 52 individuals who had been proxies for someone who had died.[4] They used structured vignettes of three separate diseases (one of which was acute stroke), and examined whether respondents believed that proxies should follow explicit instructions and thus act contractually regarding life-sustaining therapy or whether more discretionary (or covenantal) judgments were acceptable. Other variables included the "valence" of initial patient instructions (e.g., "to do nothing" or "to do everything") and the quality of information available to the proxy. They found that the patient–proxy relationship exists on a contractual to covenantal continuum and that disease course, the clarity of prognosis, instructional valence, and quality of patient instructions led to response differences. The use of interpretative or covenantal judgment was desired by patients and proxies when the prognosis was grim, despite initial instructions to pursue more aggressive care. When hopeful feelings modified initial negative instructions, proxies were more uncertain about the propriety of doing nothing.

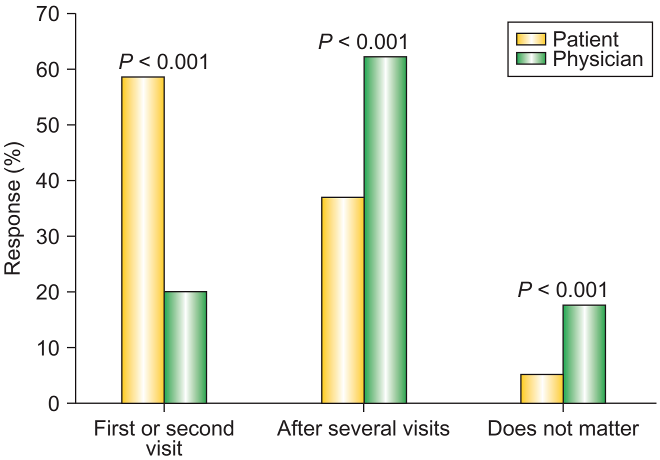

FIGURE 63-1 ■ Patient and physician opinions regarding when advance directives should be discussed. (From Johnston SC, Pfeifer MP, McNutt R, for the End of Life Study Group: The discussion about advance directives. Patient and physician opinions regarding when and how it should be conducted. Arch Intern Med 155:1025, 1995, with permission.)

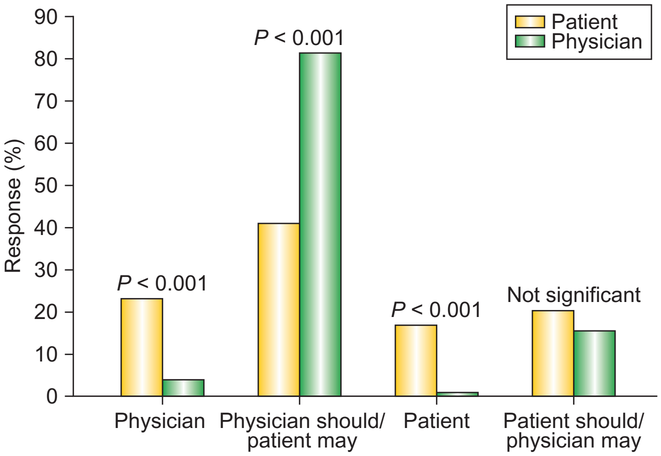

FIGURE 63-2 ■ Patient and physician opinions about who should initiate discussion about advance directives. (From Johnston SC, Pfeifer MP, McNutt R, for the End of Life Study Group: The discussion about advance directives. Patient and physician opinions regarding when and how it should be conducted. Arch Intern Med 155:1025, 1995, with permission.)

Nonetheless, patients and proxies intended that negative instructions to be left alone should be heeded. Respondents did not adhere to narrow notions of patient self-determination but made nuanced and contextually informed moral judgments that were not viewed by patients or proxies as violations of the principal's autonomy. Although respondents were better educated than the general public and were restricted to self-identified English-speaking Americans of European origin (to avoid the possible confounders of race and ethnicity), these data suggest that advance-care planning should consider both the exercise of autonomy and the interpretative function assumed by the proxy.[4]

Studies have indicated that patients want to discuss advance directives earlier than their physicians and before they are "extremely ill" (Fig. 63-1). Most believe that such discussion should occur when they are still healthy. Both patients and clinicians believe that it is the physician who should initiate the discussion (Fig. 63-2), but physicians are often reluctant or fail to do so, being concerned that they will upset or worry patients. In consequence, a crisis may lead to unplanned and unwanted interventions. Many patients believe that others (e.g., a spouse or "significant other," children, or parents) should be brought into the discussion. Most also believe that it should occur before hospitalization and over several visits. In such discussions, physicians must allow patients to speak uninterrupted and respond sympathetically, with kindness and in simple neutral terms, avoiding jargon or technical terms that may not be understood. The importance of imparting accurate prognostic information was mentioned earlier.

Many healthy subjects consider certain neurologic states to be unacceptable and express the belief that they would not want to remain alive in those circumstances. However, after developing such disability, some patients change their opinion and may experience a better quality of life than previously envisioned, as discussed later with particular regard to the de-efferented state. This possibility must be borne in mind when statements made by a patient before their illness are considered.[6]

Decisions about whether to adopt life-sustaining measures often need to be made in a context where the prognosis is uncertain. It is important to note, however, that such decisions can be changed later as the prognosis becomes clearer because no logical or ethical distinction exists between withholding and withdrawing life-sustaining measures.

For patients nearing the end of life, decisions have to be made about whether cardiopulmonary resuscitation should be attempted, if the need arises. In patients with terminal diseases, such decisions often bear more on the issue of how a patient will die than on whether death will occur, and it is important for patients and family members to understand this distinction.

A decision by a patient (or family members) needs to be made in advance, so that individual wishes can be taken into account in the event that resuscitation is required. In many European countries, physicians take an active role in advising patients and family members about the most appropriate course of action to follow, whereas many physicians in the United States believe that this is an individual decision that is best left to the patient. It is this author's view that the physician—as the most informed person in the healthcare team—should be responsible for ensuring that the patient or surrogate is sufficiently well educated about the issues to make informed decisions, guided by suggestions or recommendations when these are requested of the medical staff.

It is often helpful to discuss the possibility of organ donation with dying patients when this is a significant consideration. This makes it easier for family members, who may otherwise have to be approached about the issue shortly after the death of their relative. A variety of ethnic, religious, and cultural factors affect attitudes concerning organ donation, and these must be respected. Physicians must appreciate that patients are not obliged to donate organs and may choose to limit any donation that they make.

PROVISION OF CARE

With their increasing emphasis on surgery and advanced technology, hospitals no longer are able to provide for the long-term care of patients who are dying. By contrast, the needs of the terminally ill are often met more fully in the environment of a hospice, where a multidisciplinary team can focus on their care and support, or at home, if an adequate family structure and medical/paramedical support are available. Hospice care can also be provided to patients in their own home, with comprehensive services offered to ensure patient comfort and provide help for the family in coping with the burden placed on them. Care for patients in a home environment requires careful education of the family, reduction of probable causes of stress (such as violence, agitation, or incontinence), support of caregivers by ensuring assistance from other ancillary healthcare providers, and provision of periodic respite to the family.[7] The interests of patients nevertheless remain the prime concern. When family members appear preoccupied more with their own welfare than that of a severely demented or dying patient, the possibility of patient abuse may require consideration.[7] Abuse of the weak or elderly is becoming an increasing problem and a matter of grave public health concern.

The care of terminally ill patients should be focused on improving the quality of life rather than simply on extending the duration of life. The aim is to ensure that patients are as comfortable as possible, even during the process of dying. The emphasis is thus on the control of symptoms. Pain is the most common symptom in dying patients. Pain, discomfort, distress, fatigue, dyspnea, anorexia, nausea, vomiting, cognitive disturbances, and affective disorders all require particular care. When the ability of patients to communicate is impaired, it is necessary to infer the presence of distress by such signs as agitation, restlessness, tachypnea, and tachycardia and to initiate treatment accordingly. Many patients fear that any later inability to communicate their distress will lead to unnecessary and increased suffering. The relatives of dying patients frequently complain that signs of distress were ignored in patients unable to communicate their needs verbally. No justification exists for limiting symptomatic measures in such circumstances; overtreatment is preferable to undertreatment.

Opioids have an important role in providing pain relief when nonopioid analgesia is inadequate. Morphine is also particularly useful in relieving dyspnea, often in lower doses than is required for pain. The optimal dose is that providing adequate relief. When it is introduced for pain, morphine is best started in an immediate-release formulation. A starting dose of 5 to 10 mg every 4 hours is often adequate, but higher doses may be needed if patients have previously received another opioid, such as dihydrocodeine. A double dose at bedtime may also be helpful. Rescue supplements of morphine are necessary for "breakthrough" pain. The total daily dose of morphine should be titrated upward rapidly (e.g., by 30 to 50%) if pain relief is inadequate. Once pain is controlled, a modified-release preparation of morphine can be used. Side effects of morphine, especially nausea and constipation, may require concomitant treatment. Delirium resulting from opioid treatment may respond to substitution with an alternative opioid. It may be necessary to administer opioids by a nonoral route in patients with severe vomiting or dysphagia, those with intestinal obstruction or malabsorption, or those unable to comply with an oral regimen. Subcutaneous infusion of diamorphine may be used for pain control in dying patients. Anxiety, agitation, or delirium may respond to benzodiazepines or neuroleptic agents.

Large doses of sedatives and analgesics may have to be administered to relieve pain and distress during the withholding or withdrawal of life-supporting measures, but death is not necessarily hastened by such medication. Supportive therapy is important. Attention to the environment may be rewarding. The intensive care unit, with its harsh light, endless noise, monitoring and other equipment, and frequent alarms, is an overwhelming place that provides no respite for dying patients.

More than half of the deaths occurring in intensive care units occur after life-supporting measures are withheld or withdrawn. Withdrawal of ventilator support is often particularly distressing for both relatives and medical staff, even though this is ethically no different from limiting other therapeutic or supportive measures. Ventilator withdrawal may be accomplished by extubation or by "terminal weaning" (in which ventilator rate, positive end-expiratory pressure, or tidal volume is gradually reduced with the endotracheal tube in place). Regardless of the method used, patient comfort must be ensured, as must the family's perception in this regard. For conscious patients requesting sedation for ventilator withdrawal, Brody and colleagues recommend 2 to 4 mg of midazolam intravenously before withdrawal, and 5 to 10 mg of morphine by intravenous bolus for distress during weaning, followed by continuous infusion (50% of bolus dose per hour); in patients with tolerance to such agents because of prior use, higher doses are needed.[8] Others have used pretreatment with the equivalent of 15 mg per hour of intravenous diazepam or 15 mg per hour of intravenous morphine, increasing the dose as necessary to relieve dyspnea and anxiety, even to the point of unconsciousness if required and requested.

Neuromuscular blocking agents should be discontinued before withdrawal of ventilator support, and indeed probably in all dying patients, to allow verbal communication when this is otherwise possible and to permit signs of distress to be manifest so that appropriate treatment can be provided.[8] The masking of such signs by neuromuscular paralysis serves no useful purpose, and the inability to exhibit signs of distress in this context cannot be taken to imply that such distress is absent.

Attention must be devoted to nutrition, hydration, care of the skin, and sphincter function. The nutrition and hydration of dying patients require careful consideration. The points to consider include whether such support should be provided at all, the manner in which it is best provided, and patients' tolerance of any resulting discomfort, complications, or side effects. There are benefits of withholding nutrition and hydration to shorten life when other treatment is to be discontinued. The artificial provision of nutrition and hydration is a life-sustaining maneuver that does not differ from other maneuvers that supplement or substitute for normal bodily functions. Withdrawal of artificial nutrition and hydration, however, has particular emotional implications for the general public and many clinicians. Such a course therefore demands specific discussion with patients (when communication is possible) and family members, as well as with other members of the healthcare team who may be concerned. It is avoided by some clinicians who fear it will add to patients' discomfort. In fact, however, it is unlikely to lead to much additional distress, and by shortening life may actually limit further discomfort. When distress does follow withdrawal of nutrition or hydration, additional symptomatic measures are necessary.[8] Dryness of the mouth is often relieved by ice chips, glycerin swabs, or petroleum jelly lip balm; withdrawal of medication that may be exacerbating this symptom should also be considered. Mouthwashes may relieve poor oral hygiene, and antimonilial therapy is indicated for candidiasis, antiemetics for nausea, and opiates or benzodiazepines for restlessness or pain.[8]

Some patients develop a "death rattle" as air passes over retained secretions at the back of the throat. This may be distressing to relatives and medical staff. Glycopyrrolate (0.1 mg intravenously every 4 hours as necessary) or—in obtunded patients—atropine (1 or 2 drops of a 1% ophthalmic solution sublingually each hour) may help. Butyl scopolamine 20 to 40 mg/day orally can also be tried.

Thus, the focus is on comfort measures, and nonessential medications and interventions (such as blood tests, intravenous fluids, and the like) are discontinued. Relief of pain, agitation, respiratory difficulty, and other distressing symptoms is assured. There must be good communication with the patient, family, and primary medical practitioner, and the plan of care must be explained to them and understood. Attention should also be focused on religious and spiritual needs.

Various structured systems have been developed to facilitate care practices and monitor their results. The extent to which they improve care is not entirely clear. One such system, initially well regarded, was the Liverpool Care Pathway in the United Kingdom, but subsequent criticism led to a government review and the recommendation that it be phased out in favor of personalized care plans

SPECIAL NEUROLOGIC CIRCUMSTANCES

Palliative care is important for patients with acute stroke, whose needs are often poorly understood. It may also facilitate discussion about such difficult issues as fears of dependence, disability, and death. Symptomatic treatment and comfort measures can improve the quality of life of patients with advanced-stage chronic neurologic diseases such as Parkinson disease. The spouses and other family members of such patients are often exhausted, socially isolated, and without adequate support to help them through bereavement. Bereavement counseling may then help in the transition to a noncaregiver role.

Certain circumstances that are particularly likely to be encountered by neurologists merit brief additional comment here. Difficulties are particularly likely in circumstances in which diagnosis and prognostication are based on purely descriptive aspects of clinical status rather than more objective quantitative laboratory criteria, such as in the management of patients with disorders of consciousness. This requires physicians to be very specific about their limitations in predicting the outcome of certain neurologic catastrophes.

Persistent Vegetative and Minimally Conscious States

The persistent vegetative state is characterized by loss of awareness despite the presence of sleep–wake cycles. It occurs in patients with destruction of the cerebral cortex but preservation of brainstem function. Such patients may survive for prolonged periods if provided with nutrition and fluids. There is general agreement that they do not experience pain or suffering, based on the lack of any behavioral indications of distress and the presence of extensive cortical damage that destroys the substrate of consciousness. Life-prolonging medical treatment can be withdrawn from a patient in a persistent vegetative state when it is clear that this accords with the previously expressed wishes of the patient and the family concurs with the withdrawal of such support. In general, the provision of nutrition and hydration is not to be withheld when the patient's prognosis is uncertain; its withdrawal at a later date is, however, appropriate when it is clear that the patient's condition is hopeless, which usually requires the vegetative state to have persisted for at least 1 month. However, recovery from a vegetative state may take longer than this, depending in part on the underlying etiology.[9] Indeed, a vegetative state is generally required to last for more than 3 months after an anoxic injury or 1 year after a traumatic brain injury before it is considered permanent, and even then a slim chance remains of further recovery with time. Thus, decisions to remove life-supporting measures are commonly made while the likelihood and extent of recovery are uncertain and, consequently, may be influenced by the personal biases of treating medical and nursing staff. It is clearly appropriate in such a context to explain the prognostic dilemma to family members so that decisions are truly informed ones. Management problems may occur when the family is not of one mind about how to proceed. A case in point was that of Terri Schiavo, who was in a post-anoxic persistent vegetative state for some 8 years when her husband took legal steps—opposed by her parents—to remove her feeding tube and discontinue life-prolonging measures.[10] The resulting legal struggle continued over several years and involved various levels of the judiciary as well as state and federal legislative interventions, but support was eventually withdrawn and autopsy confirmed the presence of extensive, irreversible brain damage.

The so-called minimally conscious state designates a state in which patients exhibit inconsistent but discernible evidence of consciousness. It is thus quite distinct from the vegetative state, but it remains difficult to define. Some degree of functional recovery of behaviors suggesting self- or environmental awareness has occurred. Such behaviors may, for example, include basic verbalization or context-appropriate gestures (regardless of accuracy), appropriate emotional responses (e.g., smiling or crying) to the linguistic or visual content of emotional but not neutral stimuli, or more simple activities such as purposive behaviors in response to environmental stimuli (e.g., a finger movement or eye blink apparently to command) or pursuit eye movement or sustained ocular fixation in response to moving or prominent stimuli. Improvement from this state is demonstrated by the restoration of consistent functional communication with the patient.

The minimally conscious state may occur in different neurologic contexts in which there has been a loss of cerebral function and may be temporary or permanent. Only limited information is available about the natural history or long-term outlook, and it depends in part on the etiology of the underlying neurologic disorder. Thus, the prognosis is better for those in whom traumatic brain injury was responsible than in other instances. The likelihood of useful functional recovery declines with time, and patients remaining in a minimally conscious state for more than 12 months are likely to remain severely disabled and without a reliable means of communication, although well-publicized clinical exceptions exist. The patient Terry Wallis, for example, was in a post-traumatic minimally conscious state for some 19 years before recovering awareness and fluent speech, but then remained unaware of all that had transpired since his injury.[11] The clinical examination provides only limited help in defining the prognosis, and whether imaging and electrophysiologic techniques eventually help in this regard and in decision-making remains to be determined. In the meantime, cultural, religious, and family values will govern the responses of relatives to a patient in a minimally conscious state, and health-care providers must respect these responses and the previously expressed wishes of patients.

In the context of both the persistent vegetative and minimally conscious states, clinicians must be careful about suggesting at an early stage that no hope exists of useful recovery in order to justify decisions to discontinue life-supporting therapy when the evidence is lacking. Instead, a frank discussion of the limited information available and the generally poor (but uncertain) prognosis may be ethically more appropriate and lead to more informed management decisions.

The serial clinical assessment of patients in both the acute and chronic setting will help to detect subtle but important changes that may otherwise pass unnoticed and that may affect management. It will also help to clarify for family members the significance of any changes that they have themselves observed. For example, relatives and friends may assume that eye opening, eye movements, swallowing movements, smiling, and other motor activities represent signs of recovery when they develop in a comatose subject, and it is incumbent on physicians to explain that this is not the case so that realistic expectations can be maintained.

Functional imaging may also come to be important in the assessment of these patients. In minimally conscious patients, activation patterns similar to those of healthy subjects have been described and suggest conscious awareness. In patients diagnosed as being in a vegetative state, changes in positron emission tomography or functional magnetic resonance imaging sometimes reveal cortical activation, for example, in response to face-recognition or speech-perception paradigms, instructions to imagine motor activity, or a familiar voice saying the patient's name. Such findings suggest awareness similar to that in patients in a minimally conscious state and may help to indicate which patients behaviorally classified as in a vegetative state are in fact in a minimally conscious state or are likely to recover clinical signs of awareness, thereby providing a guide to prognosis.

There have been occasional anecdotal cases in the lay media of apparently miraculous recovery from a prolonged vegetative or minimally conscious state. The accuracy of some of these reports is unclear, as is the extent to which any recovery was clinically meaningful. Reports of arousal after deep brain stimulation of minimally conscious patients are intriguing. Chudy and associates have reported that with stimulation of the centromedian-parafascicular complex, two of four patients in a minimally conscious state regained consciousness and the ability to walk, speak fluently, and live independently, and a third patient recover consciousness, but remained chairbound.[12]

There are anecdotal reports of arousal and temporary improvement after administration of zolpidem to patients in a persistent vegetative or minimally conscious state. Noormandi and co-workers reviewed specifically the effects of zolpidem on disorders of consciousness, finding that it provided temporary benefit in some but not all patients, and specifically those with nonbrainstem injuries. Patients with post-anoxic encephalopathy or traumatic brain injury were not helped.[13] There are also reports of patients with disorders of consciousness responding to amantadine or apomorphine,[14] but the findings are conflicting and not well substantiated. It appears that in a few patients with abnormalities of arousal or responsiveness, certain interventions may lead to temporary improvement. The systematic evaluation of function in brain-injured patients and of the effects of various manipulations on arousal and prognostication may be rewarding. In the meantime, it is the responsibility of medical and paramedical staff to ensure that anecdotal case reports are not taken out of context and do not result in unrealistic expectations by family and friends attempting to come to terms with the predicament of a patient in a vegetative or minimally conscious state.

De-efferented State

Patients in a "locked-in" or de-efferented state are conscious but quadriplegic and incapable of communication except by eye closure or vertical eye movements. They typically are ventilator dependent. They may be excluded erroneously from clinical decision-making unless the impediment to normal communication is recognized and steps are taken to facilitate other means of communication.

Depending on its cause, locked-in patients may survive for many years and some may even regain some motor functions, such as some recovery of head movement. Nevertheless, the probability of regaining physical autonomy in daily life is remote. Despite their severe motor disability, many of these patients feel that their quality of life is good and certainly better than it is rated by their primary caregiver or spouse. Psychologic adjustment to their disease and its limitations relates to problem-oriented coping strategies, such as developing a communication code, and to perceived social support.[15] Thus, the widely held view that patients with severe disability inevitably have a poor quality of life, become despondent, and come to wish for death is not necessarily true. The quality of life may be acceptable to patients despite severe handicap, and although suicidal thought may occasionally surface there are typically few requests for euthanasia among such patients. Indeed, they almost always indicate their preference to be resuscitated if necessary,[15] an important consideration for those responsible for their care and interacting with affected families.

Nevertheless, some de-efferented patients may decide on withdrawal from further life support, and clinicians are obligated to respect these decisions when they have been made competently. The withdrawal of support must be accompanied by measures to minimize further pain and distress while the patient succumbs.

Advanced Dementia

Meta-analyses indicate that from 60 years of age, the prevalence of dementia doubles with every 5 years of age. Unfortunately, however, only a minority of patients with dementia or their surrogates engage in advance planning for end-of-life care or benefit from palliative care or hospice services. Patients in the early stages of progressive dementing disorders should be encouraged to make their preferences known by discussion with family and healthcare providers and by written advance directives while they are still competent. They often are reluctant to plan ahead, however, either because of a failure to accept that a fatal outcome is likely, because they find such discussions distasteful, or because they prefer to leave such decisions to others. In the absence of such written directives, a proxy decision-maker will need to act for the patient. Well-staffed comprehensive care programs for patients with dementia improve end-of-life care and planning for the future, but financial support for such programs is generally limited.

The management of patients with advanced dementia may be especially challenging for neurologists. Cognitive decline and the disintegration of personality do not justify any disregard of and loss of respect for the individual patient. Medical problems require as much attention as in patients who are cognitively intact. This is particularly difficult because demented patients are often unable to cooperate fully, making the recognition and management of such problems more demanding. The care of patients with advanced dementia requires close interaction of clinicians with other family members to improve the quality of life and to find practical solutions for the minor problems that complicate daily life. Depression may enhance an apparent cognitive decline and may even be mistaken for dementia; the possibility of its presence always merits consideration.

The long-term prognosis of patients with dementia depends in part on the type or cause of the cognitive failure and this—in turn—may affect patient survival, caregiver burden, need for institutionalization, and planning for patient needs. Patients with advanced dementia are not necessarily terminally ill but they may undergo a protracted period during which they are unable to speak or respond to their environment. Decisions about life-sustaining treatment for them are then usually made by reference to the same ethical and legal principles as for dying patients, although there is no unanimity in this regard. In such circumstances, for example, the artificial provision of nutrition and hydration in a demented patient who has lost the ability to eat is best decided based on the previously expressed wishes of the patient or the decision of a surrogate.[7] Palliative care is the preferred approach and is often provided in a nursing-home or hospice environment, although not always satisfactorily.[16]

In one study of patients with advanced dementia living in nursing homes, almost 55 percent died over an 18-month period; the probability of death within 6 months was approximately 25 percent.[16] Among those who died, pneumonia occurred in 37 percent, febrile episodes in 32 percent, and eating problems in 90 percent in the last 3 months of life. Distressing symptoms were common—dyspnea or pain for at least 5 days per month occurred in 46 and 39 percent, respectively; pressure ulcers in 39 percent; agitation in 54 percent; and aspiration in 41 percent. Such symptoms became more common as the end of life approached. Many patients underwent burdensome interventions of uncertain benefit, such as tube-feeding or parenteral therapy, or hospitalization, within 3 months of death.[16] In many instances, such interventions were not necessitated by the need to reduce physical suffering and were inconsistent with a palliative approach to care. Studies show that despite traditional medical and nursing care, many demented patients—who are unable to communicate their physical or emotional needs—experience increasing amounts of suffering as death approaches.

Ambiguity about the care of severely demented patients and their families is common. Thus, Wray and co-workers found a major difference between the decision to limit care, which usually involved the patient's family, and the decision to provide full care, which involved families less often.[17] The physicians involved in these decisions often thought that less intensive care would have been more appropriate, but nevertheless provided full care because the acute condition was potentially reversible (e.g., with antibiotics). Morrison and Siu compared the care received by patients admitted to a New York hospital for hip fracture or pneumonia and who had either advanced dementia or intact cognition.[18] The demented patients received as many burdensome procedures as the nondemented patients. Moreover, in the group with hip fracture, patients with dementia received significantly fewer morphine sulfate equivalents daily for pain relief than patients with preserved cognition, and only 24 percent received a standing order for any analgesics, even though such patients are often unable to communicate the presence of pain. Even fewer of the demented than nondemented patients had advance directives, and no documentation was found of any discussion about goals of care or decisions to withhold life-sustaining therapies in 90 percent of the patients with severe dementia.

A major problem in the management of severely demented patients is to recognize when they are actually dying. Indicators that they are approaching the end of life may be subtle physical or behavioral changes, such as nonverbal signs of pain or discomfort, that are not easily recognized by inexperienced staff unfamiliar with the patient. Whenever possible, patients should be allowed to die in familiar surroundings, such as a nursing home rather than in an acute care facility.

The benefits of tube feeding patients with advanced dementia who have difficulty in eating have been questioned. There is little or no evidence that malnutrition is prevented or that tube feeding is associated with greater comfort, improved functional status, or longer survival. To the contrary, placement of a tube may increase patient discomfort or suffering, and tube feeding may be associated with adverse effects such as the increased use of restraints. In many circumstances, hand feeding may be preferred despite the involved cost because it is more comfortable for patients.

The understanding, knowledge, and perceptions of healthcare proxies of nursing-home residents with advanced dementia influence the care that patients receive. Because the ability of patients with dementia to communicate declines with time until grossly impaired, proxies and healthcare professionals must interpret patient behavior with particular care. When proxies are well informed and have a realistic understanding of the clinical complications expected in advanced dementia, patients are less likely to undergo unnecessary aggressive interventions in the final 3 months of life. Clearly, close consultation with family members and surrogates is necessary to define a rational treatment and management approach, which can then be followed. Bereaved family members may—in turn—require continuing support by someone on the healthcare team after the patient's death.

Amyotrophic Lateral Sclerosis

For this incurable disease, early palliative care is important and is directed at maximizing quality of life as soon as the diagnosis is made. Hospice care in the terminal stages of the disease may help in the control of symptoms and with ensuring a peaceful death.

Ganzini and co-workers measured pain, quality of life, suffering, sense of hopelessness, depression, level of disability, desire for life-sustaining medical treatment, and interest in assisted suicide of patients with amyotrophic lateral sclerosis and also asked their caregivers to rate the patients' quality of life, pain, and suffering.[19] Suffering was graded as 4 or more on a 6-point scale by 20 percent of patients and correlated with increasing pain, hopelessness, and level of disability. No relationship was found, however, between ratings of pain, suffering, and quality of life and interest in life-sustaining treatment or physician-assisted suicide. Pain and depression were often unrecognized or inadequately managed by treating physicians.

Nevertheless, most patients in the dying phase of amyotrophic lateral sclerosis die peacefully and, despite the common fear of suffocation, patients rarely choke to death. The most frequent symptoms in the last 24 hours are dyspnea, coughing, anxiety, fear, and restlessness. About half the patients die at home. The main palliative measures in use include ventilatory support, percutaneous gastrostomy, morphine, and benzodiazepines.

Regardless, early involvement of multidisciplinary palliative care services (such as neurologists and other specialty physicians; nursing staff; physical, occupational, and respiratory therapists; speech pathologist; dietician; medical social worker; and pastoral counselor) in the management of patients and their families, that is, before the terminal phase of illness, would probably improve the quality of life over the course of the disease and help to ensure integrated care by physicians and paramedical personnel.

In patients with amyotrophic lateral sclerosis, ventilatory support should be discussed before the development of respiratory symptoms, and noninvasive ventilation should be considered before tracheostomy. Noninvasive positive-pressure ventilation may postpone the need for tracheostomy and mechanical ventilation, and may improve hypoventilatory symptoms, cognitive function, and quality of life. The financial, social, and emotional burden of chronic invasive ventilation must be discussed fully with patients and their families so that informed decisions can be made.

As the disease progresses, the goal of treatment evolves from optimizing and maximizing function to palliative care. Two of the most common distressing symptoms in advanced cases are dyspnea and mood disorders or anxiety, which must be treated appropriately. Pain may also occur and, if non-narcotic analgesics, anti-inflammatory drugs, and antispasticity agents are inadequate, may necessitate opioids. Sialorrhea can be managed by positioning and suction, by pharmacologic means, or with botulinum toxin injected into the parotid and submandibular glands. Low-dose radiation has also been used successfully in this context. Sleep disturbances are frequent and may be helped by treating mood disorders, respiratory inadequacy, bulbar dysfunction (by managing sialorrhea that is leading to choking episodes), and the inability to turn in bed (frequent repositioning; use of a hospital bed and mattress).

The wishes of patients with amyotrophic lateral sclerosis concerning life-sustaining therapy are not stable, and preferences frequently change over time. Frequent discussion of options is therefore important, and advance directives for end-of-life care require periodic re-evaluation. Discussions should not be delayed until there is a crisis. Issues to be discussed include the maintenance of nutrition; the desired extent of respiratory support, including the use of noninvasive and invasive ventilation; and measures to combat infection. Such discussions are never easy or straightforward, and many physicians lack any training in these areas. It is important to accept the autonomy of patients in end-of-life decisions and their right to request or refuse interventions to sustain life. The situation may be complicated by concerns about decision-making capacity due to the cognitive impairment that occurs in many patients with amyotrophic lateral sclerosis, some of whom will develop frank frontotemporal dementia. This makes it important that surrogate decision-makers are appointed early, especially if there is evidence that cognition is becoming impaired.

Patients and caregivers will not agree on all issues. Patients tend to overestimate the quality of life of their caregivers, whereas caregivers underestimate that of patients. Both patients and caregivers may endorse the future use of noninvasive mechanical ventilation, but patients are often more uncertain than caregivers. There is usually little interest in invasive ventilation. Spirituality or religion influences the readiness to accept percutaneous endoscopic gastrostomy, noninvasive or invasive assisted ventilation, and attitude toward the process of dying. Thus, psychosocial factors, personality traits, and spiritual factors, in addition to symptoms and disability, require consideration and discussion with patients and families throughout the illness.

The incidence and predictors of percutaneous endoscopic gastrostomy have been examined in a group of patients with amyotrophic lateral sclerosis.[20] Patients undergoing percutaneous endoscopic gastrostomy were more likely than otherwise to undergo tracheostomy, more likely to have had a baseline preference for the procedure, and more likely to have initiated healthcare proxies early in the disease course. The results imply that use of percutaneous endoscopic gastrostomy is part of a consistently proactive approach to the disease among patients and their supporting family. Gastrostomy may improve patients' quality of life but there is little evidence that it improves survival.

These various interventions to support nutrition and ventilation are often determined by clinical need, but their application depends on choices made by patients and surrogates, which—in turn—are influenced by such factors as cognitive and affective status, personality, educational background, cultural factors, income, and differences in healthcare systems. In some instances, interventions—which do not arrest disease progression—necessitate institutionalization and a reduced quality of life.

CONCLUDING COMMENTS

Physical distress remains common in many patients facing the end of life, but fear of suffering is probably even more common. Greater education of healthcare providers about palliative medicine and easier access for patients to hospice programs and related esources will help to improve care for those who are dying. The apprehensions of dying patients may also be diminished by the knowledge that caregivers are fully committed to prevent, limit, or treat any discomfort that might arise. It is not possible to guarantee an "easy" death, but a commitment to provide optimal care is certainly realistic and reassuring. Such care must take into account the wishes of patients and their families.

  central nervous system manifestations of, 906, 1041, 1044–1045
  diagnostic criteria for, 904
  headache in, 906
  increased intracranial hypertension in, 906
  inflammatory brain disease in, 812*t*
  magnetic resonance imaging of, 906
  movement disorders in, 1030–1031, 1044–1045
  neurocutaneous manifestations of, 352*t*, 355–356, 368–369
  nonparenchymal, 906
  otologic symptoms in, 408
  peripheral nervous system manifestations of, 906
  systemic manifestations of, 904–905
  treatment of, 906
Belimumab, for systemic lupus erythematosus, 889
Bell palsy, 310–311, 327–328, 405–406, 406*f*, 596
Bence Jones protein, 1071
Benign paroxysmal positional vertigo (BPPV), 401, 403*f*, 432
Benign tumors of nerves, 1063–1064
Benzhexol, and parkinsonian symptoms, 612
Benzodiazepines, 45, 608, 889–890, 1010–1011, 1024, 1051–1052
  akathisia and, 609
  for alcohol withdrawal seizures, 628–629, 668, 1019
  for arousal disorders, 934
  for delirium tremens, 628, 668–669
  drug-induced coma and, 607
  encephalopathy and, 606, 608
  for insomnia, 918–920, 919*t*
  hallucinatory states and, 608
  hepatic encephalopathy and, 197, 1010–1011, 1089–1090
  hepatic porphyria and, 1017
  hyperprolactinemia and, 331*t*
  hypotension caused by, 1012
  hypothermia and, 667*t*
  mood disorders and, 608
  movement disorders and, 1026, 1029*t*, 1031–1034, 1036*t*, 1039
  pharmacokinetics of, 1009*t*
  and postoperative delirium, 969, 981
  seizures and, 606, 628, 641, 988, 1012, 1017, 1021
  serotonin syndrome and, 967
  side effects of, 612, 615, 641, 920
  for spasticity, 967
  stiff person syndrome, 515
  traumatic brain injury, 166
Benztropine, and parkinsonian symptoms, 612
Beriberi, thiamine deficiency and, 243, 1071–1072
Berlin Heart EXCOR ventricular assist device, 57–58
Bernard–Soulier syndrome, 463
Beta-1 adrenergic receptors, 158
β_2-microglobulin amyloidosis, 261
Beta-3 receptor agonists, 554
β-amyloid deposition, 892
Beta-blocker initiation and postoperative stroke, 50
β-blockers, 168, 1049, 1051, 1053*t*
  for cardioprotection, 168
  hyperthermia and, 666*t*
β-interferon therapy during pregnancy, 593
Beta-receptors, 160
Bevacizumab, 420, 522*t*, 528, 533, 606, 621*t*
Bezold–Jarisch reflexes, 133
Bilevel positive airway pressure
  for obstructive sleep apnea, 926
Bing Neel syndrome, 451
BioFire PCR Film Assay, 807
Bioprosthetic heart valve, 76, 91, 96
  embolus prevention and, 50
Biotinidase deficiency, 362*t*
Bisacodyl, 227–228

Bisphosphonates, for Paget disease of bone, 384–385
Bitemporal hemianopia, 329
Bladder
  incomplete emptying of, 544
  innervation of, 542, 543*f*
  neurogenic. *See* Neurogenic bladder
  neurologic control of, 541–544
  overactive, 543, 545–546, 548, 552–555, 572*t*
  pharmacology of, 542–544
  in storage phase, 542
  urothelium of, 542–544
  in voiding phase, 542
Bladder catheters, in dementia, 1109–1110
Bladder diary, 548, 549*f*
Bladder dysfunction
  amyloid neuropathy and, 547
  autoimmune autonomic ganglionopathy and, 547
  basal ganglia lesions and, 545
  brainstem lesions and, 545
  cerebral lesions and, 545–546
  diabetic neuropathy and, 546–547
  drug-induced, 616
  Fowler syndrome, 547–548
  Guillain–Barré syndrome and, 547
  immune-mediated neuropathies and, 547
  multiple system atrophy and, 545
  myotonic dystrophy and, 547
  neurogenic, 544–548
  Parkinson disease and, 545
  peripheral neuropathies and, 546–547
  pure autonomic failure and, 547
  spinal cord lesions and, 545–546
  types of, 544*t*, 545
Bladder neuropathy, 312
Bladder scan, 548
Blast-induced trauma, 411
Blastomyces dermatitidis, 804*t*, 808–809
Blastomyces dermatitis, 790
Blastomycosis, 352*t*, 808
Blastomycotic meningitis, 808
Bleeding disorders and maternal epilepsy, 579–580
Blindness
  in cryptococcal meningitis, 817
  from onchocerciasis, 836
Blindness, cortical, 44–45, 121, 148, 356, 523, 526–527, 606, 615
Bloch–Sulzberger disease, 360–361, 361*f*
Blood lipids and stroke, 115–116, 118, 172, 175, 363, 975, 1011
Blood pressure. *See also* Hypertension; Hypotension
  postural changes effect on, 124, 124*f*, 134
Blood viscosity, reduction of, 47–48. *See also* Hyperviscosity; Cellular hyperviscosity
Blood volume, effective, 125
Blood–brain barrier (BBB), 91*f*, 102, 197, 199, 208, 243, 327, 363, 467–468, 477, 485, 492, 501, 531–532, 554, 605, 645, 690–691, 691*f*, 703–705, 707, 713, 741, 770–771, 804, 806, 809, 878, 971, 994, 1089, 1103
Blow-out fracture with muscle entrapment, 425*t*
B-lymphocyte hyperactivity, 890
Body mass index, narcolepsy and, 921
Boeck, Caesar, 867
Bone disease
  ankylosing spondylitis, 389–392, 390*f*
  diffuse idiopathic skeletal hyperostosis, 391–392
  osteogenesis imperfecta, 408–409, 409*f*
  osteomalacia. *See* Osteomalacia
  osteopetrosis, 381–384, 384*t*. *See also* Osteopetrosis
  osteoporosis. *See* Osteoporosis
  otoneurologic manifestations of, 408–409
  Paget disease of bone. *See* Paget disease of bone
  tuberculous osteomyelitis, 388–389
  vertebral osteomyelitis, 387–389, 388*f*
Bone marrow transplantation, 445, 466, 508, 792, 1042, 1073

  - vasovagal, 133, 144, 956
  - in ventricular arrhythmia, 81–83
- Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
  - causes of, 335–336, 336*t*, 527, 754

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) (*Continued*)
  diagnosis of, 335–336
  hyponatremia and, 274–275, 526
  as paraneoplastic syndrome, 500*t*
  treatment of, 275, 759
Synthetic cannabinoids, 185, 606
Synucleinopathies, 547, 935, 1100*t*, 1101, 1104–1105, 1108–1109
Syphilis
  aortitis, 36–37
  background of, 704
  benzathine penicillin for, 707
  central nervous system manifestations of, 1091
  cerebrospinal fluid examination for, 705
  chancres caused by, 706
  clinical features of, 706–707, 845–846
  congenital, 590, 707
  cutaneous lesions and, 353*t*, 354–355, 354*f*
  dementia and, 707, 1103
  diagnosis of, 704–706, 846, 1103
  general paresis of insane (GPI), 707, 1103
  human immunodeficiency virus infection and, 707
  latent, 707
  maternal, in pregnancy, 590
  meningovascular, 706, 845–846
  neurologic manifestations of, 706, 1103
    HIV and, 707, 845
  otosyphilis, 406
  pupillary responses, 434
  serologic testing for, 705
  and stroke, 180, 845–846, 1091
  symptomatic nervous system involvement in, 706
  tabes dorsalis, 180, 353*t*, 546, 706–707, 845–846
  treatment of, 707, 846
Syringomyelia, 127, 546, 956
Systemic inflammatory response syndrome (SIRS), 14, 197, 994
  description of, 197, 199, 994
  encephalopathy associated with, 994
Systemic lupus erythematosus (SLE), 77, 175, 356–358, 459, 885–890, 888*t*, 1047, 1052, 1090
  anticardiolipin antibodies in, 887
  antiphospholipid antibodies in, 887–888, 1015, 1030
  antiphospholipid syndrome and, 887, 890, 1016, 1030, 1045
  aseptic meningitis in, 888–889
  carpal tunnel syndrome in, 889
  cerebral vasculitis in, 1052
  cerebrovascular disease in, 888
  chorea in, 322, 591, 887–889, 1030
  cognitive dysfunction in, 888
  cranial neuropathy in, 888*t*
  cutaneous lesions in, 349*t*, 350–351, 356–357, 367*t*, 886*t*
  diagnostic criteria for, 886
  encephalopathy in, 1090
  headaches in, 888
  hemorrhagic stroke in, 888
  ischemic stroke in, 887–888
  migraine headaches in, 888, 1047, 1052
  myasthenia gravis and, 1076
  neurocutaneous manifestations of, 349*t*, 356–357, 362*t*
  neuropsychiatric manifestations of, 470, 1015–1016, 1091
  neuropsychiatric systemic lupus erythematosus (NPSLE), 887–889
  nonbacterial endocarditis and, 77, 181–182, 887
  and parkinsonism, 1044
  peripheral nervous system disease, 889, 1063*t*, 1066*t*
  polymyositis in, 897
  polyneuropathy in, 889
  and posterior reversible encephalopathy syndrome (PRES), 888
  psychosis in, 888–890
  seizures in, 888, 1015
  sensorineural hearing loss caused by, 408
  stroke in, 180–181, 887–889
  systemic disease, 885–887
  treatment, 889–890
  thrombosis risks in, 469
Systemic sclerosis, 368, 893–894. *See also* Scleroderma
  central nervous system disease, 893
  peripheral nervous system disease, 893
  systemic disease, 893
  treatment, 894
Systemic vasculitis, 368–369, 900–902
  central nervous system disease, 902
  peripheral nervous system disease, 902
  systemic disease, 900–901
  treatment, 902

AMINOFF'S NEUROLOGY AND GENERAL MEDICINE

SIXTH EDITION

Edited by

Michael J. Aminoff, MD, DSc, FRCP
Distinguished Professor, Department of Neurology, School of Medicine,
University of California, San Francisco, California

S. Andrew Josephson, MD
C. Castro Franceschi and G.K. Mitchell Distinguished Professor and Chair,
Department of Neurology, School of Medicine,
University of California, San Francisco, California

Aminoff's Neurology and General Medicine, 6th Edition is the standard and classic reference providing comprehensive coverage of the relationship between clinical neurology and general medicine. It defines both the neurologic aspects of general medical disorders and the general medical and other implications of various neurologic diseases. The book provides an account of clinical neurology from a different perspective and serves as an interface between neurology and the other medical specialties. Patients with neurologic disorders are often complex and inevitably have other coexisting disorders. Furthermore, many medical disorders have neurologic complications or manifestations. General medical disorders, in turn, are influenced by neurologic disease and their treatment may have neurologic consequences.

The book will be a valuable resource for all clinicians but is aimed especially at neurologists, internists, hospitalists, and primary healthcare providers. It will help neurologists to appreciate the implications of the general medical issues facing their patients and how they might best be managed, and will aid internists, family and general practitioners, hospitalists, and other physicians to gain further understanding of their patients' neurologic disorders and thereby improve patient care.

Completely revised and updated, with several of the existing chapters rewritten by new authors and chapters covering the two new topics of headache and psychogenic neurologic disorders, this new edition will again be the go-to reference for neurologists and non-neurologists alike.

KEY FEATURES

- The standard authoritative reference detailing the relationship between neurology and general medicine
- Completely revised and updated with several chapters from earlier editions rewritten by new authors and two chapters on the new topics of Headache and General Medical Disorders, and Psychogenic Neurologic Disorders
- Well illustrated, with most illustrations in full color

ISBN 978-0-12-819306-8
